Host organisms were grown at 37 °C with shaking in halophile broth containing 9 parts salt solution (20% NaCl, 2% KCl, 2% MgSO₄), and 1 part nutrient solution (4% Difco yeast extract, 4% Difco casamino acids, 3% sodium citrate, 20% NaCl, 2% KCl, 2% MgSO₄). Agar for agar plates was prepared by mixing 500 ml agar salts solution (25% NaCl, 2.5% KCl, 2.5% MgSO₄), 60 ml nutrient solution and 8 g Difco agar in 100 ml distilled water. All solutions were autoclaved at 121 °C before use. Agar for overlays was prepared by mixing 40 ml salt solution, 50 ml distilled water, 0.4 g ion agar No. 2 and autoclaving for 15 min at 121 °C. 10 ml nutrient solution was added to the hot solution and 2.5-ml aliquots dispensed in small tubes. These were allowed to solidify, melted and tempered to 60 °C as needed. Host bacteria were collected by centrifugation in mid log phase and concentrated 20 times in a medium containing 9 parts agar salts solution and 1 part nutrient solution and held at 0–4 °C. Five drops of the host suspension was added to the overlay before the addition of phage. Plates were incubated at 38 °C and plaques appeared in less than 24 h. Lysates of phage Ja.1 containing $2–3 \times 10^{10}$ phage ml⁻¹ were produced by diluting 30 ml of a late stationary phase culture of *H. cutirubrum* into 200 ml halophile medium, infecting with eight 25-h plaques and shaking vigorously, until lysis was complete, about 24 h at 37 °C. Phage dilutions were made into complete halophile medium or a similar high salt nutrient solution.
*Isolated from Great Salt Lake, USA.
†Isolated from salterns near San Francisco, USA.

Table 2 Phage Ja.1 survival in ionic solutions

Solution	Fraction surviving		
	30min	24h	96h
3.5 M NaCl, 0.05 M MgSO$_4$	1.0	1.0	1.0
2 M NaCl	0.8	0.6	0.3
1 M NaCl	0.5	10^{-5}	< 10^{-7}
0.2 M NaCl	< 10^{-7}	—	—
2 M KCl	0.8	0.6	0.5
1 M KCl	0.7	0.1	0.01
0.2 KCl	< 10^{-7}	—	—
0.02 M MgSO$_4$	0.7	0.6	0.4

A plate stock containing 2×10^{10} phage Ja. 1 ml^{-1} diluted 1:200 into various ionic solutions at 4 °C each containing 0.01 M Tris buffer (pH 7.4). Phage titres were determined at intervals after dilution. Relative rates of inactivation are similar at 37 °C.

The single step growth function for phage Ja. 1 infection of *H. cutirubrum* is shown in Fig. 2. Only 25% of the input phage are present as chloroform sensitive infective centres after a 30-min adsorption period and 25% are present as chloroform resistant, presumably unadsorbed particles. After a 2-h eclipse, maturation of phage begins and is complete in 6 h which is the normal generation time for the bacteria alone growing in the same conditions. The apparent average burst size is 140. Lysis begins only after maturation is complete and occurs over a 3–4-h period. The abrupt cessation of phage maturation before lysis suggests that a specific function limits the number of particles produced in each cell. Phage T4, a model of lytic development, continues to mature particles in an infected cell until lysis is achieved[8]. Inefficient adsorption, limited maturation, and delayed lysis in Ja. 1 infection may favour an equilibrium between phage and host populations in a closed natural habitat. These

Fig. 2 A *H. cutirubrum* culture in log phase containing 1.5×10^8 viable cells ml^{-1} was infected with 1.2×10^7 plaque forming units ml^{-1} from a plate stock of Ja.1. After a 30-min absorption period the culture was diluted times 6×10^3 into fresh medium at 37 °C. Aliquots of the diluted culture were titred at intervals before and after adding a drop of chloroform. Chloroform lyses the cells but does not reduce the titre of completed phage particles. Plaque titre in the absence of chloroform is plotted minus the number of complete, chloroform resistant, particles present at early times to derive the titre of cells producing phage plus the titre of phage released from these in the culture, ○. The titres obtained after chloroform treatment, representing all complete phage present is plotted, ●.
functions could not benefit T4 whose host, *Escherichia coli*, cannot establish a stable population outside the gut.

Viability in phage Ja. 1 is preserved only in solutions of high ionic strength. The ions and concentrations required to protect Ja. 1 reflect intracellular ionic conditions in *H. cutirubrum* and are similar to those that favour the stability of halophilic enzymes[9]. With few exceptions, enzymes isolated from *Halobacterium* require 1 M to 4 M concentrations of monovalent cations for optimum stability and activity. In most instances K$^+$ is more efficient than Na$^+$ in filling this requirement and 0.05 M Mg^{2+} often reduces or eliminates a requirement for monovalent ions. Table 2 shows that 1 M KCl affords Ja. 1 several orders of magnitude greater protection against irreversible loss of viability than does 1 M NaCl and a high degree of stability is conferred by 0.02 M Mg^{2+}. In contrast, host viability and growth is strictly dependent on Na$^+$ concentrations exceeding 2 M and the presence of other ions does not materially reduce this dependence[4]. Phage survival in 0.02 M Mg^{2+} suggests that the phage survives and may even function in more moderate environments than does its host species. At the opposite extreme, 10^8 phage Ja. 1 are destroyed by drying for 2 d at 22 °C and moderate humidity although the host species survives for many years in salt crystals[10].

Contrary to the finding for Ja. 1, marine phage[12] survives better in NaCl than in KCl although marine bacteria often have high intracellular KCl[1]. Sparse host populations in the marine environment may cause phage to adapt to extracellular conditions while seawater evaporates, such as The Salt Ponds of Yallahs, support extremely dense microbial populations. Further study of the sequence of appearance, ionic niche requirements, and cellular genetic roles of halophages may reveal their ecological function in the environmentally induced growth cycles of the halophilic flora.

Morphology and biochemistry of small, intensely fluorescent cells of sympathetic ganglia

NEURAL transmission in sympathetic ganglia has been regarded as an automatic relay involving only pre- and postganglionic neurones. It is now agreed, however, that the small, intensely fluorescent cells — at least some of

which are interneurones[1,2] — modulate transmission in the superior cervical ganglion. Greengard *et al.*[3-6] have documented the role of the ganglionic interneurone in modulating ganglionic transmission. Dopamine released from an interneurone binds to a receptor on the surface of the ganglionic neurone, activating an adenylate cyclase. The increased production of cyclic AMP leads to hyperpolarisation of the ganglionic neurone by a mechanism which is still obscure.

Studies (T.C. and T.H.W., unpublished) have shown that the morphology of the sympathetic interneurone is considerably more complex and shows more species diversity than is sometimes appreciated, which raises the possibility of major species differences in its biochemistry and in the mechanisms whereby it modulates transmission in the ganglion. We have demonstrated that the biochemistry of the interaction between the ganglionic interneurone and the principal ganglionic neurone is different in the cat from that in the cow.

Figure 1 shows the effect of dopamine on the production of cyclic AMP in bovine and feline superior cervical ganglia incubated *in vitro*. In the bovine ganglion there is a marked increase in the amount of cyclic AMP produced by even a 1 μM concentration of dopamine and, moreover, the response obtained is proportional to log dopamine concentration (is dose dependent[7]). Our work in the bovine ganglion confirms the findings of Kebabian and Greengard[8]. In the feline ganglion (Fig. 1) the situation is different. The cat ganglion proved relatively unresponsive to dopamine stimulation and, within the range of concentrations used, the cyclic AMP response was not dose dependent. We also determined the effect of *l*-noradrenaline on the cat superior cervical ganglion incubated *in vitro* to make certain that we were not attempting to stimulate with the incorrect neuro-transmitter. This compound was ineffective even at concentrations of 100 μmol l^{-1} (ref. 9). Thus, the feline ganglion contains an adenylate cyclase which is relatively unresponsive to stimulation by dopamine or *l*-noradrenaline.

These findings led us to search for a morphological basis for these biochemical differences. Do the ganglionic interneurones of cat superior cervical ganglion differ from those of the bovine ganglion in a manner which could account for the differences in the observed responses to dopamine? Morphological studies of bovine and feline superior cervical ganglia were undertaken using the method of Grillo *et al.*[10], as modified by T.C. and T.H.W. (unpublished). This method enables the preparation of sections for fluorescence microscopy and subsequent examination of the same material by electron microscopy. In both species two types

Fig. 2 Histochemical preparations demonstrating catecholamine fluorescence. *a*, Single small intensely fluorescent cell (type I) is seen in close apposition to a ganglionic neurone (bovine superior cervical ganglion). Single arrow, a principal ganglionic neurone; double arrow, a ganglionic interneurone with a process. *b*, Cluster of small fluorescent cells (type II) in the capsular connective tissue of the feline superior cervical ganglion. *c*, Capillary lumen. Bar represents 20 μm.

of small, intensely fluorescent cells were distinguished. Type I (Fig. 2*a*) has long processes which run in close apposition to ganglion cells. This is regarded as the type of cell shown by Williams[1,2] to be an interneurone in the rat: the presence of this type I ganglionic interneurone is crucial to the Greengard hypothesis. The type II cell (Fig. 2*b*) is located in the interstitial or subcapsular portions of

Fig. 3 Ultrastructure of type II small, intensely fluorescent cells in cat and cow. *a*, Cat (perfusion-fixed for fluorescence microscopy and electron microscopy) showing characteristic dense granules (1,400–1,800 Å). *b*, Cow (immersion-fixed) also exhibiting dense granules. Hollow centres of these granules are presumed to be a fixation artefact. Bar represents 1 μm.

Fig. 1 Effect of dopamine on cyclic AMP levels of superior cervical ganglia incubated *in vitro* at 37 °C. ○, Bovine ganglia; ●, feline ganglia. Control values: bovine ganglia 28.8±2.18 pmol cyclic AMP per mg protein; feline ganglia 26.9±5.7 pmol per mg protein. Each point is the mean of four to six samples ± s.e. mean. All samples were incubated in Eagle's MEM containing 1 mM theophylline. Cyclic AMP assays were carried out according to Gilman[12].

the ganglion, and has shorter processes which end in close relation to blood vessels[11]. Type II cells from both feline and bovine superior cervical ganglia exhibited similar ultrastructural features (Fig. 3a and b).

Quantitative studies of the total small, intensely fluorescent cell population in each species, using fluorescence histochemistry, showed that the bovine superior cervical ganglion contains a total population of 6,480 small, intensely fluorescent cells per ganglion (5.2 cells per mg wet tissue), and the feline ganglion contains 104 cells (4.1 cells per mg wet tissue). Thus the numbers per mg tissue are not very different. The cow ganglia contained 24% type I ganglionic interneurones, the remaining 76% being classified as type II. Of all the small, fluorescent cells examined in the feline superior cervical ganglion, only 2% were type I; the rest were type II cells. Thus type I cells are common in the cow, whereas they are virtually absent in the cat. As the dopamine receptor–adenylate cyclase complex is located on the postsynaptic membrane of the synapse between the interneurone and the principal ganglionic neurone, the scarcity of ganglionic interneurones (type I small, intensely fluorescent cells) in the cat ganglion may account for the meagre response to dopamine in this species.

These results raise the question: are all small, intensely fluorescent cells interneurones? The answer may well be no. There exist at least two types of small, intensely fluorescent cells, one of which (type I) can be compared with the classical interneurone first described in the rat by Williams[1,2]. The other (type II) is probably not an interneurone and is (at least in the bovine and feline superior cervical ganglion) associated with blood vessels, leading one to suspect a functional association with these vessels.

In summary, there are two main types of small, intensely fluorescent cell in the superior cervical sympathetic ganglion. We have noted a virtual absence of the type I cell (comparable with the interneurone in the rat) in the cat. Also absent or much reduced in the cat is the dopamine-sensitive adenylate cyclase receptor mechanism involved in neural transmission in other species. We therefore infer that the type I cell is a ganglionic interneurone capable of activating this receptor mechanism. Type II remains an enigma.

*p*H-sensitive cells at ventro–lateral surface of rat medulla oblongata

MARKED effects of *p*H changes in the cerebrospinal fluid (CSF) on ventilation have been confirmed by a number of investigators[1]. Consistent augmentation of respiration by applying acid fluids

to specific regions on the ventro–lateral surface of the cat medulla oblongata[2,3] has been shown, and similar results were observed with the brain stem of the rat[4]. The chemosensitive nature of these regions proposed from the above experiments has been substantiated by electrophysiological studies using an extracellular recording technique[5,6]. Movements of the brain as a result of respiration and cardiac activity, however, make it difficult to obtain intracellular recordings of nerve activity in these structures. Therefore, thin brain slices were used *in vitro* in the present experiment.

The brain stem of the rat at the level from the 1st cervical nerve to the roots of the vagal and glossopharyngeal nerves was excised under intraperitoneal chloralose (60 mg kg^{-1})–urethane (250 mg kg^{-1}) anaesthesia. A thin brain slice (0.3–0.5 mm thick) was dissected from either side of the ventral surface of the medulla as described previously[7]. Preparations were placed on a nylon mesh in the incubation chamber, ventral surface upwards, and perfused continuously with mock CSF at various *p*H (7.0–7.8) at 36 °C. Normal mock CSF (*p*H 7.4) had the following composition (mM): NaCl, 125; NaHCO$_3$, 25; KCl, 3.5; CaCl$_2$, 1.3; MgCl$_2$, 1.1; NaH$_2$PO$_4$, 0.51; urea, 2.2; and glucose, 3.4. A high or low *p*H solution was obtained by altering the NaHCO$_3$ concentration with constant P_{CO_2}. Solutions were equilibrated by a gas mixture containing 5.6% CO$_2$ in oxygen (P_{CO_2} 42 mmHg). In another series of experiments the P_{CO_2} was varied from 18 to 90 mmHg at constant *p*H. Transmembrane potentials were recorded using glass micropipettes filled with 3 M KCl having a resistance of 20–30 M Ω.

After 30 min incubation, a microelectrode was inserted into various parts of the surface layer (up to about 200 μm deep) and negative potentials from -50 to -75 mV, which indicated cell membrane activity, could be recorded at the regions lateral to the pyramid. The mean ($\pm$s.e.) membrane potential was -62 ± 2 mV at *p*H 7.4 and no significant differences in the membrane potential were seen in cells located at different portions of the ventral medulla. When the *p*H of the perfusing solution was altered from 7.0 to 7.8, however, cells located at the area medial to the root of XIIth cranial nerve, just lateral to the pyramid, showed apparent potential changes. Figure 1a shows a continuous recording of membrane potential from a single cell of this area. The membrane potential of this cell was about -78 mV at *p*H 7.8 and was depolarised gradually to about -58 mV by application of a low *p*H (7.0) solution. The average membrane potential of cells in this area was -55 and -75 mV at *p*H 7.0 and 7.8, respectively. We were unable

Fig. 1 Effect of changes in *p*H of perfusing solution on membrane potential of cells at the surface layer of the rat ventral medulla *in vitro*. a, Record from a single cell at the area medial to the XIIth cranial nerve (Loeschcke's area). Note the significant changes in potential with changes in *p*H. b, Record from a single cell at 1 mm cranial to the root of XIIth cranial nerve and 1 mm lateral to the pyramid. In both a and b *p*H was changed with constant P_{CO_2} (42 mmHg). MP, Transmembrane potential; XII, XIIth cranial nerve; C$_1$, 1st cervical nerve. Asterisk in schematic representation of the ventral medulla represents site at which potential was recorded. Bar, 1 min.
Fig. 2 Effect of changes in P_{CO_2} of perfusing solution on membrane potential of a cell at the area medial to the root of XIIth cranial nerve *in vitro*. pH was kept constant at 7.4, adjusting $NaHCO_3$ concentration. MP, Transmembrane potential. Bar, 1 min.

to record apparent spontaneous discharges from these cells during depolarisation when a low pH solution was applied. The membrane potential of cells in other areas did not change with alteration in pH of the perfusing solution, which indicates that cells have no sensitivity to changes in the hydrogen ion concentration of the extracellular fluid (Fig. 1b). On the other hand, when the P_{CO_2} of the perfusing solution was altered, without altering the pH by adjusting the $NaHCO_3$ concentration, membrane potentials of cells of all the surface area remained constant.

Figure 2 was obtained from a single cell located at the root of XIIth cranial nerve. In this case the membrane potential was about -64 mV at pH 7.4 with P_{CO_2} 42 mmHg and the potential was maintained as the P_{CO_2} was changed from 90 to 18 mmHg. Therefore, cells located at the area medial to the roof of XIIth cranial nerve (Loeschcke's area) seem to be characterised by being sensitive specifically to extracellular pH and not to P_{CO_2}. The same characteristics of unique pH sensitivity have also been demonstrated by *in vivo* studies[3,5,6] in which ventilation and neuronal discharges recorded from the ventral medulla were observed with the same perfusion experiments.

The site of localisation of pH-sensitive cells is in accord with the area at which the application of low pH solution causes the highest and most rapid augmentation of respiration in the cat *in vivo*[1,3]. Other areas which have been responsible for the respiratory chemosensitivity to changes in CSF pH have been located at the surface of the ventral medulla near the roots of the vagal and glossopharyngeal nerves (Mitchell's area)[1]. In the present experiment, however, there was no observed change in potentials recorded from the cells of this area with changes in pH or P_{CO_2}. It is suggested that cells located in deeper (more than 200 μm) layers of this area may be sensitive to pH (ref. 8).

pH or P_{CO_2}-sensitive cells have been reported in the abdominal ganglion of the marine mollusc *Aplysia*[9,10], and have also been found in cortical and spinal neurones of the rat[11,12]. In the present experiment pH-sensitive cells were shown to exist in the specific region of the medulla which has been assumed to be involved in the chemical regulation of respiration[1]. Whether this cell will exhibit spontaneous activity *in vivo* and be responsible for driving the ventilation or not, is not yet known. It is possible, however, that respiratory responses to changes in the pH of the CSF or brain extracellular fluid, and to changes in acid–base status of blood, may partly be initiated through this cell.

BCG suppresses growth and metastasis of hydatid infections

THE asexually proliferating larvae of the cestode *Echinococcus multilocularis* have an intriguing resemblance to malignant tumours. Indeed, until 1856 when Virchow demonstrated the parasitic nature of these cyst masses in man, such lesions were commonly diagnosed as carcinomas of the liver[1]. In the laboratory, infections with this parasite can be propagated vegetatively by transplanting the metacestode into the peritoneal cavity of susceptible rodent intermediate hosts[2]. The protoscolices transform into small cysts which grow and metastasise by peripheral herniation and the detachment of minute vesicles[3].

Macrophages from donors which have been inoculated with microorganisms such as *Besnoitia, Toxoplasma* or BCG can nonspecifically destroy tumour cells *in vitro*[4-6]. BCG has been successfully used in the active, nonspecific immunotherapy of malignant tumours *in vivo*[7,8] and we report here that this same treatment may also be effective in the immunoprophylaxis and immunotherapy of *E. multilocularis* infections.

Pretreatment of the experimental cotton rat host (*Sigmodon hispidus*) with 26.4×10^8 colony-forming units (CFU) of BCG suppressed the growth and metastasis of an intraperitoneal inoculum of 200 protoscolices (Table 1). Thus, autopsy 50 d after inoculation revealed that only two of the four BCG-treated cotton rats of this group had developed echinococcosis. These two infected animals bore cyst masses weighing 0.5 g and 1.5 g which were composed of one and two foci respectively. In contrast, the four untreated control animals bore an average hydatid cyst weight of 14 g ($P < 0.01$) composed of an average of 40.5 distinct foci ($P < 0.005$).

BCG treatment 2 weeks after intraperitoneal inoculation of 200 protoscolices did not limit the establishment and growth of the hydatid infection. All animals within this group developed infections the weights of which were indistinguishable from controls ($P > 0.10$). BCG treatment after inoculation did, however, severely suppress the number of parasitic foci of infection which developed from the inoculum. Whereas controls bore an average of 40.5 foci of infection, treated animals bore only 4.8 ($P < 0.005$); the number of foci were also significantly greater ($P < 0.025$) in this group than in that treated before infection. The severity of this suppression is underlined by the fact that one protoscolex can give rise to more than 20 foci of infection by metastasis in cotton rats[9].

Our study indicates that prior BCG treatment suppresses the growth and metastasis of an intraperitoneal infection with *E. multilocularis*. BCG treatment of established infections, on the other hand, only limits the parasite metastases, whereas growth (assessed by the total weight of the cyst biomass) seems to proceed normally. These findings further emphasise the striking similarities between this parasitic infection and the growth and proliferation of malignant tumours. Baldwin and Pimm[10] have reported that pulmonary metastases from primary rat hepatomata can be similarly restricted by BCG treatment. They report that, again, this treatment had no influence on the occurrence or growth

Table 1 Effect of BCG treatment on growth and metastasis of *E. multilocularis*

Untreated infected controls		BCG treatment 1 week before inoculation		BCG treatment 2 weeks after inoculation	
Total weight of cyst mass (g)	No. of foci	Total weight of cyst mass (g)	No. of foci	Total weight of cyst mass (g)	No. of foci
10.5	47	1.5	2	8.8	3
9.0	29	0.0	0	12.0	3
12.6	36	0.5	1	20.0	8
23.9	50	0.0	0	12.7	5
Mean 14.0	40.5	0.5	0.8	13.4	4.8

Twelve 5-week-old cotton rats were each inoculated with 200 protoscolices of *E. multilocularis*, and autopsied 50 d later for hydatid cyst masses. Eight of these animals had been treated with an intraperitoneal injection of 26.4×10^6 CFU of lyophilised BCG (lot no. 1707-6; Institut de Microbiologie et d'Hygiène de Montréal) in 0.5 ml distilled water. Four of these latter animals had been treated 1 week previously and the other four rats 2 weeks after inoculation with the parasite.

rates of primary tumours (assessed by the survival of experimental animals).

The treatment dose of 26.4×10^6 CFU of BCG was tolerated well by our animals although all cotton rats treated before or after inoculation with the parasite developed small intraperitoneal granulomatous lesions.

We are therefore continuing the search for a treatment regimen that will maximise the immunoprophylactic and immunotherapeutic effects of BCG in hydatid disease without the production of granulomas.

Host growth induced by genetic tumour grafts

SPONTANEOUS tumours in *Nicotiana* were first reported by Kostoff[1] and are called genetic tumours[2]. They arise on certain interspecific tobacco hybrids[2], and it has been proposed that certain genes when appropriately combined in a hybrid promote the development of tumours[3,4]. Though in bacterially induced crown gall tumours the tumour state is transmissible from a tumour cell to a normal cell in the absence of viable bacteria[5,6], efforts to demonstrate an ability of genetic tumours to induce tumour development across a graft union have failed[2]. Attempts to graft *Nicotiana glauca* × *Nicotiana langsdorffi* hybrid tumour tissues from sterile culture to non-parental species of *Nicotiana* were unsuccessful because the grafts died[7,8]. Here we report the successful grafting of *N. glauca* × *N. langsdorffii* amphidiploid (GGLL) tissue from sterile culture on to *N. tabacum* cv. Wisconsin 38. Within a month of grafting, the graft (GGLL tumour tissue) induced the development of host (*N. tabacum*) shoots in wound sites and some grafts became chimaeral.

We shall describe one of the three separate grafting experiments we performed. Fifteen grafts were made, 11

produced GGLL tumours, and four grafts induced the development of one or more host shoots within a month of grafting. In one graft the shoot came from the side of the tumour, in another from the tumour region (Fig. 1*a*), and in the other two cases shoots came from the wound area where the graft did not take. Sussex *et al.*[9] never observed shoot development from comparably wounded internodal areas of the same strain of *N. tabacum*, and we have wounded plants and have grafted numerous pieces of *N. tabacum* tissues into *N. tabacum* plants without ever observing shoot development from an internodal wound.

One shoot growing out of a graft (Fig. 1*b*) was rooted and the genotype of its tissue layers was determined. Its morphology was *N. tabacum*, its seed germinated into *N. tabacum* plants, and its pith regenerated in culture to produce *N. tabacum* plants. Thus the three layers in its shoot apical meristem, T_1, T_2, and C, were genetically *N. tabacum*. In another instance a sectorial chimaera was produced (Fig. 1*c*). As this shoot grew, the GGLL sector was eliminated, but by removing the apex, we forced an axillary bud from the GGLL sector to develop. This bud produced a shoot which was also a mixture of graft and host cells as indicated by tumour production, leaves of intermediate shape, and flowers with morphological characters of both GGLL and *N. tabacum*.

Bacteria-free crown gall tumour cells are reported to produce or contain one or more substances which cause neighbouring cells to become tumorous[5,6]. As indicated from previous work[2,7,8] and from the results presented here, it is unlikely that genetic tumour cells can influence cells with a non-tumorous genotype to become tumorous. The genetic tumour graft does, however, influence host cells to divide and organise shoot meristems Since host shoots emerged from graft tissue, the tumours must in some cases be chimaeral, and this assumption is strengthened by the observation of one chimaeral shoot. Although it is possible that tumorous host cells exist among the graft cells, it is more plausible that host cells are induced to divide under the influence of graft growth regulators of the auxin and cytokinin types. That is, GGLL tumours produce auxin and cytokinin[10], and when *N. tabacum* plants are wounded and the wound exposed to these growth regulators, shoot meristems develop (C.N.M., unpublished). In addition, no growth is observed on the host side of the graft union whereas cell division and growth occur on the host side of the graft union during tumour induction with sterile bacterial tumour tissue[5,6].

Although crown gall tumours and genetic tumours exhibit similar hormonal autonomy in tissue culture and retention of abnormal growth on grafting[11], these results suggest there is a fundamental difference in their capacity to influence non-tumorous cells of a host into which they are grafted. Genetic tumours arise spontaneously or appear following injury or external hormone application[2,12]. In the case of crown gall, both injury and the presence of
Fig. 1 GGLL tumour tissue was grown in sterile culture on Linsmaier and Skoog medium[15] without hormonal supplement. Small pieces (0.075 to 1.0 cm²) of GGLL tumour were grafted to the top or into a V-shaped lateral notch in the stem of greenhouse grown *N. tabacum* plants. Before grafting, plants were decapitated, and graft tissue was always placed in an internodal area. Plants were used after bolting but before anthesis (flowering) and axillary buds were usually removed as they grew out. *a, b, N. tabacum* shoots growing out of grafted tumour tissue; *c*, chimaeral shoot growing out of graft tissue. Note leaf in upper right hand corner: upper half is *N. tabacum* and lower half is GGLL. Magnification: *a*, ×0.38; *b*, ×1.5; *c*, ×0.2.

bacteria are required for tumour initiation. Since it has not been possible to demonstrate the presence of foreign DNA in sterile bacterial tumour cells[13,14], the possible genetic relationship between the suspected 'tumour inducing principle' elaborated by the bacterium and the ability of bacteria-free tumour cells to induce tumour development is unclear. The fact that genetic tumour cells cannot transmit their tumour state though crown gall cells can, suggests that genetic tumour development and maintenance results from endogenous, non-transmissible gene regulation whereas crown gall could be elicited and maintained by a transmissible factor of external origin.

Target cell for oncogenic action of polycythaemia-inducing Friend virus

ONCORNAVIRUSES carry information for two distinct functions: virus multiplication and expression of oncogenicity[1,2]. The polycythaemia-inducing Friend virus (FVP) (as the Rauscher leukemia virus) infects and replicates in many types of cells cultured *in vitro* but as yet, no system for both infection *in vitro* and subsequent expression of oncongenic function has been described[3,4]. Morphological transformation of unidentified target cells occurs *in vivo* after infection of susceptible mice by FVP[5]. Transformation is characterised by the rapid and massive appearance of hyperbasophilic cells, so called Friend cells, only in the spleen red pulp, about 30–40 h after virus inoculation. Thereafter, an erythrocytic maturation starts and proceeds without influence of endogenous or exogenous erythropoietin, the physiological humoral factor for normal erythropoietic differentiation. The number of hyperbasophilic Friend cells and erythroblasts increases; these cells invade the organism and the animal dies 1–2 months after infection.

Oncogenic potencies *in vivo* could result from the need for a precise cell type or cell function to enable the expression of the oncogene[6]. Haematopoietic cells are required for the initiation of Friend disease[7]. Different authors have concluded that the target cells (that is those cells which become hyperbasophilic and multiply after virus infection) for viral oncogenic action *in vivo* were, variously, the multipotent stem cells of the haematopoietic system[8], or a myelopoietic cell[9]. Others claimed that the target cells were probably the erythropoietin responsive cells or closely related precursors[5,6].

From these indirect results, the answers to at least three questions remain unclear. First, is the multipotent stem cell of the haematopoietic system, the so-called colony forming unit, a target cell for oncogenic action of the virus? Second, is the target cell a precursor of the erythrocytic line only? Third, do the transformed hyperbasophilic cells differentiate only along the erythrocytic line?

Here we present results which, in our opinion, give direct answers to these questions, by using a method which could be easily adapted for other leukaemia viruses.

We took advantage of the well known property of the haematopoietic stem cells; they give rise, in the spleen of irradiated syngeneic recipients, to macroscopic colonies constituted of differentiated haematopoietic cells[10]. Nine days after the graft, most of the colonies contain only a single haematopoietic cell line either erythroid, neutrophilic granuloid, megakaryocytic or eosinophilic granuloid in a decreasing order of frequency[11]. Polycythaemia induced by intraperitoneal administration of packed syngeneic red cells into mice stopped the production of endogenous erythropoietin and resulted in the suppression of the erythroid spleen colonies[12]. Such suppressed erythroid colonies remain in the spleen as small undifferentiated colonies and do not convert to another cell type[13]. Three or four days after the cell graft, erythropoietin responsive cells appear in these small colonies since administration of exogenous erythropoietin results in the immediate appearance of pronormoblasts. As postulated by Lajtha, this capacity to respond to erythropoietin is achieved only after a number of cell cycles[14] (Fig. 1).

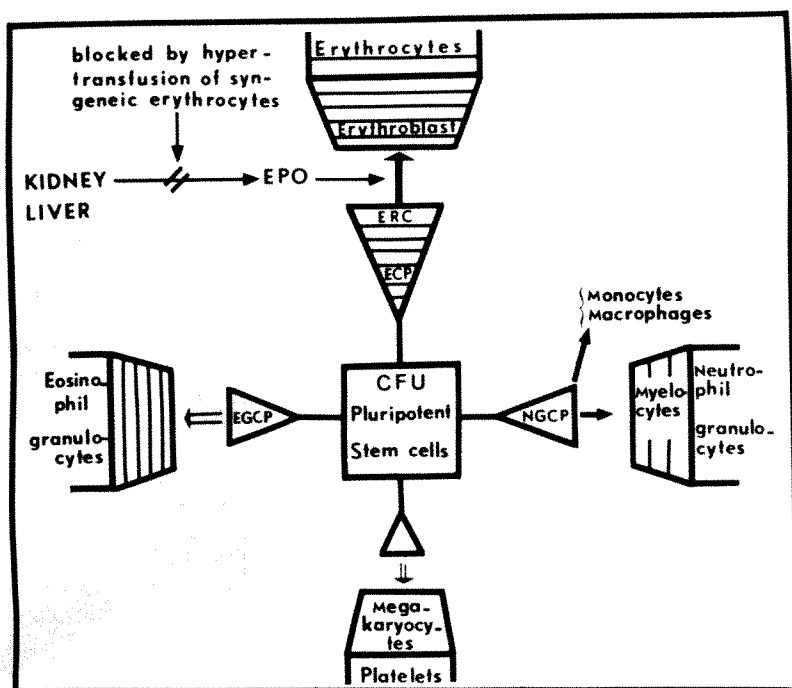
The experimental data were the following: hypertransfused, irradiated C3H/Hemg mice (Carshalton, England) were grafted with 3×10^5 syngeneic normal spleen cells (this number of cells give rise to a mean number of 10 colonies per spleen). On days 2, 4 or 6 after the graft, the mice were inoculated intravenously with 0.2 ml of highly infectious plasma (10^5 focus forming units (FFU)) from polycythaemic


Fig. 1 Simplified schema of the murine haematopoietic system. Normal steady state[14]: The pluripotent haematopoietic stem cell compartment (CFU) is a self-maintaining population. A 'first step' differentiation event transforms the pluripotent stem cells into committed precursor cells (ECP, erythroid committed precursor; NGCP, neutrophilic granuloid committed precursor; EGCP, eosinophilic granuloid committed cells). These transit populations undergo a number of cell cycles during their maturation but without the capability for prolonged self maintenance. A 'second step' differentiation triggers the late forms of the committed cells and initiates the maturation process of the identifiable haematopoietic cell line. The mechanisms or factors which control the different haematopoietic cell line productions are as yet ill defined. The 'second step' differentiation is well understood in the case of erythropoiesis. A humoral factor erythropoietin (EPO) has been demonstrated to stimulate erythropoietin responsive cell (ERC) proliferation and recruitment, to induce ERC differentiation and to promote the erythropoietic maturation. Hypertransfused-plethoric state: Injections of washed syngeneic red blood cells suppress EPO production and result in the arrest of the erythroid maturation process. Identifiable erythroid cells disappear from haematopoietic organs but ERC remain present at any time. There is abundant evidence that the ECP is constantly supplied by an outflux from the pluripotential compartment and an intrinsic rate of ERC self-replication[15].

mice infected with FVP. Three days after virus inoculation, the spleens were removed, fixed in Helly's solution or buffered formalin with added saccharose, embedded in paraffin or methacrylate and sliced sagittally into 2–3 μm sections. Sections were stained with diorthoanisidine, an indicator of the peroxidase activity of haemoglobin, and with azur B and fuschin acid for detection of basophilic and acidophilic cells. Haemoglobin synthesis was also investigated by autoradiographic determination of ^{55}Fe incorporation. ^{55}Fe (45 μCi per mouse, specific activity 3.85 Ci g^{-1}) was injected intravenously as ferric chloride, 3 h before killing. Spleen sections mounted on glass slides were dipped in Ilford K5 emulsion and exposed for 3–4 weeks.

Spleens of mice injected with FVP on d 4 after grafting and harvested on d 7, contained as expected, the differentiated neutrophilic, megakaryocytic and eosinophilic colonies. In addition, there were small colonies of hyperbasophilic Friend cells (20–50 per section) in which baso-

philic and some polychromatophilic erythroblasts, positive to diorthoanisidine staining, were observed. The labelling of both typical hyperbasophilic Friend cells and erythroblasts in autoradiograms confirmed initiation of haemoglobin synthesis.

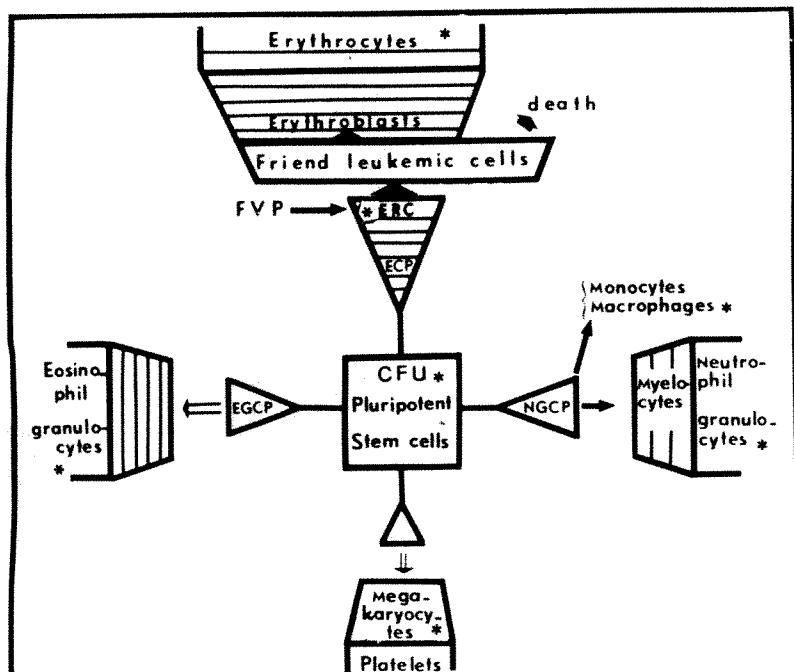
Spleens of mice killed 9 d after cell graft, that is 3 d after infection of FVP (day +6), contained similar but larger colonies. In these mice as well as in the former group, the distribution of the various histological types of colonies (erythroid 52%; granulocytic 28%; megakaryocytic 9%; mixed 5%; and undifferentiated 6%) was not significantly different from the distribution of colonies in spleens of non–plethoric-irradiated mice receiving the same spleen cell suspension. This indicates that practically all the presumptive erythroid colonies contained target cells for the virus. In the 9-d-old erythroid colonies obtained after injection of spleen cells into plethoric-irradiated and virus-infected hosts, the ratio of maturing erythroblasts to the large


Fig. 2 Schema of the leukaemogenesis by Friend leukaemia virus. Oncogenic potency of the Friend virus (FVP) is expressed only at the 'late' erythroid committed precursor level. After viral transformation Friend leukaemic cells multiply and differentiate along the erythrocytic pathway. EPO is not required to initiate the pathological erythropoietic differentiation. As indicated by kinetic studies, Friend leukaemic cells are not self-maintaining[16] (they die or differentiate). Then the progression of the disease requires a constant recruitment, of target cells from the ECP and CFU compartments. The viral replicative ability is not restricted to the erythroblastic cells.
*The most primitive haematopoietic stem cells and the different haematopoietic cell lines are infected by the virus but their development remains practically normal.

hyperbasophilic precursor cells was smaller than in the erythroid colonies observed the spleen of irradiated normal mice, suggesting a delayed or ineffective erythropoiesis. Spleens of mice inoculated by the virus on day 2 and killed on day 5 after the cell graft, contained small clusters of 5–10 hyperbasophilic Friend cells in association with only young basophilic erythroblasts. Twenty-four hours earlier (2 d after infection) no hyperbasophilic Friends cells could be observed. Since transformation requires 30–40 h (ref. 5), it can be postulated that the target cells for the virus were present only on or after day 3 or 4. Referring to the age structure of maturation process in the erythroid committed compartment[14], this suggests that FVP needs a mature precursor cell to express its oncogenic potency.

With respect to the three initial questions, these results directly indicate that: (1) the multipotent stem cell of the haematopoietic system is not a target cell for the virus. Colony forming units (CFUs) are present in all types of colonies, and even, as shown by Trentin et al.[11], in a greater number in the granulocytic colonies. Hyperbasophilic Friend cells were, however, never observed within granuloid nor megakaryocytic colonies. (2) The viral gene which induces transformation can be expressed only in an erythroid committed cell (the erythropoietin responsive cell or a closely related precursor) and transformation is immediately followed by erythroid maturation. (3) Only the erythroid pathway of differentiation is open to hyperbasophilic Friend cells (Fig. 2).

Through use of colony formation by the multipotent haematopoietic stem cell, we have been able to examine further the early interaction between a leukaemia virus and the haematopoietic cells.

Characterisation of human cells transformed *in vitro* by urethane

CELLS derived from several animal species, including mouse[1,2], hamster[3] and rat[4], have been transformed *in vitro* from the normal to the malignant state by diverse chemical carcinogens. In similar conditions, however, attempts to transform human cells have usually been unsuccessful and as far as we know, such transformation has been reported only once[5]. This was a case of two cell lines treated with urethane, obtained from siblings with von Recklinghausen's disease, a familial disorder transmitted by an autosomal dominant gene, and characterised by multiple fibromas with a high predisposition to malignant

transformation *in vivo*[6]. Although morphologically altered foci of transformed cells were reported, there was the possibility that a few tumour cells in the original population had been selected for by urethane. Therefore we characterised in detail the urethane-treated and untreated cultures. We have found that human cells can indeed be chemically transformed *in vitro*.

The control cells we used were designated as NFS-1. One transformed colony (designated urethane) was derived from a single morphologically altered focus in an NFS-1 culture treated with 1.1×10^{-2} M urethane. A second transformed colony (designated urethane/FeLV) was derived from a single focus obtained in a urethane-treated NFS-1 culture preinfected with feline leukaemia virus. Since morphologically altered foci occurred in numerous urethane-treated cultures[5], whether or not infected with FeLV, there was no evidence that FeLV was acting as a cocarcinogen. We used this culture for characterisation because it is one of only two continuous cell lines obtained from various attempts to isolate and grow morphologically altered foci.

Trypsin–Giemsa banding[7] revealed (Table 1) no abnormal metaphases in the untreated NFS-1 cells, while all metaphases in the urethane cell line at passage 30 were aneuploid. Most metaphase cells contained 94 or 95 chromosomes. An abnormal marker chromosome (M_1) was found in 19 of the 20 metaphases analysed (Fig. 1). An additional marker chromosome (M_2) was found in 14 of 20 metaphases (Fig. 1). Thus the transformed cells were derived from a single parent transformed stem cell. Similar marker chromosomes were found at passage 259 (Table 1).

The urethane/FeLV line also had an aneuploid chromosomal pattern at passage 25. This pattern was different from that of the urethane cell line, since most metaphases contained between 68 and 71 chromosomes, and no metaphases had the marker M_1 or M_2 chromosome. But, four additional marker chromosomes, M_3 to M_6, not found in

Fig. 1 Marker chromosome patterns revealed by the Giemsa–trypsin banding technique: *a*, Similar marker chromosomes, M_1 and M_2, from the urethane cell line. The normal No. 7 and No. 14 human chromosomes from the same three metaphases are shown for comparison. M_1 probably arose from a deletion of the short arm of a number 7 chromosome. *b*, Representative examples of the marker chromosomes M_3–M_6 found in the FeLV/urethane cell line. M_4, M_5 and M_6 are dicentric chromosomes.
Table 1 Chromosome number and marker chromosome distribution of NFS-1 and urethane or urethane/FeLV transformed cells

Cell line	Passage no.	Chromosome no.							Number of metaphases with given markers					
		44–45	46	65–67	68–71	72–93	94–95	96–105	M_1	M_2	M_3	M_4	M_5	M_6
NFS-1	15	3	47						0	0	0	0	0	0
Urethane	30					3	14	3	19	14	0	0	0	0
	259					4	2	14	18	8	0	0	0	0
Urethane/FeLV	25			6	14				0	0	16	7	8	5

the urethane cell line were seen at various frequencies (Fig. 1). The marker chromosome M_3 was found in 16 of 20 metaphases and additional marker chromosomes M_4, M_5, and M_6 were found in 7, 8 and 5 of 20 metaphases, respectively (Table 1). This suggests clonal evolution and separate parental origin for both transformed cell lines.

Untreated NFS-1 cells formed no colonies on soft agar, whereas the established urethane cell line (Table 2) formed numerous large colonies.

We also examined the intracellular and extracellular fibrinolytic activity of the NFS-1 cells and the two urethane-treated lines because greater fibrinolytic activity is usually associated with human malignant cells than with their normal counterparts[8]. The control NFS-1 cells contained little fibrinolytic activity (that is, the level found in normal human fibroblast cultures), whereas the transformed cells showed marked fibrinolytic activity (Table 2).

We also tested the urethane cell line for its ability to produce tumours in newborn hamsters treated with anti-thymocyte serum[8]. Animals injected with 2×10^6 control NFS-1 cells were treated with antithymocyte twice weekly for the first 2 months. No tumours developed in 5 months. A similar number of cells from the urethane line, however, produced rapidly growing fibrosarcomas within 3 weeks (Table 2). When placed back in cell culture, they had the same chromosome patterns as the injected human cells, and also showed high fibrinolytic activity (data not shown). The cell line containing FeLV was not tested for tumori-genicity, since we did not wish to risk contaminating our animal facilities with FeLV.

We believe that the cultures described represent the first documented chemical malignant transformation of human cells. The possibility that a few malignant cells were selected from the NFS-1 culture can be excluded for several reasons. First, repeated attempts to develop continuous cell lines from the untreated parent cultures have failed. Second, as previously reported there was no measurable cytotoxicity nor lag in growth in the NFS-1 cells after

treatment with the doses of urethane used[5]. Third, there was no opportunity for contamination of these transformed cell lines with other human cell lines, since no long term human cell line was present in the laboratory where the work was carried out.

The strongest evidence that the two established cell lines were derived from different parent NFS-1 cells is that each line had not only a markedly different model chromosome number but also dissimilar marker chromosomes. Although the original NFS-1 cells could have two distinct malignant parent lines present before treatment with urethane, this is unlikely since previous studies have shown that human malignant tumours are most often derived from one malignant stem cell[9,10].

It is interesting that both transformed cell lines had high extracellular and intracellular fibrinolytic activity, whereas the parent cell line did not. This is consistent with studies in other species in which the parent cells contained low fibrinolytic activity, whereas chemically transformed cells had a high activity[8]. This marked difference between normal and transformed human cells may be an important criterion for the presence of human transformed cells in attempts to establish a human model system for chemical transformation. We believe that documentation of the malignant nature of these cells in culture indicates that each of the original morphologically altered colonies[5] was also malignant, but could not be developed into continuous cell lines for unknown reasons. This would be consistent with the difficulty in establishing continuous cell lines from human tumour material[11,12]. We therefore conclude that chemical transformation of human cells does occur and is frequently expressed as foci or morphologically altered cells. Tissue culture conditions, however, are usually inadequate for the establishment of long term cell lines from these transformed cells.

Table 2 Fibrinolytic activity, growth in soft agar and tumour formation of transformed and untransformed human cells

Cell line	Passage no.	Fibrinolytic activity			Colonies in soft agar per 10^4 cells plated	No. hamsters with tumours / No. hamsters injected
		Extracellular DS	HS	Intracellular U per mg protein		
NFS-1	15	1	1	1	0	0/7
Urethane	25	52	76	57.1	250	2/3
	259	58	77	69.5	342	5/7
Urethane/FeLV	25	64	68	29.9	N.D.	N.D.

Extracellular fibrinolytic activity was measured by plating 5×10^5 cells on to ^{125}I-fibrin dishes in medium containing 10% (v/v) corresponding serum (DS, dog serum; HS, human serum).

Fibrinolytic activity after 24 h, is expressed as the percentage of radioactivity released into the supernatant compared with the total radioactivity of ^{125}I-fibrin per dish[8]. Intracellular fibrinolytic activity was assayed in aliquots of cell lysates prepared in Tris-HCl buffer, pH 8.1 (0.1M) containing Triton X-100 (0.5%). The cell lysates (10 µl) were incubated for 2 h in 35 mm ^{125}I-fibrin dishes containing 2.5 ml of 1% HS in Tris-HCl, pH 8.1, and the radioactivity released was measured. The radioactivity released by 100 U of urokinase in identical conditions was taken as 100% fibrinolytic activity. One unit of activity was defined as that amount of activity which released 10% of the urokinase activity in 2 h at 37 °C. The protein content in the cell lysates was determined by the method of Lowry[11]. The methods used for the soft agar and tumorigenicity studies were similar to those previously described[8].

Incorporation of acetylcholinesterase into synaptic vesicles is associated with blockade of synaptic transmission

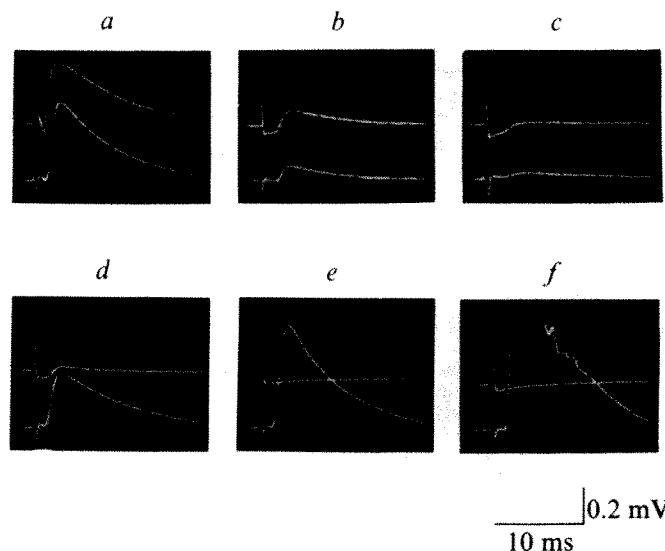
THE transmission of nerve signals across cholinergic synapses involves the presynaptic release (or secretion) of acetylcholine (ACh) which, by acting on specific sites of the postsynaptic membrane, induces changes in the postsynaptic transmembrane potential. According to the vesicle hypothesis[1], ACh is packed inside synaptic vesicles which release their contents from the nerve terminal on contact with the presynaptic membrane. Although there is abundant experimental evidence supporting the hypothesis[2], some papers question its validity[3-6]. The most important alternative hypothesis postulates that the releasable ACh is free in the cytoplasm[3-6] and that the vesicles are a secondary reservoir containing 'bound' ACh.

If the vesicle hypothesis is correct, enzymatic destruction of the ACh contained inside the vesicles should inhibit synaptic transmission. A direct way of testing the vesicle hypothesis would be to incorporate into the synaptic vesicles an enzyme that destroys the transmitter substance, and then to measure the resulting effects on transmission. Several groups[7-9] have succeeded in incorporating the enzyme horseradish peroxidase into the synaptic vesicles of various nerve terminals. In some cases[7,9], this was accomplished by stimulating the nerve terminals at a high rate for enough time to cause vesicle depletion, and then allowing the terminals to rest with the enzyme present in the bathing solution. During the rest period, vesicles containing the enzyme appeared at the terminal. Using this technique, we show here that the incorporation of exogenous acetylcholinesterase (AChE) into the synaptic vesicles of nerve terminals of the frog sartorius neuromuscular junction is associated with a marked inhibition of synaptic transmission, as would be predicted by the vesicle hypothesis.

In 16 experiments, non-curarised pairs of sartorius neuromuscular preparations, each pair taken from the same frog,
Fig. 1 Muscle contractions recorded with force transducers. *a*, Experimental; *b*, control. At the start of period 1, both preparations were stimulated simultaneously at 12 Hz. Stimulation was continued for 20 min in normal Ringer's. At the end of this period, the Ringer's solutions were exhanged for AChE–Ringer's (*a*) or for normal Ringer's (*b*), and the preparations were allowed to rest in the absence of stimulation for 45 min. Shortly before the start of period 2, both solutions were exchanged for normal Ringer's. At 2, a second cycle of stimulation identical to the first was begun. The response of E during this period was greatly diminished. Shortly before the end of period 2, the solutions were again exchanged for normal Ringer's, and the preparations were allowed to rest for an additional 45 min. At 3, a third period of stimulation was begun. Little further recovery of *a* was seen during this period.

were simultaneously stimulated through the nerves at 12 Hz for 20 min. At the end of the stimulation, the Ringer's solution bathing the experimental muscle of each pair was exchanged for Ringer's containing 0.5–1.0 mg ml⁻¹ AChE (Sigma, type V). The control muscle of each pair received either normal Ringer's, Ringer's containing 0.5–1.0 mg ml⁻¹ bovine serum albumin (Sigma), or Ringer's with paraoxon-inactivated AChE (0.5–1.0 mg ml⁻¹) dialysed against Ringer's before use. After a rest of 45 min, the bathing solutions of both experimental and control muscles were exchanged for normal Ringer's. Then the preparations were tested again for muscle contraction in response to nerve stimulation. A typical result is shown in Fig. 1. In most

Fig. 2 Endplate potentials recorded extracellularly. *a*, Experimental (top trace) and control (bottom trace) were stimulated in normal Ringer's at 20 Hz. Responses were recorded at time 0 (*a*), after 5 min of stimulation (*b*), and after 13 min of stimulation (*c*). After a total of 20 min of stimulation the bathing solutions were exchanged for AChE–Ringer's (experimental, 0.5 mg ml⁻¹) or for paraoxon-inactivated AChE–Ringer's (control, 0.5 mg ml⁻¹). The preparations then rested for 50 min. Shortly before *d*, the bathing solutions were exchanged for normal Ringer's. The response in *d* was recorded after 50 min of rest, and in *e*, after an additional 45 min of rest. The response in *f* was recorded after 9 min exposure to neostigmine methyl sulphate (0.5 mg ml⁻¹). The experimental showed no recovery of endplate potential during the later periods of stimulation, *d*, *e*, or *f*.

0.2 mV
10 ms


cases (13 out of 16) the experimental preparation showed an obvious diminution in contraction, whereas the control showed a significant recovery. Occasionally, it was necessary to repeat the cycle of stimulation and rest (in one case, four times) to elicit the effect. The fact that paraoxon-inactivated esterase and albumin did not inhibit transmission indicates that ACh hydrolysis was necessary.

In a different series of experiments, Fatt's method of extracellular recording of endplate potentials (e.p.p.s) was used[10]. Paired preparations were curarised (1–1.5 mg l^{-1} D-tubocurarine, Abbot) and AChE- and albumin-containing Ringer's were used following the sequence described in Fig. 2. As in non-curarised preparations, the AChE treatment (in seven of nine cases) greatly diminished or abolished the postsynaptic response to nerve stimulation, whereas the response of control preparations recovered to the pre-stimulation value. In these experiments too, the procedure in some cases had to be repeated more than once to obtain the effect. Preincubation of the preparations at 4 °C or brief stimulation during the rest period seemed to interfere with the effect.

Several attempts to reverse the AChE effect were made with both curarised and non-curarised preparations by introducing a second stimulation period (20 Hz, 20 min), in AChE-free Ringer's. Heuser and Reese[7] reported that a second stimulation of terminals already loaded with exogenous horseradish peroxidase resulted in the disappearance of enzyme-containing vesicles. In our experiments, however, no recovery of the AChE-inhibited preparations was observed.
Fig. 3 Electron micrograph of nerve terminal stained for incorporated AChE ($\times 67,500$). The nerve–muscle preparation was stimulated at 20 Hz for 20 min and rested for 45 min in AChE–Ringer's. After washing several times with normal Ringer's, the preparation was fixed in 2.5% glutaraldehyde in 0.2 M sodium cacodylate, pH 7.4, and then stained for cholinesterase activity[14], osmicated, dehydrated, and embedded in Epon. Dimethyl sulphoxide (0.1%) was included in the staining reagent. Black deposits in the synaptic vesicles indicate the presence of AChE activity. Controls which were stimulated and rested in normal Ringer's and then treated as above, had no reaction product in the vesicles. Deposits of reaction product in the synaptic cleft were also seen in controls.

The above mentioned inhibition of the postsynaptic response could be explained by hydrolysis of ACh in the synaptic cleft. There is, in fact, some evidence that AChE can enter and leave the cleft[11–13]. To test this possibility, preparations were stimulated at a slow rate (about 2 min^{-1}) in the presence of AChE (0.5–1.0 mg ml^{-1}) in the Ringer's. With this non-fatiguing stimulation no effects on muscle contraction were observed for several hours. Presumably, vesicle recycling and incorporation of exogenous AChE at this rate of stimulation occurs only very slowly. Additional evidence against the extracellular action of exogenous

AChE is the fact that in preparations where synaptic transmission was completely blocked as described above, the addition of a cholinesterase inhibitor (neostigmine methyl sulphate, K & K, 1 mg l^{-1}) did not restore the e.p.p.s (Fig. 2f).

To determine the location of the exogenous AChE in the presynaptic terminal after stimulation to fatigue and rest in the presence of the enzyme, preparations so treated were fixed, and then stained for the demonstration of cholinesterases according to Crevier and Belanger[14]. In the preparation shown in Fig. 3, 15–20% of the synaptic vesicles contain electron-dense reaction product indicative of cholinesterase activity.

These results show that the incorporation of exogenous AChE into synaptic vesicles is associated with inhibition of synaptic transmission at the frog sartorius neuromuscular junction, suggesting that the ACh available for release is contained in the synaptic vesicles. These results, however, do not rule out the possibity that there is a releasable cytoplasmic store of ACh which is in equilibrium with the intravesicular pool. This latter possibility is compatible with the results of Tauc *et al.*[6] who showed that injection of AChE into the axoplasm of an *Aplysia* cholinergic neurone resulted in inhibition of transmission.

An interesting further application of the technique described here might be the use of this or other transmitter-inactivating enzymes to identify the transmitter substance in different synapses.

Differences between detergent-extracted acetylcholine receptor and "cholinergic proteolipid"

SNAKE venom α-toxins[1] in combination with reversible[2,3] or alkylating[4,5] cholinergic ligands give a selective labelling of the cholinergic (nicotinic) receptor protein (AChR)[6–8]. Since this protein is membrane-bound and therefore expected to possess hydrophobic properties, two different methods have been used for its dissolution and purification: (1) chloroform–methanol extraction[8] and (2) non-denaturing detergent extraction in aqueous media[2,3]. The former solubilises the so-called "cholinergic proteolipid" which, still in organic media, binds charged cholinergic ligands[9]. The latter procedure has made possible the purification of the

AChR by affinity chromatography and the study of the binding of the above-mentioned ligands in physiological media (for reviews see refs 6–8). Furthermore, the serum of rabbits immunised against the purified AChR[10–12] blocks *in vivo* the physiological response to cholinergic agonists[10,11], thereby confirming that the detergent-extracted AChR is indeed involved in the permeability change caused by acetylcholine. On the other hand, the physiological importance of the "cholinergic proteolipid" remains undetermined, though the challenge to the actual purification[13] has recently been refuted[14]. It is therefore the aim of the present work to compare the "cholinergic proteolipid" and the detergent-extracted AChR from the same sources: the electric organs of *Electrophorus electricus* and *Torpedo marmorata* using the selective labels α-toxin[15] and the covalent affinity reagent 4-(N-maleimido)-phenyltrimethylammonium iodide[4] in combination with immunodiffusion tests[11].

Frozen electric tissue from *Electrophorus electricus* was thawed, homogenised in water, lyophilised and extracted with chloroform–methanol (2 : 1 v/v) as described by La Torre *et al.*[16]. The crude organic extract was partitioned with one fifth its volume of water, and the proteolipids of the organic phase precipitated with four volumes of diethyl ether at −20 °C. After standing overnight, the precipitate was redissolved in chloroform–methanol (2 : 1 v/v), concentrated *in vacuo*, and chromatographed through the organophilic dextran gel Sephadex LH 20 using chloroform–methanol mixtures[16]. The proteolipid fraction III (the so-called "receptor proteolipid")[9,16] was isolated for further study. In other series of experiments, fresh and lyophilised electric tissue were extracted with chloroform–methanol at various temperatures (25 °C, −50 °C, −80 °C) according to ref. 17. After evaporation of the organic solvent at +25 °C or −25 °C, the samples were re-extracted by adding Triton X-100 in *Electrophorus* Ringer's solution (160 mM NaCl, 5 mM KCl, 2mM $MgCl_2$, 2 mM $CaCl_2$, 2.5 mM Na phosphate buffer pH 7) to a final 1% detergent concentration and stirred for 1 h at room temperature. The detergent extracted fractions were analysed for their binding activity with ^3H-α-*Naja nigricollis* toxin (15 Ci mmol^{-1}) (ref. 15) and for their ability to react with rabbit antibodies raised against purified acetylcholine receptor from *Electrophorus* (anti-AChR), using the Ouchterlony immunodiffusion test[11] (Fig. 1). The Triton X-100 extracted AChR was purified from *Electrophorus* membrane fragments by affinity chromatography[18].

Fig. 1 Ouchterlony double diffusion in 1% agarose gel and 0.025 M Veronal buffer pH 8.2. 1, Triton X–100 extract of proteolipid fraction III (ref. 16); 2, 3, AChR purified by affinity chromatography in the presence of Triton X–100 (ref. 18); 4, 5, 6, 7, Anti-AChR sera raised in four different rabbits. The presence of the Triton X-100-extract of proteolipid fraction III in hole No. 1 does not induce any deviation of the precipitation lines between AChR and anti-AChR: no cross reaction can be seen between AChR and the proteolipid fraction III.
Fig. 2 Ouchterlony double diffusion in 1% agarose gel and 0.023 M Veronal buffer pH 8.2. 1, Anti-proteolipid fraction III sera, raised in two different rabbits; 2, 5, Proteolipid fraction III in 1% Triton X–100; 3, 4, 6, 7, AChR purified by affinity chromatography in 1% Triton X–100. Precipitation lines are seen between hole 1 and holes 2 and 5. The presence of AChR in holes 3, 4, 6 and 7 induces no deviation of the precipitation lines: no cross reaction occurs between AChR and rabbit anti-proteolipid fraction III sera.

Rabbit antisera were also raised against proteolipid peak III from *Electrophorus electricus* electric tissue. Three rabbits each received 500 μg proteolipid peak III in 0.5 ml Freund's adjuvant; the dose was repeated after one week and after a further 2 weeks. The ability of the rabbit antibodies to react with proteolipid peak III and with purified AChR was tested using the Ouchterlony immunodiffusion test[11] (Fig. 2).

Regardless of the temperature of extraction[17] and subsequent concentration, the proteolipid protein transferred to 1% Triton X-100 or emulsified in water, before or after chromatography on Sephadex LH 20, does not show binding of ^3H-α-toxin nor does it react against anti-AChR antisera. Similarly, no cross reaction between the AChR[18] and the organic extract or the purified "cholinergic proteolipid" of La Torre *et al.*[16] was observed in these immunodiffusion tests.

In another series of experiments 25 μg of the AChR protein purified by affinity chromatography[18] (2,400 nmol ^3H-α-toxin bound per g of protein) was incubated overnight with Cl_3CH–CH_3OH (2 : 1 v/v) at 0 °C, 4 °C and 25 °C. After evaporation of the organic solvent with N_2, the residual aqueous samples were assayed for α-toxin binding and immunoprecipitation. In all cases, the ability to bind the cholinergic ligand and to react against the anti-AChR antisera were lost. The immunological and the toxin binding assays on water-solubilised proteolipids might be negative because of a possible partial denaturation of the so-called "receptor proteolipid" during transfer to aqueous solvents, although the detergent-solubilised proteolipid retains its antigenicity to rabbit anti-proteolipid peak III serum as seen in Fig. 2. The AChR was therefore covalently labelled, before its extraction with organic solvents, with 4-(N-maleimido)-phenyltri-^3H-methylammonium (^3H-MPTA), by a procedure similar to that used by Karlin and Cowburn[5] with 4-(N-maleimido)-benzyltri-^3H-methylammonium (^3H-MBTA). This allowed the AChR to be followed

Table 1 ³H-MPTA labelling of AChR-rich membrane fragments from *T. marmorata* (800 nmol ³H-α-toxin bound per g of protein)

	³H-MPTA
In the absence of α-toxin	2,400 c.p.m. μg⁻¹ protein
After preincubation with 30 μg ml⁻¹ of unlabelled α-toxin	8 c.p.m. μg⁻¹ protein
CM extraction of labelled membrane fragments	
(1) From aqueous phase (15 μg protein)	
CM extract	50 c.p.m.
Aqueous phase	34,600 c.p.m.
(2) From lyophilised membranes (48 μg protein)	
CM extract	2,500 c.p.m.
Solid residue	110,000 c.p.m.

Chloroform—methanol (2:1 v/v) (CM) extraction of labelled membrane fragments : the receptor-rich membrane fragments from the electric organ of *Torpedo marmorata* were prepared according to ref. 19. They were then labelled with ³H-MPTA following the procedure of Karlin[5]. The receptor-rich membrane fragments (800 nmol α-toxin sites per g of protein) were incubated for 10 min in the presence of 1 mM dithiothreitol in buffer I (0.1 M NaCl, 1 mM EDTA, 0.01M Tris-HCl, pH 8). This reduction was stopped by adding 0.5 M Na Phosphate buffer pH 6.7 and cooling to 0 °C. After centrifugation at 100,000g for 90 min, the pellet was resuspended in buffer II (0.15 M NaCl, 1 mM EDTA, 0.01 M Na phosphate buffer pH 7.0). An aliquot was incubated for 90 min at 20 °C with an excess of α-toxin from *Naja nigricollis*, the rest being incubated without α-toxin at the same temperature. The two samples were then run in parallel. They were labelled with ³H-MPTA (about 2 Ci mmol⁻¹) for 2 min at 25 °C. The labelling was stopped with 2-mercaptoethanol. The membrane fragments were then washed by threefold centrifugation followed by resuspension of the pellet in buffer III (0.15 M NaCl, 1 mM EDTA, 0.01 M sodium phosphate buffer, pH 7.0). (1) The labelled membrane fragments were extracted with CM. The extract was partitioned with H₂O and the "theoretical upper phase"[16] was prepared with Cl₃CH : CH₃OH—H₂O (3:48:47 by volume) and separated by centrifugation (3,000g, 10 min). This procedure was done three times and the radioactivity was measured in the combined upper phases and in the washed CM extract. (2) The membrane fragments were first lyophilised and then extracted with CM, and filtered. The radioactivity was measured in the residue and the CM extract.

even in a denatured state. Table 1 shows the results of the affinity labelling with ³H-MPTA of the AChR-rich membrane fragments from *Torpedo marmorata* prepared according to ref. 19.

The native membrane fragments bound 800 nmol of ³H-α-toxin per g of protein; after reduction by dithiothreitol, 2,400 c.p.m. of ³H-MPTA (about 2 Ci mmol⁻¹) were covalently attached per μg of protein. Preincubation of the membrane fragments with 30 μg ml⁻¹ α-toxin before affinity alkylation reduces by 99.7% the amount of ³H-MPTA retained by the membrane fragments confirming that, under these conditions, the labelling of ³H-MPTA is specific for the AChR site.

Samples of the ³H-MPTA labelled membrane fragments were extracted with chloroform—methanol (2 : 1 v/v) and the crude extract extensively washed with H₂O (Table 1). No radioactivity was recovered in the organic phase. All the radioactivity was recovered in the combined aqueous phases and in a precipitate which formed at the water–chloroform–methanol interface. When the chloroform–methanol (2 : 1 v/v) extraction was performed on lyophilised tissue, as described by La Torre *et al.*[16], only 1.7% of the radioactivity was found in the organic extract, the rest being recovered in the residue.

The experiments using affinity alkylation of the membrane-bound AChR from *Torpedo marmorata*, in coincidence with those carried out on the material extracted from *Electrophorus electricus*, indicate that in agreement with Karlin[7] the AChR subunit(s) carrying the site(s) for binding α-toxin or MPTA and recognised by the anti-AChR antisera[10-12] are not extracted with chloroform–methanol (2:1 v/v). The organic-extracted "cholinergic proteolipids"[9,16,17] from the same sources are therefore different

from the detergent-extracted AChR in all these respects.

Possible mechanism for action of prolactin on mammary cell sodium transport

PROLACTIN, like other polypeptide and glycoprotein hormones from the pituitary gland, exerts its effects on target cells through interaction with receptors on the plasma membrane[1-4]. Unlike several other pituitary hormones, this does not occur through activation of adenyl cyclase[5], and the mechanism of action of prolactin must therefore lie elsewhere.

In this study we have investigated a possible mechanism which is derived from the earlier (in evolution), osmoregulatory function of prolactin. In estuarine fishes, prolactin maintains internal osmolarity by regulating Na⁺ diffusion across the gills, and by controlling the activity of Na⁺/K⁺-activated ATPase, the active monovalent ion pump, in gills and kidney[6]. Prolactin may therefore act similarly on mammary alveolar cells, which are of epithelial origin, through the regulation of monovalent cation transport.

Measurement of sodium²² transport in response to prolactin, growth hormone and albumin was carried out using slices of lactating mammary tissue incubated with ²²Na⁺ as described in Table 1. The results of these experiments show a highly significant decrease in tissue ²²Na⁺ after addition of prolactin, and a less significant decrease after growth hormone. The growth hormone preparation had less than 0.5 IU per mg prolactin potency, but it is possible that this was sufficient to cause the decrease.

In further experiments, incubation of mammary tissue slices in the presence of 5 × 10⁻⁵ M ouabain resulted in a 10% in-

crease in tissue $^{22}Na^+$ content. Incubation with ouabain plus prolactin abolished the decrease in $^{22}Na^+$ observed after prolactin alone, and resulted in tissue $^{22}Na^+$ content similar to incubations with ouabain alone.

In these experiments, tissue $^{22}Na^+$ content after incubation would be caused by $^{22}Na^+$ entry by diffusion, opposed by the activity of the Na^+ pump (Na^+/K^+-activated ATPase) in extruding intracellular Na^+. Ouabain selectively inhibits this Na^+ pump[8], and was used in these experiments to demonstrate whether the reduced $^{22}Na^+$ content of the tissue caused by prolactin occurred as a result of lowered Na^+ entry or accelerated Na^+ extrusion. As ouabain abolished the prolactin effect, the data suggest that the action of prolactin is on the Na^+ pump to increase Na^+ transport out of the cell.

Monovalent ion concentrations in lactating mammary tissue were measured after incubation in the presence or absence of prolactin. With rabbit tissue (Table 2), and with guinea pig tissue (I.R.F. and J.M.R., unpublished), significantly lower tissue Na^+ concentrations resulted from incubation with prolactin. Tissue K^+ concentrations did not change significantly, but tissue Cl^- was significantly decreased after incubation with prolactin. Because of the permeability of the apical membranes of the cells to K^+ and the high concentration gradient to be expected between intra- and extracellular K^+ in this system, any changes in cell K^+ transport may well be masked.

The observed decrease in tissue Na^+ when prolactin is present in the incubation indicates that prolactin directly stimulates the transport of Na^+ out of the cell, presumably by increasing the activity of Na^+/K^+-activated ATPase. To confirm this, we are at present investigating the influence of prolactin on isolated mammary membrane fragments having Na^+/K^+-activated ATPase activity. Note that cytological studies have located both the Na^+/K^+-activated ATPase and the prolactin receptors on the same restricted region of the alveolar cell membrane[2,10]. The studies of Cowie[11] on milk composition in the rabbit provide supporting evidence for the effect of prolactin on monovalent ion transport, as he showed a rise in milk Na^+ and Cl^- in late lactation, which could be reversed by prolactin. As the ionic composition of milk reflects alveolar intracellular ionic composition[12], it is likely that monovalent cation concentration in the milk is regulated by ion transport at the basal membrane of the cell, and thus would be responsive to prolactin.

It seems likely therefore that an early response of mammary alveolar cells to prolactin is the activation of the Na^+ pump leading to a decreased intracellular Na^+ concentration, and a

Table 1 Effect of prolactin, growth hormone or albumin on $^{22}Na^+$ content of mammary gland slices

Lactating mammary alveolar tissue was obtained from rabbits 10–20 d *post partum*, killed by cervical dislocation with minimum disturbance. For 3 d before killing, bromocriptin (CB154, gift from Professor E. Flukiger and Dr H. Friedle, Sandoz, Basle) was administered daily at 1 mg kg^{-1} subcutaneously, to inhibit prolactin secretion[7]. The mammary alveolar tissue was cooled, chopped into 0.7 mm slices (McIwain chopper), and washed in Tyrode's solution (*p*H 7.4) at 0 °C before use. Prolactin (NIH P/S9), growth hormone (NIH B 17GH gifts from the National Institutes of Health) and bovine serum albumin (Commonwealth Serum Laboratories, Melbourne) dissolved in Tyrode's solution were used as described. To measure $^{22}Na^+$ transport, 0.1 g tissue slices were incubated in 2 ml Tyrode's solution containing 1% rabbit serum at 37 °C for 2 h in an oscillating (200 cycles min^{-1}) water bath, in the presence of 0.1 μCi $^{22}Na^+$. To this incubation medium were added 20 μg prolactin, growth hormone or albumin. After incubation the supernatant was decanted, the slices washed at 0 °C for 15 min in Tyrode's solution, blotted and $^{22}Na^+$ content determined in a well-type scintillation counter.

Table 2 Monovalent ion concentrations in slices of lactating mammary alveolar tissue from rabbits after incubation with increasing concentrations of proclactin

Prolactin concentration ($M \times 10^{-8}$)	Monovalent ion concentration (meq kg^{-1} tissue; mean ± s.e.m.)		
	Na^+	K^+	Cl^-
0.00	114.1 ± 2.1	23.7 ± 0.9	90.2 ± 2.7
4.35	107.9 ± 2.2*	25.3 ± 1.2	78.3 ± 4.2†
8.70	104.8 ± 3.4†	22.9 ± 1.0	82.5 ± 2.7*
17.40	105.0 ± 2.2†	25.1 ± 1.1	84.0 ± 3.0

$*P < 0.05$; $†P < 0.01$.

Lactating rabbits were used on three separate occasions for these experiments and the data combined. Each rabbit was treated with bromocriptin as described in Table 1. Each experiment comprised 20 samples of 500 mg 0.7 mm slices of mammary tissue, incubated in Krebs bicarbonate buffer, *p*H 7.4, for 1 h with continuous bubbling of 95% O_2–5% CO_2. Prolactin was added to the incubation medium in three sets of five samples in each experiment at the concentrations shown, which correspond to 0.05, 0.1 and 0.2 μg per mg tissue. After incubation, the tissue was homogenised with an overhead homogeniser (Ultra-Turrax, Type TP1810 Janke and Kunkel K.G., Staufen i. Breisgau) in 4 ml deionised water. Monovalent ion content was measured using an Atomic Absorption Spectrophotometer (AA100, Techtron, Melbourne, Australia) and the chloride content determined by titration[9].

marked change in the intracellular Na^+/K^+ ratio. These changes may act as an intracellular messenger in the biosynthetic events resulting from prolactin stimulation, as alterations in monovalent cation concentrations have been shown to stimulate nuclear activity in insect salivary glands in a hormone-like response[13]. Investigations of mammary alveolar cell responses to changes in monovalent cation concentrations may thus shed light on the mechanism of action of prolactin.

We thank the Nuffield Foundation for support, and Mr T. Buckley and Mrs K. Tadros for assistance.

Internal regulation of iron absorption

McCANCE and Widdowson[1] concluded that body iron content is regulated by variation in the amount absorbed and not by variation in excretion, and many workers have since attempted to define the factors which relate iron absorption to the needs of the body. Although there is a large body of data on the intracellular mechanisms of absorption[2] this has not advanced our understanding of the physiology of regulation.

There are three main theories describing the regulation of iron absorption. The first proposes that this control is exercised mainly by the gut mucosa. The epithelial cells of the small intestine incorporate iron from the plasma during their development, and it has been suggested that the amount taken up by these cells reflects the iron status of the body and that this in turn conditions them to allow the passage of more or less iron[3]. Within the cell this

control may be related to the cell's ability to synthesise ferritin[3] (which may retain iron and so prevent the transfer of unwanted iron to the plasma), to the degree of saturation of a hypothetical carrier protein[3,4] or to the iron requirements of the cell for haem synthesis[5]. Changes in the rate of plasma iron turnover have, however, been shown to affect iron absorption and it has been thought that this, rather than changes in plasma iron concentration, may be the main determinant of the iron status of the developing epithelial cell[6].

The second, related, theory proposes that control is a function of the different characteristics of the two iron-binding sites of the transferrin molecule in the plasma[7]. The number of molecules with two iron atoms will, it is assumed, reflect the level of body iron stores and determine the concentration of iron in the mucosal cells. This may then regulate the transfer from the mucosa to the plasma as in the first theory. It is suggested, however, that one transferrin iron-binding site is preferentially relieved of iron by the red cell precursors of the marrow and is also particularly avid for intestinal iron. This superimposes a second controlling factor on iron absorption whereby it may be related to the demands of erythropoiesis as well as to the level of the iron stores[7].

The third theory involves a humoral factor which is secreted either in direct or inverse proportion to body iron requirements and which signals the gut to increase or decrease iron absorption. Conrad[8] has commented on a number of experiments exploring this hypothesis.

There is no direct experimental evidence to support either the transferrin or the humoral control theories. The mucosal mechanisms which have been proposed do not explain all the observed phenomena and indeed recent observations have cast doubt on some of the earlier conclusions. These were based on measurements of the iron content of the whole gut wall and seemed to show an inverse relationship between mucosal iron and iron absorption[6,9]. Direct measurement of the iron content of epithelial cell homogenates has now shown that there is no direct relationship between epithelial cell iron and absorption[10-12]. Moreover, iron-deficient epithelial cells have a capacity for ferritin synthesis equal to that of normal cells[13]. The iron or ferritin content of the mucosal cell does not seem to be the controlling factor in iron absorption. The basic question remains — how is iron absorption induced to respond to the rate of erythropoiesis and the level of iron stores? We suggest that this regulation may best be explained by a consideration of internal iron exchange.

Iron circulating in the plasma bound to transferrin exchanges with iron in all cells of the body. An exchangeable iron pool may be defined as iron available for binding by circulating transferrin irrespective of its site or chemical form. Its size will depend not only on cellular iron concentration but also on the transferrin-binding sites in different tissues. The probability of an iron atom from a given tissue being picked up by a free receptor site on a transferrin molecule is proportional to the ratio of exchangeable iron in that tissue to the exchangeable iron in the whole body. The number of iron atoms picked up in this way per unit time is equal to the number cleared from the plasma. This is reflected in the experimentally measured plasma iron turnover. Iron transfer from the intestinal epithelium to the plasma is therefore proportional to

$$\frac{\text{Intestinal exchangeable iron}}{\text{Total exchangeable iron}} \times \text{Plasma iron turnover}$$

In general the total exchangeable iron in the body is directly related to the level of storage iron and our hypothesis explains why low iron stores are associated with increased iron absorption and high stores with reduced

absorption. It predicts that this relationship will hold not only in patients with iron deficiency or iron overload but also in normal subjects; this has been observed[14,15]. This hypothesis also shows how an increase in iron absorption may follow an increase in plasma iron turnover as a result of erythroid overactivity. It also explains why this is not always found. When increased erythropoiesis is associated with haemolysis, increased haemoglobin catabolism results in an increased amount of iron in the reticuloendothelial system. This increases the total exchangeable iron and will counterbalance the effect of plasma iron turnover on iron absorption, and thus a stable haemolytic anaemia may be associated with normal iron absorption[16].

In conclusion, the present hypothesis offers a simple rational explanation of the relationship between several endogenous factors which can influence iron absorption, and provides a framework for further investigation.

Appearance of hypoxanthine guanine phosphoribosyltransferase activity as a consequence of mycoplasma contamination

MYCOPLASMAS are common contaminants of cells in culture and are often responsible for profound alterations in the metabolism of infected cells[1,2]. Such alterations include chromosomal aberrations[3,4] and changes in host cell enzyme activities[5]. We have reported that amniotic fluid cell cultures contaminated with mycoplasmas revealed a significant increase in chromosomal aberrations over those seen in uninfected cultures[6]. This finding demonstrated that the presence of these organisms in amniotic fluid cell lines poses a potential hazard to prenatal chromosome diagnosis.

In addition to chromosomal disorders many inherited metabolic disorders can now be diagnosed prenatally, including biochemical defects involving diminished or complete absence of enzyme activities[7]. The studies reported here were designed to determine whether cells lacking a specific enzyme activity may acquire significant levels of activity as a consequence of mycoplasma infection. The cell line chosen for these studies was D98/AH-2, a human cell line which lacks measurable hypoxanthine guanine phosphoribosyltransferase (HGPRT) activity[8]. HeLa cells were used as a positive control for human HGPRT activity.

D98/AH-2 and HeLa cells were grown in Eagle's basal medium supplemented with 10% calf serum, 28 mM HEPES buffer and 100 U ml^{-1} penicillin and subcultured

twice weekly. Actively dividing D98/AH-2 cells were infected with 1×10^6 colony forming units (CFU) of *Acholeplasma laidlawii* or *Mycoplasma hyorhinis*, two common contaminants of cell cultures[1,2]. The infected cells were assayed for HGPRT activity 7 d and 28 d after infection. The HGPRT activities of the two mycoplasma strains were assayed separately.

Representative HGPRT activities are shown in Table 1. Pellets of both *A. laidlawii* and *M. hyorhinis* contained high levels of HGPRT activity. D98/AH-2 cells, as expected, had no measurable activity. Significant levels of HGPRT activity were however found in the infected cultures. In particular, cells infected with *M. hyorhinis* had levels of activity similar to that of the HeLa control. The levels of HGPRT activity probably represent a conservative estimate of the actual activity since 5–40% of inosinic acid was apparently converted to inosine and was not included in our calculated activities. This was probably due primarily to mycoplasmal 5'-nucleotidase activity[10], although D98/AH-2 5'-nucleotidase activity may have been a contributory factor. It is of interest to note that cells infected with *M. hyorhinis* had much higher levels of enzyme activity than did cells infected with *A. laidlawii*, whereas both mycoplasma strains alone have comparable activity.

An attempt was made to correlate activity with a degree of contamination by measuring the CFUs of mycoplasmas in the cell pellets. This provides a relatively crude estimate of the number of viable mycoplasmas[11], but it permits the inference that the low HGPRT activities in cells infected with *A. laidlawii* were due to lower mycoplasma : cell ratios than those cultures infected with *M. hyorhinis*. This is further supported by the fact that no inhibition of mycoplasmal HGPRT activity was seen when D98/AH-2 cells were mixed with high numbers of *A. laidlawii* just before the HGPRT assay (Fig. 1), indicating that D98/AH-2 cell extract was not inhibitory to the acholeplasma HGPRT. In a separate series of experiments hypoxanthine was added to cell cultures at the time of infection in an attempt to induce higher levels of mycoplasmal HGPRT activity. As shown in Table 1 no significant increase was noted in D98/AH-2 culture infected with *M. hyorhinis*. The apparent increase in HGPRT activity in cells infected with

A. laidlawii in the presence of hypoxanthine may merely represent the inaccuracy of the quantitative assay of viable mycoplasmas associated with the cells.

Electrophoretic analysis of mycoplasmal and cell extracts was done to compare the mobilities of the mycoplasmal and human HGPRT enzymes. Slab gel electrophoresis of infected cells showed bands of activity only for those infected with *M. hyorhinis* (Fig. 1). Distinct bands due to *A. laidlawii* activity were seen only when these mycoplasmas and uninfected cells were mixed together just before extraction. Both mycoplasmal HGPRT activities migrate to a position distinct from that of human HGPRT.

We wish to draw notice to the extra band arrowed in the HeLa cell profile in Fig. 1. These cells were obtained from a laboratory subsequently shown to possess mycoplasma contaminated cell lines (E.J.S. and J.T., unpublished observations). Unfortunately this particular cell line was lost before routine mycoplasma testing was performed. All subsequent electrophoretic analyses of HeLa HGPRT activity using cells known to be free of mycoplasma did not, however, reveal this band.

Our results clearly indicate that the presence of mycoplasmas as contaminants of cell cultures can lead to altered enzyme patterns. This finding is of considerable importance since it suggests that errors in prenatal diagnosis may occur if amniotic fluid cell cultures are contaminated with mycoplasmas. Of particular relevance is the prenatal diagnosis of the Lesch–Nyhan syndrome in which HGPRT activity is diminished[12]. We have also demonstrated significant levels of hexosaminidase A activity in mycoplasmas (E.L.S., J. Tallman, and E.J.S., unpublished observations); the enzyme which is used for pre- and postnatal diagnosis of Tay-Sachs disease[13]. Mycoplasmas also express adenine phosphoribosyltransferase activity at levels higher than those observed in cultured human cells when calculated on a total protein basis (J.A.T. and E.J.S., unpublished observations).

The degree of mycoplasma contamination reached in our deliberately infected cultures is comparable with levels encountered in accidentally contaminated cell lines. Because of the high frequency of mycoplasma contamination found in tissue culture facilities we believe it is

Table 1 HGPRT activities of *A. laidlawii* and *M. hyorhinis* in cell cultures

Sample	HGPRT activity (c.p.m. in inosinic acid/µg protein/min of assay)	Approximate no. of viable mycoplasmas/0.1 ml packed cell volume (± 0.5 log$_{10}$)
A. laidlawii	27.46	3.0×10^9
M. hyorhinis	17.45	1.1×10^9
D98/AH-2 cells	No activity	Negative
D98/AH-2 cells infected with *M. hyorhinis*	18.27	1.9×10^8
D98/AH-2 cells infected with *M. hyorhinis* in the presence of 10^{-4} M hypoxanthine	5.58	8.0×10^7
D98/AH-2 cells infected with *A. laidlawii*	No activity	2.0×10^7
D98/AH-2 cells infected with *A. laidlawii* in the presence of 10^{-4} M hypoxanthine	2.87	2.0×10^7
HeLa	17.75	Negative

Mycoplasmas were grown in broth for 2–4 d at 37 °C, then collected by centrifugation at 10,000 r.p.m. for 20 min, washed twice with phosphate buffered saline (PBS) and the pellets stored at -37 °C until the time of assay. Cell cultures were collected by trypsinisation, washed twice with PBS, pelleted and stored at -70 °C. In one series of experiments 10^{-4} M hypoxanthine was added to the growth medium at the time of infection in an attempt to induce higher levels of mycoplasmal HGPRT activity. Extracts of mycoplasma and cell pellets were prepared by sonication. The assay was started by the addition of the sample extract to 100 µl of reaction mixture containing 0.25 µCi ^{14}C-hypoxanthine (specific activity 5.37 Ci mM^{-1}); magnesium chloride 5 mM; 5-phosphoribosyl-1-pyrophosphate 1 mM; Tris buffer (pH 7.4) 55 mM; and bovine serum albumin 150 µg. The reaction was carried out at 37 °C and samples removed at 0,10 and 30 min. The reaction in each case was stopped by the addition of formic acid (to 0.66 M) and immersion in a dry ice–methanol bath. Hypoxanthine, inosine and inosine monophosphate were separated by spotting 5-µl samples on Eastman Chromogram Cellulose TLC sheets using non-radioactive markers for identification and 5% Na$_2$HPO$_4$ as a solvent. Spots were visualised with ultraviolet light, cut out and counted by scintillation spectrometry.

imperative that prenatal diagnostic centres should institute routine screening of their amniotic fluid cultures for mycoplasmas. Since cultured skin fibroblasts are also used for the postnatal biochemical diagnosis of many inherited metabolic disorders, mycoplasma contamination could interfere with these determinations as well. If further studies show that mycoplasma contaminants of cell cultures have enzyme activities which migrate distinctly from human enzymes by gel electrophoresis, then this procedure could be used to distinguish between their respective activities.

These results should also serve as a warning to investigators involved in somatic cell genetics, where contaminating mycoplasmal enzyme activities may be confused with isoenzyme expression[14] and 'reactivation' of enzyme activities after somatic cell hybridisation[15]. A further potential hazard to this area of cell biology is the known capacity of mycoplasmas to induce chromosomal aberrations, including translocations[3,4,6], which could lead to problems of assigning gene activities to specific chromosomes[16].

IMP dehydrogenase, an enzyme linked with proliferation and malignancy

PREVIOUS studies conducted in this laboratory demonstrated that in a spectrum of liver tumours with different growth rates there is an imbalance in the activities of key enzymes and competing pathways of carbohydrate, pyrimidine, DNA and ornithine metabolism[1–4]. Recent investigations on purine metabolism showed that in the hepatomas there was an increased capacity in the *de novo* pathway of biosynthesis of inosine 5′-monophosphate (IMP), as reflected in the increased activity of glutamine PRPP amidotransferase (EC 2.4.2.14) and a decrease in IMP catabolism[5,6]. These observations directed our attention to the metabolic fate of IMP because this purine nucleotide is at a strategic position in purine metabolism (Fig. 1). Control at such branching points is exerted primarily by modification of the activity or of the rate of synthesis of the first enzymes of the divergent pathways. In this instance, in normal conditions, a balance is maintained by both positive and negative feedback effects. Thus ATP is required for GMP biosynthesis and GTP for AMP biosynthesis; conversely, GMP and AMP each inhibit their own production[7]. In normal or malignant proliferation, or in response to a hormone stimulus, changes in control frequently involve reprogramming of gene expression. The theoretical framework and predictive value of generalisations about such biochemical changes (termed the molecular correlation concept) have been elaborated[1,3].

Briefly, in tumours, three classes of behaviour of enzymes and pathways were distinguished. Enzymes or pathways of the first group show a positive or negative correlation with tumour growth rate; these alterations seem to indicate a linking with the degree of expression of malignancy. Parameters of the second group are consistently increased or decreased in all tumours, regardless of growth rate, and thus seem to be linked with the malignant transformation *per se*. The third group includes parameters which show apparently random increases or decreases[1]. For a fuller understanding of the control of the guanine nucleotide pathway, therefore, it became necessary to study the first enzyme of this pathway, IMP dehydrogenase (IMP: NAD oxidoreductase, EC 1.2.1.14) in conditions of normal and neoplastic growth. This enzyme has been examined in several mammalian tissues[8–18], including mouse sarcoma cells[12] and human placenta[14]. Comparative studies in homologous normal and malignant tissues have not, however, been reported.

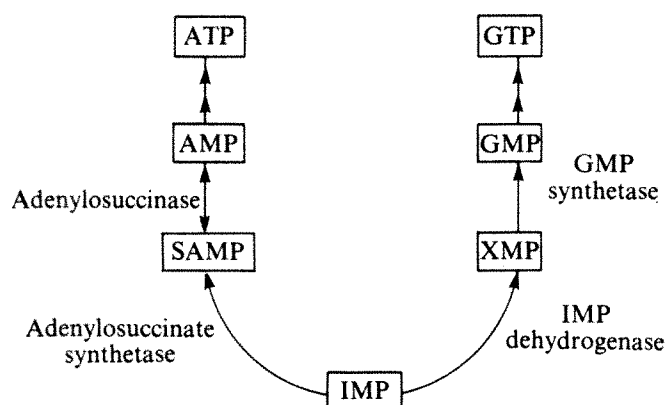
IMP dehydrogenase cannot be measured accurately in crude tissue homogenates, because of interfering activities. The extraction technique and optical assay described in the legend to Fig. 2 were developed, from earlier methods[10,12], to give optimal activity with liver and hepatoma preparations. In the conditions described, rates were linear for at least 30 min, and proportional to enzyme concentration up to a level of 0.0015 IU ml^{-1}. No measurable nucleotidase activity was present. Normal and tumour-bearing


Fig. 1 Simplified schematic metabolic map of the two principal competing routes for utilisation of inosine 5'-monophosphate. IMP, inosine 5'-monophosphate; SAMP, adenylosuccinate; XMP, xanthosine 5'-monophosphate; AMP and ATP, adenosine 5'-mono- and triphosphates; GMP and GTP, guanosine 5'-mono- and triphosphates, respectively.

rats were maintained as described previously and the preparation of regenerating liver, studies on differentiating animals, killing of rats and excision of livers and neoplasms were as reported elsewhere[1-3]. The growth rates of the various hepatoma lines ranged from 2 weeks to 11.5 months, measured by the time required for the tumours to reach a diameter of 1.5 cm. The IMP dehydrogenase activity and protein content in 11 transplantable hepatomas and in livers of control normal rats are compared in Fig. 2. In liver, the mean activity was 2,140 pmol substrate converted per h per mg of protein present in the 100,000g supernatant (coefficient of variation 15%). One gram (wet weight) of liver contained 88 mg of soluble protein. IMP dehydrogenase activity was elevated in all the hepatomas examined; even in the slowest growing tumours, with intervals of over a year between successive transplants, at least a 2.5-fold increase was seen. Moreover, the enzyme activity correlated with growth rate, and the increase, relative to normal liver, reached 13-fold in the most rapidly proliferating hepatomas. All increases were statistically significant at the 0.1% level, and the coefficient of correlation of IMP dehydrogenase activity with the exponential growth rate constant was 0.945 ($P<0.001$). The enzyme activity in renal tumour MK3 was increased threefold over the value observed in normal control kidney cortex.

It was important to determine whether the IMP dehydrogenase of hepatomas had different properties from the liver enzyme. For this purpose the rapidly growing hepatoma 3924A was chosen. The pH profiles of the liver and hepatoma enzymes were identical, with optima at pH 8.1. Both enzymes were inhibited by excess NAD$^+$ at concentrations above 0.25 mM, the inhibition reaching 50% at 0.62 mM. Both enzymes were also subject to product inhibition by XMP (competitive with IMP and non-competitive with NAD$^+$) and by NADH (non-competitive with both IMP and NAD$^+$). Liver and hepatoma dehydrogenases were inhibited equally by NADPH (50% inhibition, under usual assay conditions, at 0.14 mM) and by GMP (competitive with IMP, K$_i$ 96 mM). These patterns, together with initial velocity data, suggested that the kinetic mechanism of liver and hepatoma IMP dehydrogenases was identical with that of the sarcoma 180 and human placenta enzymes[12,14]. Within the limits of experimental error, kinetic parameters were identical for the liver and hepatoma enzymes, and were as follows (the terminology is that of Cleland[17]): K_a for IMP, 11.6±2.5 μM; K_{ia} for IMP, 34.6±4.6 μM; K_b for NAD$^+$, 24.3±3.8 μM; K_i for XMP, 25.9±3.1 μM; K_i (slope) for NADH, 360±66 μM; K_i (intercept) for NADH, 260±10 μM. Thus, the hepatoma

IMP dehydrogenase has properties similar to those of the normal liver enzyme.

To study the behaviour of IMP dehydrogenase in proliferating, non-malignant, adult hepatic tissue, we used the technique of partial hepatectomy[18]. Figure 3 shows that in the regenerating liver IMP dehydrogenase activity started to rise 6 h after operation, reached a peak of about five times the normal activity by 24 h, and then declined rather slowly. It is noteworthy how early the activity started to increase; most of the key enzymes of nucleic acid biosynthesis only start to rise after 12 h[2,18]. Another valuable system for the study of control of hepatic enzymes is the neonatal liver, which provides a population of differentiating, proliferating liver cells. On a basis of enzyme activity per unit of wet weight, the activity of IMP dehydrogenase in livers of 1-d-old rats is nearly four times the adult level, slowly declining thereafter with increasing age. But the average size of liver cells in newborn rats is less than 40% of the adult size. When our results were expressed on the basis of IMP dehydrogenase activity per cell (cell counts being determined by visual counting of orcein-stained nuclei in homogenates[1]) the per-cell activity in neonatal liver was only slightly (25%) higher than the adult value.

To evaluate this enzyme in the context of cell proliferation and function in the whole animal we measured IMP dehydrogenase in a wide variety of rat tissues. The highest activities were found in thymus, spleen, bone marrow and testis, which were, respectively, 10.5, 8.6, 3.3 and 2.1 times the liver specific activity. Successively lower activities were observed in brain, lung, intestinal mucosa, renal cortex, adipose tissue, red blood cells, and skeletal and cardiac muscle.

Fig. 2 IMP dehydrogenase activity in rat hepatomas. 10% (w/v) homogenates were prepared in 0.25 M sucrose, buffered to pH 7.4 with Tris-chloride. 100,000g supernatants were fractionated with ammonium sulphate, and the fraction precipitating between 30% and 40% saturation contained all the IMP dehydrogenase activity. This precipitate was resuspended and dialysed against 2 × 200 volumes of assay buffer (0.1 M potassium phosphate, pH 7.4 plus EDTA, 1 mM and mercaptoethanol, 0.5 mM). Samples were assayed at 290 nm, in the same buffer, at 37 °C in a Gilford 2400-S recording spectrophotometer. The concentration of NAD$^+$ in the assay was 0.2 mM and that of IMP was 0.17 mM. The protein concentration of the 100,000g supernates was determined by the Biuret reaction. The data are means ±s.e. of five or more animals in each group and results are plotted as percentages of corresponding control liver values.
Fig. 3 IMP dehydrogenase in rat liver following partial hepatectomy (○) and sham operation (●). Enzyme was prepared and assayed as described in Fig. 2.

From this study a number of conclusions may be drawn. First, a relationship of IMP dehydrogenase activity with cell proliferation is evident. This correlation is most clearly apparent in the spectrum of transplantable hepatomas of different growth rates, and is further emphasised by the high activity found in regenerating liver, and in thymus and spleen. The correlation, however, is not absolute, as the lower activities in neonatal liver and in intestinal mucosa demonstrate. Second, the low absolute activity of this enzyme, even in the most rapidly dividing tissues, suggests that it may be one of the key rate-controlling enzymes in nucleic acid biosynthesis. The activity found in regenerating liver, for example, would be sufficient to allow the liver RNA and DNA content to be doubled in about 18 h. In fact, the doubling time for regenerating liver is about 4 d; it seems that under these conditions, and also in the fastest-growing tumours, IMP dehydrogenase must operate at around 20% of its maximum velocity. Last, the regulation of the synthesis of this enzyme is undoubtedly changed in malignancy. Even the slowest growing hepatomas with mass-doubling times of more than 40 d, have a 2.5 to 3.5-fold elevation compared with normal liver, and the rapid hepatomas, with growth rates comparable with that of regenerating liver[1,3], have, on average, almost twice as much IMP dehydrogenase activity as is observed at the peak following partial hepatectomy. Moreover, in hepatomas, the enzyme activity elevation is permanent.

The ubiquitous increase of IMP dehydrogenase in hepatomas indicates the linking of this enzyme alteration with the neoplastic transformation. Superimposed on this reprogramming of gene expression is the positive correlation of this enzyme activity with the rate of growth of the liver neoplasms, indicating a linking of this enzymatic imbalance also with the expression of the degrees of malignancy.

Efficiency of light conversion by the blue-green alga *Anacystis nidulans*

THE conversion efficiency of light energy into chemical energy, measured by production of organic matter, can be high with unicellular organisms. As photosynthesis becomes light saturated at relatively low light intensities, such high efficiencies are not usually obtained with high intensities of incident light. The saturation level, however, increases with increasing temperature. Blue-green algae grow well at high temperatures[1-3], suggesting that they may be efficient producers of organic matter. As the protein content of algae in general is high, growth of these organisms could have important implications for food production, especially in tropical areas, where both light intensity and temperature are favourable. We have therefore investigated some parameters influencing yield of production of *Anacystis nidulans* at high light intensities.

High growth rates require an adequate supply of carbon dioxide for cell production. As a result of a high ratio of outer surface area chlorophyll content, favourable for CO_2 diffusion, unicellular organisms can profit much more from enhanced CO_2 availability than leaves of higher plants.

Using a medium according to Kratz and Myers[4] we found that an increase in A_{680} of 42% (the *in vivo* chlorophyll maximum) resulted from 6 h illumination with incandescent lamps (50 W m^{-2} photosynthetically active light), if the cells were flushed with air enriched with 5% CO_2. The absorbance increase for a culture flushed with plain air was only 10% of that of cells flushed with enriched air, indicating that CO_2 was a limiting factor in these conditions. In the latter culture the phycocyanin–chlorophyll ratio, measured by A_{625} and A_{680}, decreased from a value of 1.4 to 1.8, found with rapidly growing cells, to about 0.8 (Fig. 1). A marked increase in growth rate and in phycocyanin–chlorophyll ratio resulted if these cultures were switched from air to CO_2-enriched air. Such an increase also followed when the rate of flushing with air was tenfold increased and the bubble size decreased. If the culture was flushed with plain air but 2% sodium bicarbonate was added to the culture medium and the pH readjusted to 7.5, growth proceeded at a rate similar to that of cells flushed by CO_2-enriched air. After 1.5 d, however, the pH of this culture had risen to 11, phycocyanin was bleached and the cells eventually died.

An intensity of 50 W m^{-2} from incandescent lamps was not sufficient for maximal growth with cells flushed with CO_2-enriched air, indicating that photosynthesis was not

saturated. If the intensity was doubled, the rate of absorption increase also doubled (temperature 40 °C, flushing rate 8 l h^{-1}).

After 4 d continuous illumination with 50 W m^{-2}, growth stopped. Removal of the cells by centrifugation and renewed inoculation with fresh cells in the same phase of growth as at the start of the experiment did not result in resumed growth. Investigation of the ultraviolet absorption spectrum of the supernatant suggested that at least the nitrogen source was depleted. Removal of the cells, renewed inoculation and addition of 50% fresh growth medium resulted in a vigorous growth for 18 h. After that time the cells turned yellow and growth stopped. The absorption spectrum of the yellow cells and absorption difference spectra with normal cells indicated that phycocyanin disappears, chlorophyll concentration decreases and that of a carotenoid increases markedly (Fig. 1). Thin-layer chromatography of acetone extracts from the cells showed that the same acetone-soluble pigments are present in both types of cell, but the yellow ones contain, besides less chlorophyll, an appreciably greater content of a xanthophyll. Ultraviolet absorption spectra of the supernatant indicated the excretion of various polypeptides[5], which may act as growth inhibitors and modifiers of the absorption spectrum.

Anacystis receiving light from fluorescent tubes (Philips TL 33, also equivalent to 50 W m^{-2}) grow at a similar rate to cells illuminated with incandescent lamps in the same conditions of CO_2 availability, temperature and light intensity. Cells irradiated with white light from a high pressure mercury lamp (from which the ultraviolet was eliminated) at the same energy, grow about eight times less rapidly. Besides an inefficient absorption ratio by the two photosynthetic pigment systems, the latter effect may be the result of the large fraction of blue light absorbed by xanthophylls. No energy transfer from these pigments to chlorophyll of either pigment system is found in blue-green algae[6].

We also found that a pigment system, containing both xanthophylls and the 745 nm pigment which occurs in *Anacystis*[7,8] could be precipitated from lamellae treated with sodium dodecyl sulphate (SDS). The fluorescence action spectrum of the 753 nm fluorescence band, emitted by the latter pigment form, shows bands in the carotenoid region, indicating some energy transfer between these non-

Fig. 1 Absorption spectrum of *Anacystis* grown for 2 d in a medium flushed with air + 5% CO_2 (. . . .) and plain air (- - -, × 12) at 35 °C and 1.2 10^4 lx from incandescent lamps. Continuous curve gives the absorption spectrum of yellow cells, obtained after reinoculation of exhausted growth medium with fresh cells and addition of 50% fresh medium.
Fig. 2 Fluorescence action spectrum and absorption spectrum of a pigment complex isolated by SDS treatment from *Anacystis* cells which were disintegrated by the French press method. The complex emits a fluorescence band with a maximum at 753 nm. - - -, *A*; ———, fluorescence excitation.

fluorescent xanthophylls and fluorescing P745 (Fig. 2). The function of this pigment system in the energy scheme of this alga is not yet understood.

The growth pattern in the first few days after inoculation shows that, under favourable conditions of CO_2 availability, nutrients, temperature and spectral composition of the light, photosynthesis proceeds with much greater efficiency, even at high light intensities, than in the green alga *Chlorella*[9].

From the values measured during growth the conversion yield Q of electromagnetic into chemical energy can be calculated. An irradiation intensity of 50 W m^{-2} on a bottle with 200 cm^2 side area (volume 1 l) corresponds, after 1.5 d growth, to 3.6 kcalorie radiant energy taken up by the cells in 6 h (average A 700–400 75%). This illumination results in a cell production with a dry weight of 0.20 g l^{-1}. According to Oswald[10] the energy content of algae in general varies between 4.6 and 6.5 kcalorie g^{-1}, a value close to that derived from Rabinowitch[11]. If we take an average value of 5.5 kcalorie g^{-1}, *Anacystis* cells produced in 6 h, contain an energy equivalent to 1.1 kcalorie. From these values we obtain a conversion factor (energy efficiency) of $Q=0.30$. The latter is only an approximate value constant over most of the growth period and is of the same order of magnitude as that expected from the optimal values for photosynthesis measurements, corresponding to a quantum efficiency of eight and derived from short time experiments[11].

Our measurements indicate that *Anacystis* may be grown in conditions in which high intensity radiation is converted into chemical energy with a high yield.

Evidence for heterogeneity in heterochromatin of *Drosophila melanogaster*

IN *Drosophila melanogaster* the heterochromatin comprises the whole of the Y chromosome, about the proximal third of the X chromosome and the centromeric areas of chromosomes 2 and 3[1-4]. It appears throughout the cell cycle as darkly staining and highly condensed chromatin[2,3] and replicates later than euchromatin during the synthetic period[5]. The heterochromatin of *Drosophila* is considered genetically inert because it contains very few mappable genes, although it has marked genetic effects in determining the well known position effect[1]. It has recently been found that the heterochromatin of *Drosophila* corresponds to the C bands[6] and contains highly repetitive DNA[7-12]. None of these characteristics has, however, so far been of any use in solving the problem of the functional role of the heterochromatin. On the other hand, *Drosophila* offers unique possibilities for solving this problem, since in this organism it is possible to construct chromosomes containing different quantities of centromeric heterochromatin[4,13] and thus study the functions of this material. Obviously this type of approach requires a preliminary study on the possible heterogeneity of the heterochromatin. An initial result in this type of study has been obtained by showing that the heterochromatin regions of *D. melanogaster* fluoresce differently after staining both with quinacrine[14-16] and with the compound 33258 Hoechst[17]. Here we describe experiments in which the heterochromatin of *Drosophila* was differentiated by means of treatment of the living gangliar cells with 33258 Hoechst, which is known to decondense the centric heterochromatin of the mouse[18].

Use was made of third instar larvae of the Oregon stock and of a stock heterozygous for the translocation (2 ; 3) bw^{v4} (ref. 4). The nerve ganglia obtained from the dissection of the larvae were placed in a water solution containing NaCl (0.7%), foetal calf serum (20%) and 33258 Hoechst (40 μg ml^{-1}). After 2, 4, 6 and 8 h in this solution the ganglia were fixed and then squashed in acetic orcein[19,20]; 2 h before each fixation, colchicine was added to the culture solution, up to a final concentration of 10^{-4} M.

Figure 1 shows the effects of the treatment of the living gangliar cells with 33258 Hoechst. As may be seen, this treatment produces no alteration in the euchromatin, whereas it has a very marked effect on certain heterochromatic regions in which specific areas of decondensation are clearly visible. We emphasise that we observed no metaphases with chromosome aberrations or with heterochromatin decondensation patterns different from those shown in Fig. 1. The frequency of the various types of metaphase shown in Fig. 1 varies, however, with the fixation time (Table 1).

The data shown in Fig. 1 and Table 1 reveal that the heterochromatin of *D. melanogaster* responds in the following way to the treatment with 33258 Hoechst.
(1) The heterochromatin of the second chromosomes is not influenced.
Fig. 1 The effect of 33258 Hoechst on the metaphase chromosomes of gangliar cells of *Drosophila melanogaster*: *a*, ♀ and *b*, ♂ normal non-treated cells; *c*, ♀ and *d*, ♂ cells treated for 4 h with H33258; *e*, ♀ and *f*, ♂ cells treated for 6 h with H33258; *g*, ♂ and *h*, ♂ cells treated for 8 h with H33258. In all the treated cells an area of drastic decondensation of the centromeric heterochromatin of a single arm of the 3rd chromosomes (↑) and the intermediate decondensation of part of the heterochromatin of the X chromosome (▲) can be seen. The male cells (*d*) and (*f*) show an area of drastic decondensation close to the centromere of the Y chromosome. In the male cells (*g*) and (*h*) the Y chromosome appears intermediately decondensed with the exception of some blocks of heterochromatin that remain compact. In the metaphases (*e*) and (*f*) the 4th chromosomes appear elongated and with the sister chromatids partially split. As may be seen the regions of drastic decondensation on the third chromosomes and on the Y chromosome seem to be isochromatid breaks. Under the microscope, however, it is often possible to observe very slender filaments of chromatin that connect the apparently broken chromatid ends.

(2) The heterochromatin of the right arm of the third chromosomes is not influenced. On the other hand, a distal portion with respect to the centromere of the heterochromatin of the left arm is drastically decondensed. The degree of decondensation of this heterochromatin portion does not vary with the time of fixation. The area of decondensation was assigned to the left arm of the third chromosome by using the stock heterozygous for the translocation (2 ; 3) bw^{v4} (Fig. 2).

Table 1 Effects of 33258 Hoechst on gangliar cells of *D. melanogaster* at various times of fixation after the treatment

Post-treatment time of fixation (h)	Sex	No. of cells scored	Normal cells (%)	Cells showing (%)				
				d.d.3 i.d.X	d.d.3 i.d.X d.d.Y.	d.d.3 i.d.X e.4	d.d.3 i.d.X d.d.Y e.4	d.d.3 i.d.X t.d.Y e.4

	♂♂	386	13.2	—	71.5	—	1.2	14.1
8	♀♀	153	—	20.8	—	79.2	—	—
	♂♂	132	—	—	12.6	—	2.3	85.1

Abbreviations: d.d.3=drastic decondensation on the third chromosomes; i.d.X=intermediate decondensation on the X chromosome; d.d.Y=drastic decondensation on the Y chromosome; e.4=fourth chromosomes elongated; t.d.Y.=total decondensation, except for certain regions, of the Y chromosome.

(3) Part of the heterochromatin of the X chromosome (presumably the greater part of that localised in XL) is not influenced; the remaining part, at all times of fixation, is seen to be intermediately decondensed.

(4) The Y chromosome, at all times of fixation, displays an area of drastic decondensation near the centromere. After 6–8 h of treatment it all appears intermediately decondensed with the exception of some blocks of heterochromatin which remain compact.

It is interesting to note that in the cells treated for 6–8 h the fourth chromosomes also appear elongated and with the sister chromatids split. We consider that this results from decondensation of heterochromatic material, since the fourth chromosomes, although they show no positive heteropycnosis in interphase[2,3], nevertheless display heterochromatic genetic properties[1], are late replicating[5] and positive in the C bands[6].

Taken as a whole, the present data indicate that, in relation to treatment with 33258 Hoechst, the heterochromatin of *D. melanogaster* can be divided into at least three types: that which is insensitive to this compound, that which is intermediately decondensed and that which is drastically decondensed. It is, however, possible that there are differences between the heterochromatin of the X chromosome, which decondenses right from the first fixation times, and that of the Y chromosome and the fourth chromosomes, which decondense after 6–8 h of treatment.

As regards the nature of the areas sensitive to the treatment with Hoechst, we believe that, in all probability, they contain DNA that is rich in AT. This is suggested by two considerations. First, the compound 33258 Hoechst decondenses all the mouse heterochromatic centric regions[18] in which we know that satellite DNA rich in AT is localised[21,22]. Second, all heterochromatic areas of the chromosomes of *Drosophila*, decondensed by the bibenzimidazole derivative correspond to areas that fluoresce brightly after staining with quinacrine[14–16] or 33258 Hoechst[17], which are both fluorescent probes specific for DNA rich in AT[17,23–25].

It is more difficult to establish the respective nature of the intermediately decondensed and the drastically decondensed regions. In principle, however, it is logical to assume that the degree of decondensation depends on the relative AT concentration in these regions. In this respect it could be suggested that in the intermediately decondensed regions are localised the two light satellites of *D. melanogaster*, which band at an approximate density of 1.690 g cm⁻³ in neutral CsCl (refs 8 and 10). The drastically decondensed regions, on the other hand, might contain the *Drosophila* d(A–T) rich satellite DNA[10,26,27] (1.675 (ref 26)—1.678 (ref 27)—1.672 (ref 10) g cm⁻³). In this respect it is interesting to note that all these light satellites have been shown, by *in situ* hybridisation, to have chromocentric localisation in the polytene chromosome preparations[8,10]. Futhermore the d(A–T) rich satellite DNA would be localised preferentially, though not exclusively, in the Y chromosome[26], which, as we have shown, contains a region of drastic decondensation.

Poly(U) polymerase in rat brain

MUCH interest has centred recently on the discoveries of ribohomopolymer sequences in RNAs of eukaryotic cells. Poly(A)$^{1-3}$, poly(U)^4 and poly(G)^5 regions have been found in nuclear and cytoplasmic RNA fractions. These sequences are thought to have special implications for regulation of biological functions of RNAs. It seems likely that these ribohomopolymer sequences are synthesised in a post-transcriptional process Poly(A) polymerases have been reported$^{6-7,13}$ and enzymatic activities catalysing short (two to five nucleotides) chains of poly(U) have been reported in cytoplasmic and microsomal fractions in rat liver^{8,9}. Enzymatic activities which polymerise four different ribohomopolymers independently have been found in nuclear ribonucleoprotein particles^{10}.

We have reported the presence of RNA-dependent RNA polymerase requiring four nucleoside triphosphates as substrate in an enzyme fraction of rat brain^{11} With this in mind, a poly(U) polymerase was separated from the same organ and was shown to have a primer requirement for RNAs of larger size, such as ribosomal RNAs (rRNAs), and viral RNA. The enzyme catalyses sequential polymerisation of poly(U) chains from the 3'-hydroxyl end of RNA. We report here studies on the isolation and characterisation of a new poly(U) polymerase. The activity of poly(U) polymerase was demonstrated in a supernatant which was solubilised with 0.4 M ammonium sulphate from the microsomal fraction (see legend to Table 1). This enzyme activity had an absolute requirement for a primer. The presence of creatine phosphate and creatine kinase stimulated the reaction, indicating that ribonucleoside phosphorylase is not involved and that ribonucleoside triphosphates rather than diphosphates are the actual substrates. Only slight incorporations, less than 10% of incorporation of ^{3}H-UMP, were demonstrated in the presence of other nucleoside triphosphates (^{3}H-ATP, ^{3}H-GTP and ^{3}H-CTP) as substrates (data not shown).

Primer specificity of the poly(U) polymerase was surveyed in the presence of several other primers (Table 2) rRNAs from rat brain, liver and *Escherichia coli* had higher activities than smaller RNAs in a transfer RNA (tRNA) fraction from the same sources. Kinetics of the synthesis showed that the efficiency of smaller RNA in a tRNA fraction as a primer was about 30% that of rRNA at any incubation time (Fig. 1). Qβ phage RNA also had a similar level of primer activity as rRNAs; but the primer activity of the fragmented Qβ phage RNA (4S) was the same as the activity of smaller RNAs in tRNA fraction. These results show the poly(U) polymerase preferred larger RNAs as a primer than smaller RNAs. The molecular

Table 1 Properties of poly(U) polymerase from rat brain

Assay conditions	^{3}H-UMP incorporated (pmol)
Complete system	26.8
+ DNase (10 µg)	27.9
+ RNase A (10 µg)	0
+ Actinomycin D (2 µg)	22.9
− Mg^{2+}	0.9
− Dithiothreitol	18.7
+ ATP, GTP, CTP (0.1 µmol each)	27.0
+ Phosphocreatine (1 µmol)+ creatine phosphokinase (10 µg)	34.9
− RNA	0

Reaction mixture contained in a final volume of 0.25 ml: 22 µmol Tris-HCl pH 8.3, 0.75 µmol MgCl$_2$, 0.125 µmol dithiothreitol, 0.1 µmol ^{3}H-UTP (2×10^6 c.p m. 0.1 µmol^{-1}), 5 µg 28S rRNA from newborn rat brain, 20 µg enzyme protein. Incubated at 36 °C for 30 min, stopped by addition of saturated pyrophosphate–sodium phosphate (1M), pH 7.4 (1:1) mixture and TCA. Enzymatic activity was measured by converting ^{3}H-labelled nucleoside monophosphates into acid-insoluble material. ^{3}H-labelled samples were counted in a liquid scintillation counter (Beckman LS 100) All procedures were done at 0 °C unless otherwise indicated. Wistar rats 8–12-weeks old were used. Fresh rat brain was homogenised in a glass-Teflon homogeniser with 10 volumes ice-cold buffer (10 mM Tris-HCl, pH 7.4, 15 mM KCl, 5 mM 2-mercaptoethanol). Mitochondria and cell debris were removed by centrifugation at 12,000g for 30 min. Supernatant was centrifuged at 105,000g for 60 min to obtain microsomal fraction. Microsomal pellet was suspended in 0.4 M ammonium sulphate solution, pH 7.4, and gently homogenised in a glass-Teflon homogeniser. After 60 min standing, microsomal fraction was centrifuged at 105,000g for 60 min. Supernatant was brought to 30% saturation by adding 100% saturated ammonium sulphate and left standing for 20 min. Resulting precipitate was removed by centrifugation at 17,000g for 10 min. The 30% saturated ammonium sulphate supernatant was brought to 45% saturation with solid ammonium sulphate and left standing for 20 min. Precipitate was collected by centrifugation at 17,000g for 10 min. Pellet was dissolved in SB (10 mM Tris-HCl, pH 7.4, 5 mM MgCl$_2$, 0.5 mM 2-mercaptoethanol) Protamin sulphate (30 µg ml^{-1}) was added to the dissolved pellet and was centrifuged at 17,000g for 10 min after 20 min of standing. An equal volume of 100% saturated ammonium sulphate was added to the supernatant, and after 20 min standing, pellet was collected by centrifugation at 17,000g for 10 min. Precipitate was dissolved in SB and 0.3 volumes glycerol was added to the medium. This enzyme fraction was stored at −60 °C.

weight of the tRNA is known to be about 20,000, and that of Qβ RNA 1,000,000 Considering the molecular sizes of tRNA and rRNA, tRNA should show higher activity at the same absorbance level, and this may also be true for

Fig. 1 Time course of reaction of poly(U) polymerase. Conditions of incubations were as in Table 1, except that the time of incubation varied O, 18S rRNA from rat brain; △, rat liver tRNA; □, minus RNA.
other ribohomopolymer polymerases[13]. We believe that poly(U) polymerase has a primer specificity for larger RNA molecules, that it has some important role in the regulation of metabolism of larger RNAs, such as mRNA, rRNA or heterogeneous nuclear RNA (HnRNA).

Native DNA could act as a primer for the synthesis, but denatured DNA could not. The poly(U) polymerase may be capable of serving native DNA as a primer at a reduced rate, or a different enzymatic entity in the poly(U) polymerase fraction using native DNA as a primer, may be active. These points may be clarified by further purification of the enzyme.

The average length of the newly incorporated poly(U) sequence was determined. Table 3 shows the chain length of the product increasing during the 45 min incubation period. The products formed by the poly(U) polymerase clearly indicate that the reaction is sequential polymerisa-

Ribohomopolymers were synthesised using 28S rRNA from rat brain (5 μg per 0.25 ml) in 20-fold standard reaction mixtures at the time of incubation indicated and extracted with 0.1% SDS–phenol, precipitated with two volumes ethanol, dissolved in water and precipitated with 5% perchloric acid. Samples were then washed four times with 2.5% perchloric acid and finally with 66% ethanol–water. Alkaline hydrolysis was carried out with 0.33 N KOH at 36 °C for 18 h. Hydrolysed samples were chromatographed with standards of UMP and uridine on cellulose sheets (10×10 cm, Funakoshi) in a solution (isobutyric acid 13.2 ml, NH₃OH 0.2 ml, H₂O 6.6 ml). The appropriate areas were cut out and extracted with 0.01 N HCl. Radioactivity was then counted in a scintillation counter.

Table 2 Primer specificity of poly(U) polymerase

Primer	³H-UMP incorporated (pmol)	% Rate with *E. coli* rRNA
28S rRNA (rat brain)	32.2	77

Poly(C)	20.2	48
Poly(G)	0	0

Conditions of assay as described in Table 1, except that various nucleic acids were used as primers Each primer was tested at a concentration of 5 μg 0.25 ml⁻¹. Qβ phage RNA was prepared as described previously[12]. RNA was isolated from brains (cerebrum) of 3-d-old Wistar rats. Brain was cut up with scissors and stirred for 30 min at 4 °C in a solution containing 0.1 M Tris-HCl, pH 7.4, 10 mM MgCl₂, 0.5 mM 2-mercaptoethanol, 5 μg ml⁻¹ DNase This procedure was followed by adding 0.4% (w/v) sodium dodecyl sulphate (SDS) and incubating at 20 °C for 8 min. An equal volume of water-saturated phenol was added, and the mixture was shaken vigorously for 15 min at 4 °C. After centrifugation at 12,000g for 15 min, upper aqueous fraction was obtained. This phenol treatment was carried out four times, and extraction with ether was performed three times. The ether was flushed out with nitrogen gas, two volumes cold ethanol added; this was left to stand overnight at −20 °C. The mixture was centrifuged at 9,000g for 10 min, and the pellet was dissolved in TM (0.01 M Tris-HCl, pH 7.4, 5 mM MgCl₂). After ethanol precipitation, the pellet was again dissolved in TM. Supernatant after centrifugation at 12,000g for 20 min was used for further purification. RNA fraction was incubated with 20 μg ml⁻¹ DNase at 36 °C for 30 min and was purified by the SDS–phenol extraction method described above. To obtain rRNA and tRNA, extracted RNA fraction described above was layered on 25 ml 5–30% glycerol gradient (0.01 M Tris-HCl, pH 7.4, 0.1 M NaCl, 5 mM EDTA) and ultracentrifuged in an SW 25.1 rotor at 21,000 r.p.m. for 18 h. Corresponding tRNA and rRNA fractions were collected by ethanol precipitation. RNAs from *E. coli* and rat liver were prepared as from brain. Fragmented Qβ phage RNA(4S) was prepared as follows. Intact Qβ phage RNA (1 mg ml⁻¹) was hydrolysed in 0.1 M KOH for various incubation times at 36 °C, and the hydrolysate adjusted to pH 7.0 with 2.5% HClO₄. Hydrolysate was then layered on 25 ml 5–30% glycerol gradient (0.01 M Tris-HCl, pH 7.4, 0.1 M NaCl, 5 mM EDTA) and ultracentrifuged in an SW 25.1 rotor at 21,000 r.p.m. for 18 h. RNA sedimenting at the 4S position was collected by ethanol precipitation. To produce the new ends, the 4S RNA (0.36 mg ml⁻¹) was incubated at 36 °C for 4 min with sufficient alkaline phosphatase from *E. coli* to release 0.45 μmol p nitrophenol min⁻¹ as measured in the alkaline phosphatase assay described by Wilkie and Smellie[9]. Qβ phage RNA(4S) was prepared by SDS-phenol extraction method described above.

tion. Radioactivity of ribonucleoside 5′-phosphates (pppUp, ppUp or pUp) in the alkaline hydrolysate of radioactive products was not recovered, indicating that the poly(U) sequences were not synthesised *de novo* but formed by the successive addition of nucleotides to a pre-existing primer RNA.

To determine whether a sequential polymerisation occurs from the 3′-hydroxyl end of primer RNA or not, a nearest neighbour analysis using α-³²P-UTP was carried out. Qβ RNA and poly(C) were used as primer RNAs. Preparation of the products and thin-layer chromatography were carried out as described in the legend of Table 3. Using Qβ RNA, the ratio of radioactivity (UMP/(CMP+AMP)) increased during the 45 min incubation period from 5.92 (15 min) to 13.72 (45 min). At 45 min incubation, recovery of radioactivity in AMP, CMP and UMP was 4.6%, 2.2% and 93.3%, respectively. With poly(C), the ratio of radioactivity (UMP/CMP) also increased from 1.62 (15 min) to 3.20 (45 min). The 3′-hydroxyl end of Qβ RNA is known to be C–C–A (ref. 17) The recovery of radioactivity in CMP seems to be the result of removal of AMP during the preparation of Qβ RNA or incubation. This experiment clearly indicates that polymerisation occurs from 3′-hydroxyl end of RNA.

The precise biological implications of ribohomopolymer sequences in RNAs of eukaryotic cells remain obscure. It seems unlikely that the presence of poly(A) sequences is a prerequisite for translation[15]. It has recently been reported that mRNA having a poly(A) sequence on its 3′-end is more stable than poly(A)-free mRNA[16] It is known that HnRNAs containing poly(U) sequences are unstable compared with those containing poly(A)[4] The poly(U) polymerase catalysing sequential polymerisation from the 3′-hydroxyl end of RNA had a primer requirement for RNAs of larger size. We speculate that this enzyme has special significance in the regulation of metabolism of larger RNAs, such as mRNA, rRNA or HnRNA Wilkie and Smellie detected a poly(U) polymerase in the microsomal fraction of rat liver[8,9]. The enzyme, however, catalyses the synthesis of short (two to five nucleotides) chains of poly(U) and has no primer specificity, unlike our poly(U) polymerase. We are in the process of looking for poly(U) polymerases having similar properties in organs other than the brain.

N-terminal sequences of secretory piece and of α chains of different allotype in rabbit secretory IgA

The translocation hypothesis[1,2] states that in the process of antibody synthesis any one of a number of immunoglobulin heavy chain V genes is available for union with any of the class-specific C genes. Whereas almost all structural data support the widely held view that all V genes are able to translocate to any of the class-specific C genes, some data suggest that this may not be the case. Wilkinson[3] found the N-terminal sequence PCA–Ser–Ser (PCA, pyrrolidone carboxylic acid) to be present in a rabbit α chain preparation but absent in pooled rabbit γ chains. Other workers[4,5] have described an N-terminal heavy chain sequence apparently confined to the IgM class of human immunoglobulins.

We have reinvestigated the former result in view of the finding that secretory piece (SP), a polypeptide chain present in secretory IgA (sIgA) but absent from IgG, has a molecular weight of 60,000–70,000 (refs 6 and 7), in both the native and fully reduced state, rather than being a disulphide-linked dimer with subunits of molecular weight 25,000 (ref. 8). Wilkinson isolated his α chain preparation after complete reduction of rabbit sIgA using gel filtration with Sephadex G-200; secretory piece could have contaminated this preparation and provided the novel N-terminal peptide The fact that the yield of the PCA–Ser–Ser peptide from the α chain preparation was 14–16% (ref. 3) and that the ratio of α chain to SP in the intact molecule is 4:1 (ref. 7) suggested that the above reasoning may be correct.

Wilkinson[3] compared the N-terminal PCA peptides of rabbit α chains of allotype a1 and a3 with peptides isolated in an earlier study of γ chains of the two allotypes[9]. The *a* locus allotypic specificities are located in the V region of rabbit heavy chains of all the known classes and have been shown for γ chains to be associated with multiple differences in primary structure[9,10]. Differences seen in the N-terminal PCA peptides of rabbit γ chain[9] (see Table 1) of the two allotypes proved similar in α chains of different allotype except for the additional peptide PCA–Ser–Ser found in α chain of both a1 and a3 specificity in a yield of 0 15 mol mol⁻¹.

In this study, preliminary experiments on totally reduced and alkylated sIgA showed, by alkaline urea and SDS gel electrophoresis, that the α chain fraction was indeed contaminated by secretory piece. We therefore tried to separate the α chain fraction from secretory piece. sIgA was isolated from clarified rabbit colostrum using the method of Cebra and Robbins[11] with slight modification. Attempts to separate α chain from SP after complete reduction and alkylation of sIgA, either by gel filtration, preparative gel electrophoresis or immunoadsorbents, proved fruitless (A.P.J. and L.E.M., unpublished). We purified secretory piece by taking advantage of the fact that not all SP is covalently bound to the sIgA molecule[8]. Thus, in our preparation, gel filtration in 3 M guanidine[8] released about 50% of the SP from sIgA; this fraction was pure on SDS gel electrophoresis and was free of any light chain contamination as judged by anti-light chain antisera. The N-terminal half of the α chain was eventually freed of the remaining covalently bound SP by peptic digestion of sIgA for 20 h at 37 °C in 0.1 M glycine-HCl pH 2.4 (A P J. and L.E.M., unpublished) followed by gel filtration on G-200 in 0.1 M phosphate buffer, pH 6.8. Such treatment digested SP and the α chain Fc region into peptides releasing a large fragment, $F(ab')_{2\alpha}$, equivalent in component structure to the well defined $F(ab')_2$ fragment released by peptic digestion of IgG (ref. 12). The $F(ab')_{2\alpha}$ fraction was unreactive with antisera to SP.

The isolated SP and $F(ab')_{2\alpha}$ from both allotypes a1 and a3 were completely reduced and alkylated, digested with Pronase and the PCA peptides collected in the unretarded fraction from Dowex 50 (×2; H⁺ form). Purification of the

Yields as mol peptide per mol polypeptide chain.

PCA peptides from the Dowex 50 fractions was carried out using gel filtration and paper electrophoresis as described by Wilkinson[9].

The N-terminal PCA peptides isolated from SP, Aa1 $F(ab')_{2\alpha}$ and Aa3 $F(ab')_{2\alpha}$, are described in Table 1 and compared with the γ chain peptides described previously[9]. Peptide yields were calculated using the same assumptions used in the earlier studies[3,9]. The yields of the peptides PCA–Ser–Val–Glu and PCA–Ser–Leu–Glu (Table 1) from the $F(ab')_{2\alpha}$ fragment of a1 allotype proved similar to those derived from γ chain as did the yields of peptides PCA–Ser–Leu–Glu and PCA–Glu–Gln from Aa3 $F(ab')_{2\alpha}$ (ref. 9). There was no indication of the peptide PCA–Ser–Ser in either $F(ab')_{2\alpha}$ digest; but this peptide was isolated in good yield (65%) from the SP digest (Table 1). Although, unlike Wilkinson[3], we digested light chains together with the N-terminal region of α chain, we isolated no PCA peptides other than those normally found in γ chain. This reflects the fact that the vast majority of the rabbit light chain fraction is of the unblocked K type.

We conclude that the N-terminal sequence of rabbit secretory piece is PCA–Ser–Ser and that the earlier report[3] that this represented a sequence unique to rabbit α chain V region was incorrectly made because of the inability to separate these two polypeptide chains before characterisation Although our finding does not rule out the possibility that some V region subgroups may be confined to a certain

class of heavy chain it does remove some structural evidence against a simple translocation hypothesis.

We thank Professor R. R. Porter for discussion and Mr A. C. Willis for technical assistance.

Possible role for poly(A) as an inhibitor of endonuclease activity in eukaryotic cells

A NUMBER of laboratories have reported the isolation from eukaryotic cells of mRNAs linked covalently at their 3'-OH termini to polyadenylic acid (poly(A))[1–4]. The chain of adenylic acid residues has been found also at the 3' termini of RNAs isolated from several well characterised viruses[5–7]. Although considerable evidence exists to suggest that the insertion of poly(A) on the RNA chains destined to become mRNA is a post-transcriptional event[8], there is at present little understanding of the part poly(A) plays in the subsequent stages of protein synthesis.

In this communication we should like to suggest a possible role for the polynucleotide in maintaining the structural and functional integrity of mRNA. The role is based on the observation that poly(A) can act as a general inhibitor of endonuclease activity and in so doing can prevent the degradation of mRNA in the cytoplasm. The enzymes used in this study have been isolated from microbial and from human sources. Their purification and properties have been described elsewhere[9–11].

Poly(A), much like the ordered polynucleotide, polyguanylic acid (poly(G)), was found to act as a strong inhibitor of a microbial ribonuclease isolated from *Citrobacter* sp.[9,12]. The inhibition of enzyme activity induced by poly(G) can be only partially reversed by increasing concentrations of buffer. In contrast, the inhibition induced by poly(A) is strongly dependent on the ionic strength of the buffering mediums (Fig. 1). As the molar concentration of buffer is increased, the inhibitory effect of poly(A) is · reduced until, at the highest buffer concentration studied, the presence of the polynucleotide has relatively little effect on enzyme activity (Fig. 1). On the other hand, poly(G), in the highest molarity buffer, remains a powerful enzyme inhibitor.

Since there is considerable variation in the number of nucleotide residues in poly(A) at the end of individual mRNAs[14], it was of interest to study the relationship between chain length and the inhibitory properties of the polynucleotide. As shown in Fig. 2, the two shortest chains with an average monomer length of 25 (25) and 45 (45) residues respectively inhibited enzyme activity to essentially the same degree (I_{50}=4 5×10^{-6} M). The intermediate-sized polymer with an average monomer length of 90 residues
Fig. 1 Reversal by increasing concentrations of Tris-HCl buffer of polynucleotide-induced inhibition of *Citrobacter* RNase activity. Enzyme activity was measured in 1 ml of a reaction mixture consisting of varying concentrations of Tris-HCl buffer (pH 7.1), 0.5 μmol of poly(U) and 15 U of enzyme. After incubation for 5 min at 37 °C, the reaction was stopped by the addition of 1 ml of 2 N perchloric acid containing 20 mM lanthanum nitrate and the reaction vessel was placed in an ice bath for 20 min. The mixture was then clarified by centrifugation and the A_{260} of the acid-soluble nucleotides measured[13]. When the effects of the polynucleotide on enzyme activity were to be studied, poly(A) (5×10^{-6} M) and poly(G) (2.5×10^{-6} M) were added, before the addition of enzyme, to separate reaction mixtures. RNase activity measured in a control vessel (●) and in the presence of poly(A) (○) and poly(G) (△).

(90) was a better inhibitor (I_{50}=2.9×10^{-6} M) than either of the smaller chains. Finally, the polymer having the highest molecular weight (average monomer length of 315) proved to be the best inhibitor of all (I_{50}=2.1×10^{-6} M). Although greater inhibition of enzyme activity was observed as the average chain length of poly(A) was lengthened, the increase was gradual and did not seem to be so strongly controlled by chain length that inhibition was a step function of average molecular weight in the region available for study. The gradual decrease in inhibitory properties associated with decreasing chain length suggested that below a certain size, inhibition by poly(A) would not occur. The

Fig. 2 Inhibition of *Citrobacter* RNase activity by various molecular weight fractions of poly(A). Average monomer length (Miles Laboratories) based on intrinsic viscosity and sedimentation velocity, 50% range: □, 25 (25–51); △, 45 (39–82); ○, 90 (62–108); ●, >300. Enzyme activity was measured as in Fig. 1, except that 55 μmol of Tris-HCl buffer (pH 7) was used in all the determinations
Table 1 Reversal by polyamines of poly(A)-induced inhibition of RNase activity

RNase	Concentration of poly(A)	—	MgCl₂	Enzyme activity (ΔA_{260}) of cation added Putrescine	Spermidine	Spermine
Citrobacter	—	1.31	1.35	1.29	1.52	1.49
	5.0×10^{-6}M	0.29	0.30	0.33	1.25	1.50
Human plasma	—	2.10	2.27	2.39	2.47	2.26
	1.5×10^{-5}M	0.78	0.78	0.97	2.23	2.10
Human spleen	—	1.05	1.11	1.38	1.43	1.21
	2.0×10^{-6}M	0.08	0.78	0.50	1.44	1.27

Citrobacter RNase activity was measured as in Fig. 1, except that 40 μmol of potassium phosphate buffer (pH 7.1), were used in place of Tris-HCl. When the effects on enzyme activity of poly(A) and/or cations listed above were studied, 0.005 μmol of poly(A), followed by 0.5 μmol of cation were added before the addition of enzyme to reaction mixtures similar to those described above. The hydrolysis of poly(C)(1.5 μmol) used as a measure of the activity of human plasma RNase was assayed as described elsewhere[10]. Here also poly(A) (0.015 μmol) and 0.5 μmol of cation were added to the reaction mixtures before the addition of 21 U of enzyme. The human spleen RNase activity[11] was measured in a reaction mixture (1 ml) containing 1 μmol of potassium phosphate buffer (pH 6.2), 40 μmol of poly(U) and 10 U of human spleen RNase. After incubation for 15 min at 37 °C, enzyme activity was measured by the production of acid-soluble nucleotides[14]. Poly(A) (0.002 μmol) and cations (0.4 μmol) were added also to reaction mixtures before the addition of enzyme.

critical chain size could not be determined, however, because of the lack of availability of a graduated series of smaller polymer chains.

Another characteristic of polynucleotide inhibition of RNase activity is that it is readily reversible when the highly charged polyamines are added. As is apparent from Table 1, the poly(A)-induced inhibition of a number of RNases can be reversed with these substances. At concentrations of poly(A) sufficient to cause severe reductions in enzyme activity of both the *Citrobacter* and a human plasma RNase, only spermine or spermidine could restore activity to uninhibited levels. Putrescine and a variety of metal cations tested (represented by Mg²⁺ in Table 1) were ineffective in reversing the inhibition. Enzyme activity of a third RNase (from human spleen), although completely inhibited by poly(A), could be restored by spermine or

spermidine, and to a lesser extent by Mg²⁺ and putrescine.

The influence of poly(A) on RNase activity was of interest from the point of view of enzyme stability as well. The association between polynucleotide and enzyme was found to protect the RNase from thermal inactivation. Thus, in the absence of the polynucleotide, the half life of a human liver RNase (unpublished results) was 20 min (Fig. 3), whereas in the presence of poly(A), the half life of the enzyme was found to be increased by as much as fivefold.

The results of these studies suggest a model whereby poly(A), at the terminus of a mRNA, acts to prevent the degradation of the mRNA. The polynucleotide would do this by binding to, and thus inhibiting, any RNase in the vicinity of the mRNA. With this in mind, it is entirely conceivable that translation can occur with an RNase bound to the poly(A) moiety at the end of the mRNA chain. This would also help explain the long lived mRNAs of eukaryotic cells in contrast to the rapidly degraded ones of prokaryotes[15]. Degradation of the mRNA can, nonetheless, be assured by any of a number of means that would dissociate the complex formed between the mRNA-poly(A) and the RNase. An increase in ionic strength or in polyamine concentration would, of course, be examples of factors causing dissociation of the complex and thereby reversing the inhibition of the enzymes. The association between RNase and polynucleotide also provides a means of storing the enzyme for long periods, thus ensuring that the protein, although quiescent, is not denatured and is immediately active when needed. In effect, the mRNA-poly(A) chain might carry its own "self-destruct" mechanism. Studies are in progress attempting to verify the model *in vivo*.

Fig. 3 The effect of poly(A) on the thermal inactivation of human liver RNase. To one of two flasks, each containing 40 U of human liver RNase in 0.1 M potassium phosphate buffer (pH 6.4), 0.25 μmol of poly(A) were added. The final volume in each vessel was brought to 1 ml and the mixtures incubated at 37 °C. Aliquots (25 μl) withdrawn from each vessel at 5-min intervals were tested for enzyme activity in a reaction mixture containing 0.25 mg of yeast RNA and 100 μmol of potassium phosphate buffer (pH 6.4)[11]. After 15 min at 37 °C, the reaction was stopped by the addition of 1 ml of 2 N perchloric acid and the mixture chilled for 20 min. The A_{260} of acid-soluble nucleotides was measured after clarification of the mixture by centrifugation. Enzyme activity (●); enzyme activity in presence of poly(A) (○).

Stereoselective blockade of the dopamine receptor and the X-ray structures of α and β-flupenthixol

THE introduction of neuroleptics of the phenothiazine and thioxanthene classes has revolutionised the treatment of schizophrenia and there is increasing evidence[1-3] that links this antipsychotic action to a blockade of dopamine receptors in the brain. The thioxanthene compounds are of particular interest as, because of the presence of an exocyclic double bond and a substituent in the tricyclic nucleus, they exist as *cis–trans* geometric isomers about the double bond with respect to the ring substituent (Fig. 1). Virtually all the neuroleptic activity is confined to the *cis* isomer[4].

One of the most potent drugs in this group is flupenthixol. (Fig. 1); a mixture of the *cis* (α) and *trans* (β) isomers is a clinically efficaceous antipsychotic agent[5] but in dopamine receptor related animal tests the α isomer is much more potent than the β form[4] (Table 1). In *in vitro* studies using the dopamine sensitive adenyl cyclase system of the rat corpus striatum as a model of the dopamine receptor, the α isomer is a very potent blocker of the dopamine induced enzyme stimulation whereas the β isomer is almost inactive[6] (Table 1).

In an attempt to explain how chlorpromazine is able to block dopamine receptors, attention has been focused on a possible spatial complementary relationship between certain

portions of the crystal structure of chlorpromazine and dopamine[1]. Further support for this concept has been obtained from a detailed conformational analysis of 15 drugs of the tricyclic class[7]. As flupenthixol displays such a marked degree of stereoselectivity in blocking dopamine receptors, it is believed that X-ray analysis of the two isomers could provide additional insight into the various interatomic distance and overall conformational requirements for effective dopamine receptor antagonism. Although the *cis* and *trans* geometrical isomers will have differing physical properties this is unlikely to be the sole factor accounting for their differential pharmacological potency, as neuroleptics possessing optically active centres, such as butaclamol, also show a high degree of stereoselectivity[7-9].

Crystals of each isomer were obtained and the cell dimensions and other related parameters for each compound were found:

α-flupenthixol: orthorhombic; *Pbca*; $a = 8.827$, $b = 20.048$, $c = 20.251$ Å; 8 molecules per cell; final R factor 0.066 for 1,094 reflections.
β-flupenthixol: monoclinic; $P2_1/c$; $a = 9.011$, $b = 15.218$, $c = 18.493$ Å; $\beta = 120.37°$; 4 molecules per cell; current R factor 0.072 for 2,308 reflections.

Diffractometer data for both compounds were collected using Cu-K_α radiation to a resolution of 0.89 Å ($2\theta_{max}$ of 120°) and each structure was solved by the application of locally programmed (G. M. Sheldrick, unpublished) multisolution direct method techniques. Complete details of these structures will be published elsewhere. Figure 1 shows a general view of each isomer based on approximately equivalent orientations of the tricyclic nucleus. The *cis* or *trans* configuration at the exocyclic double bond is clearly apparent and each side chain exhibits markedly different conformation although the piperazine rings favour the –CF$_3$ 'side' of the molecule in either case. Principal torsion angles for the side chain are shown in Fig. 1. The dihedral angles between the aromatic ring mean planes are 152° and 143° for α and β-flupenthixol respectively.

Various lines of evidence support the concept that the preferred conformation of dopamine at its receptor site is the fully extended *trans* form[7]; therefore, it has been suggested that the binding site for dopamine's amino group is about 5.1 Å from the centre of the aromatic ring[7]. There is also evidence that the dopamine receptor antagonism by the neuroleptics is
Fig. 1 α and β isomers of flupenthixol computed from the crystallographic coordinates, together with a chemical representation of the molecules (shown in the α form) on which is indicated labelling referred to in the text. The values of some principal torsion angles (in degrees) for each isomer are shown alongside the bond to which they refer, and where an ambiguity in definition occurs, an arrow marks atoms used in the calculations.

Table 1 Comparison of the effects of α and β-flupenthixol on various dopamine receptor systems

	Antagonism of apomorphine induced stereotypy in rats ED_{50} (mg kg^{-1}) (ref. 4)	Antagonism of amphetamine induced stereotypy in rats ED_{50} (mg kg^{-1}) (ref. 4)	Ki for dopamine sensitive adenyl cyclase antagonism[6]
α-flupenthixol	0.3	0.07	1.0×10^{-9} (M)
β-flupenthixol	> 80	> 160	$> 5 \times 10^{-6}$ (M)

competitive[10,11] and for simplicity this can be considered to indicate occupation, by the neuroleptic, of the same site as the natural agonist. Thus it is of interest to contrast significant intramolecular distances between α and β-flupenthixol. In α-flupenthixol the distances of N1 from the centres of the two aromatic rings A and B (Fig. 1) are 5.82 Å and 7.46 Å respectively, and the corresponding distances from N2 are much longer, with N2–A = 7.75 Å and N2–B = 10.26 Å.

This suggests that N1 could bind at the receptor site normally occupied by the amino group of dopamine whereas the aromatic ring A would interact at the site normally influenced by the benzene ring of dopamine. The importance of N1 rather than N2 as the atom involved in the antagonistic binding is supported by comparison with similar distances found in α-chlorprothixene[7,12], a pharmacologically active compound which, however, has only a single N atom in the side chain. There is a marked difference in the almost inactive β-flupenthixol where N1–A = 6.09 Å, N1–B = 6.46 Å, N2–A = 8.24 Å and N2–B = 9.30 Å, indicating that the α-isomer exhibits a better 'fit' as a dopamine antagonist. Extrapolation from results of crystal structure determinations to the conformation of molecules in physiological conditions has always to be interpreted with caution, but the absence of any unusually close intermolecular contacts in the crystal structures suggests that the observed conformation is not the result of packing forces and that a closely similar conformation could be found in vivo.

The A and B rings of the tricyclic nucleus are differentiated by the presence of the –CF$_3$ moiety. This group is of evident importance for pharmacological activity although its mode of action is not clearly understood. It is perhaps of interest to note that the molecular asymmetry introduced in the tricyclic nucleus by the –CF$_3$ group is enhanced in the α form where the difference in the distance of N1 from the centres of the aromatic rings is greater than in the β form[7].

The X-ray studies reported here were carried out on the free bases. An X-ray analysis of the dihydrochloride salts is in progress to investigate the effect of positive charges on the nitrogen atoms of the piperazine ring on the conformation of these molecules.

We thank the MRC for financial support and the SRC for provision of the diffractometer. Olga Kennard is on the External Staff of the MRC. Dr I. Moller-Nielsen of H. Lundbeck and Co., Denmark, provided the specimen crystals.

Alteration of cavity geometry by structural modification of clathrate host molecules

IN the course of systematic studies[1] of the synthesis and properties of clathrate inclusion compounds we found that compound II, formed by adding a methyl group to the clathrating compound I, also exhibits clathrating properties. It was evident, however, both from preliminary crystallographic measurements and from their very different selectivities towards guest molecules that the cavities in the host structure of I and II differ markedly[2]. We present here details of the cavities in II and compare them with those reported earlier for I (ref. 3).

I   II
The cyclooctane clathrate of II, which was selected for crystallographic study, is trigonal with a unit cell ($a = 33.629(9)$; $c = 8.239(3)$Å) containing 18 molecules of $C_{19}H_{22}OS$. A host–guest (cyclooctane) ratio of 4.5:1 was measured by ^1H nuclear magnetic resonance for a CDCl$_3$ solution. The space group is either R3 or R$\bar{3}$; (ref. 4) the centrosymmetric space group (R$\bar{3}$) was chosen by analogy to the structure of the clathrates of I (ref. 3) and this choice has been justified by successful analysis. The structure was solved by direct methods using 1,915 independent reflections measured with Mo–K$_α$ radiation on a Hilger–Watts automatic diffractometer, and refined to a current R value of 0.119. All 22 of the hydrogen atoms of the host molecule have been located and allowed for; it has not yet been possible, however, to allow effectively for the guest molecules and this should allow further reduction in R.

Figure 1 illustrates the general similarity of the clathrate host structures of I and II. Both structures contain groups of six molecules the hydroxyl groups of which are linked by
Fig. 1 *A*, Structure of compound I looking on to the *a–c* plane. The guest molecule, 2,5,5-trimethylhex-3-yn-2-ol, is not shown. *B*, Structure of compound II looking on to the *a–c* plane. The (disordered) cyclooctane guest is not shown. In both cases, two host molecules which lie above and below the cavity as viewed in the direction, have been excluded, apart from their hydroxyl oxygen atoms.

0 1 2 3 Å

hydrogen bonds to form a distorted hexagon, alternate molecules lying on opposite sides of its plane. Two such sextets are stacked in each *c* axis repeat and their bulkier parts interlock to form cages. The major differences between the two structures (marked contractions in *c* and in therefore the length of the cavity) are the result of a change in the interlocking pattern which is directly attributable to the introduction of the methyl group in II. Minor changes are: shorter O···O distances in II (2.766(12) compared with 3.035(8) Å) and a more puckered

Fig. 2 Section through the van der Waals' surface of the cavity for I (*A*) and II (*B*).

ring of oxygens (displacements from the mean plane of +0.34 Å (compare 0.22 Å in I)); and the introduction of distortion into the half-chair heterocyclic ring. In I the ring *gem*-dimethyl carbon and the methylene carbon are almost symmetrically displaced (0.38 and 0.34 Å) on opposite sides of the ring, whereas in II the distances are 0.23 and 0.45 Å.

The marked change in cavity shape is most readily appreciated by comparing their van der Waals' surfaces. Thus, Fig. 2*a* shows that the cavity in I has a pronounced waist at $Z = \frac{1}{2}$ which is formed by six *gem*-dimethyl groups protruding into the cage. Figure 2*b*, on the other hand, shows the complete elimination of this waist in II—indeed the central section of this cavity is the widest: the 'hour-glass' surface of I is converted into the 'chinese-lantern' shape of II.

Marked variations in clathrating specificity and in crystallographic data have been reported[5] in a range of specially made chemical variants of the inorganic $M(SCN)_2(R\text{-pyridine})_4$ clathrates (M = Fe, Ni, Co; R = Me, Et, vinyl, and so on). Another deliberate modification of an organic clathrate cage was recently reported[6] by Emert and Breslow who succeeded in introducing a hydrophobic 'floor' into the cavity of β-cyclodextrin, but the alteration in the cavity reported above is much more general and drastic. This report, therefore, provides the first detailed analysis of the changes produced by a piece of planned clathrate engineering.

In the article "Depths of origin of Kenyan basalts and implications for the Gregory Rift" by G. G. Goles (*Nature*, 255, 391; 1975) the received date is incorrect. It should read Received February 24; accepted April 9, 1975.

matters arising

Superfoetation in fishes and the cost of reproduction

THIBAULT[1] has examined the effects of juvenile mortality on reproduction of normal and superfoetatious females of the family Poeciliidae and concluded that superfoetation conferred no selective advantage in an unpredictable environment in which mortality was catastrophic. A life-table model for the evolution of superfoetation shows this to be wrong.

The net reproductive rate of a population (R_0) summarises the interaction between survivorship and fecundity. In general,

$$R_0 = \sum_{x=0}^{\infty} l_x m_x \qquad (1)$$

where l_x is age-specific survivorship and m_x is age specific fecundity. A consequence of superfoetation is that females produce fewer young more often than usual. For example, *Poecilia reticulata* females 30–35 mm long produce about 24 young every 21 d (ref. 1). They are not superfoetatious. By contrast, *Poeciliopsis lucida* and *P. monacha* are superfoetatious and females 30–35 mm long produce about 11 young every 11 d (ref. 1). A more general comparison of superfoetatious and normal life histories is given in Table 1.

The net reproductive rate of a superfoetatious female producing young twice as often as a normal female is:

$$R_0 = m_x B_s (1 + p_s + p_s^2 + \ldots) \qquad (2)$$

Here, m_x is the number of young produced in interval x, B_s is survivorship to the age of first reproduction for superfoetatious females, and p_s is survivorship to subsequent reproductive intervals. Equation (2) can be simplified[2,3]

$$R_0 = m_x B_s / (1 - p_s) \qquad (3)$$

Similarly, the net reproductive rate of a normal female is:

$$R_0 = n_y B(1 + p^2 + p^4 + \ldots) \qquad (4)$$

Where n_y is brood size, B is survivorship of a normal female to reproductive

age, and p is survivorship to subsequent (x) intervals (Table 1). Equation (4) can be rewritten

$$R_0 = \frac{n_y B}{(1 - p^2)} \qquad (5)$$

We can define the circumstances in which superfoetation and normal patterns of reproduction have equal net reproductive rates, that is, when

$$m_x B_s / (1 - p_s) = n_y B / (1 - p^2) \qquad (6)$$

or when

$$p = \sqrt{\{1 - [(n_y B / m_x B_s)(1 - p_s)]\}} \qquad (7)$$

Whether or not superfoetation is advantageous depends on survivorship to age at first reproduction, subsequent survivorship, and the degree to which brood size is depressed in superfoetatious females. Our example comparing *P. reticulata* with *P. lucida* and *P. monacha* is illustrative. The species are of similar size when they first reproduce. Therefore, we assume equal survival to age at first reproduction. Brood size for the superfoetatious species is half that of the normal female[1], so $m_x = 1$ and $n_y = 2$. Thus equation (7) becomes

$$p = \sqrt{(2p_s - 1)} \qquad (8)$$

The difference in adult survivorship (D) when net reproductive rates are identical for both strategies is defined as

$$D = \sqrt{(2p_s - 1)} - p \qquad (9)$$

D increases as adult survivorship declines (Fig. 1). When the probability of a normal female surviving to produce another brood (11 d in our example[1]) is less than 50%, superfoetation cannot evolve. When survivorship is in excess of 80%, superfoetation results in a higher net reproductive rate if it increases adult survival as little as
Fig. 1 Relationship between adult survivorship (p) of normal females and the minimum increase in survivorship (D) for superfoetation to be a more advantageous reproductive strategy.

2.5%. *P. lucida* and *P. monacha* occur in unstable environments and invade flood expanded habitats[1] possibly characterised by low competition and predation and, consequently, by high adult survival. As superfoetation will reduce the peak cost of reproduction and further increase adult survival, we interpret it as an adaptation that increases reproduction in transient environments.

fishes without superfoetation in tranisent environments characterised by low levels of predation and competition, and consequently high adult survivorship. Although the mechanics of the model seem sound, its theoretical applicability breaks down on examination of the biology of poeciliid fishes.

In the Rio del Fuerte of north-western Mexico, *Poeciliopsis monacha* inhabits small pools in headwater arroyos carved in solid bedrock. The raging torrents of the rainy season revert in the dry season to congested and isolated pools of a few litres of water. Fishes become compacted, are heavily parasitised and appear emaciated. Aquatic arthropod and reptilian predators are abundant, imposing

and J. Schultz, unpublished). Superfoetation does not seem to be an adaptation solely to transient environments; levels of superfoetation, instead, seem correlated with increased stability and decreased levels of competition. Moreover, approximately 85% of the species of poeciliids lack superfoetation which further attests to the flexibility of the more common and more widely distributed reproductive mechanism.

Further, there is no reason to assume that superfoetation reduces the peak cost of reproduction. Some *Poeciliopsis* have evolved high degrees of maternal contributions to developing embryos with pseudoplacentas (R.T. and J.S., unpublished). The maintenance of several

lomas. Further studies in our laboratory and in others showed that these conclusions were not correct.

The new data showing our misinterpretation were as follows. First, when TdT activity is determined in partially purified extracts from thymus, the highest activity is observed in the presence of oligo (dA) as primer, and of dGTP as substrate. When myeloma extracts were used, no activity was detected with this combination. In our previous study, the TdT activity was determined using $d(pT)_4$ with dATP or dTTP; this system seems to have very low efficiency. Second, further studies of the profile of the activities on the phosphocellulose chromatograms with thymus extracts showed an overlapping, but not an exact correspondence of the peaks obtained with oligo (dA)/dGTP and with $d(pT)_4$/dATP. The $d(pT)_4$/dATP activity was not modified in the thymus after hydrocortisone treatment of mice. It was recently shown that TdT is drastically decreased in these conditions[2,3].

Therefore, the activity we described[1] does not correspond to terminal deoxynucleotidyltransferase, but to another deoxynucleotide-polymerising enzyme, the nature of which remains to be determined.

We thank D. Baltimore, R. MacCaffrey, T. A. Harrison, P. C. Kung and A. E. Silvertone for help in the analysis of myeloma and thymus activities which led us to the correct interpretation of our results.

predation pressure on all size classes of *Poeciliopsis*[2]. Conjecture that these environments are characterised by low levels of intraspecific competition and predation and high adult survivorship, is unfounded.

Downstream from headwater environments, the Fuerte broadens and is somewhat stable with a diversity of lentic and lotic habitats. Inhabited by *P. lucida*, these tributaries are home to an equally diverse array of aquatic predators as well as avian predators. The robustness of fishes in this habitat reflects reduced levels of competition. These tributaries drain into the main stems of the Fuerte with deep and flowing permanent water and stable temperature regimes. Superfoetated *P. prolifica* is found in these environments.

In terms of stability, stream size, and competition levels, the habitat of *P. monacha* lies at one extreme, being transient with competition pronounced. The environment of *P. prolifica*, in contrast, is stable with low levels of competition. The environment of *P. lucida* is intermediate in these characteristics. Predation pressure is variable among the environments. Populations of reproducing *P. monacha* average 1.4–1.5 broods per female developing simultaneously; *P. lucida*, 1.8–2.0; and *P. prolifica* 4–5 (R.T.

broods, each with specific nutritive and metabolic demands, may instead enhance the cost of reproduction.

In extending a hypothetical life table (Table 1) to enable calculation of *r* (the intrinsic rate of increase[3]), fishes without superfoetation have a slight advantage. Regardless of female survivorship, the ability to produce a large number of young in the initial reproductive period may be adaptive in transient environments where *r* selection is operative.

Superfoetation must convey some evolutionary advantages to viviparous fishes; however, the causative selective force, to me, still remains an enigma.

Terminal deoxynucleotidyl-transferase in murine myelomas

WE have published[1] results suggesting the presence of terminal deoxynucleotidyltransferase (TdT) in murine mye-

Double helix of tropomyosin

LONGLEY[1] has suggested that the supercoil pitch length (*P*) of tropomyosin (TM) may be 114 Å. The arguments in favour of this value are based on the assumptions that TM molecules are optimally packed in the tactoids formed using Mg^{2+} and Ca^{2+} (ref. 2) and also that TM presents an axially and azimuthally pseudo-equivalent aspect to consecutive actin molecules.

Although it is known[3,4] that two-stranded ropes may pack optimally when there is a relative axial stagger of *P*/4, it remains to be shown that TM packs in this way in Mg tactoids. Indeed, the Mg

tactoid geometry may simply be explained as follows: the distribution of acidic residues of a TM chain has approximate mirror symmetry about a point $\sim 70\text{Å}$ from the N terminus. The assembly of the tactoids may not be controlled solely from packing considerations, but may be dominated by the bridging effect of Mg^{2+} between acidic moieties of oppositely directed molecules. If TM molecules were optimally packed in the positively and negatively stained tactoids, there is still no *a priori* reason to believe that $P/4$ should be equated to the observed 28 Å axial period.

Even with an axial pseudo-period of about 19.5 residues in acidic and in apolar residues not in series I and II (refs 5 and 6), azimuthally-identical pseudo-equivalent actin–TM interactions could only occur if an actin separation along one strand ($\sim 2 \times 19.5$ residues) corresponds to a multiple of P' (unless the two chains of TM are homologous and in axial register, in which case actin separations could correspond to a multiple of $P'/2$). P' is the supercoil pitch length measured along the helical axis of the supercoil. On packing grounds, it has been suggested that the two chains of TM may have a relative axial stagger of 14 residues[6–8] thus facilitating head-to-tail assembly of TM molecules, but recent evidence has cast doubts on this conclusion[9,10].

Irrespective of the relative chain stagger in TM, the length and flexibility of side chains may enable the first and/or second chain of TM to make pseudo-equivalent interactions with an actin strand even if precise azimuthal relationships are not maintained (see, for example, Hulmes *et al.*[11] for collagen).

Theoretically, the pitch length of α-fibrous proteins may be found directly using a measurement of the axial separation of the equatorial and near equatorial reflections in the X-ray diffraction patterns[12]. Inherent accuracy, however, is usually low as a result of partial overlapping of the relevant data. Also the possibility that axial sampling moves the maxima of the molecular transform cannot be completely eliminated[13]. P has been estimated for α keratin[14] (140–170 Å); paramyosin[4,15] (136–140 Å and 178 Å) and honeybee silk[16] (140 Å), but not for TM. If the head-to-tail assembly of TM molecules in the grooves of the thin filament form a regular supercoil and troponin has an invariable azimuthal relationship with TM and actin, then $nP = 410 \pm 4\text{Å}$ (ref. 17) where n is integral. If $n = 3$, then $P = 137\text{Å}$ and there would be six half-turns of supercoil associated with seven actin molecules. As McLachlan and Stewart (private communication) have also pointed out, TM would then present pseudo-equivalent aspects to all seven actins with which it makes contact, as $3P = 7P'/2 = 410\text{Å}$ where $P'/2 \sim 2 \times 19.5$ residue translations

of an α helix or, equivalently, an actin separation.

The pitch length of an α-fibrous coiled coil cannot be continuously reduced without a concomitant increase in the deformation of bond lengths and angles. The point at which the coiled coil structure reaches a minimum energy state is not known, although it is tempting to speculate that this may occur when P is about 140 Å, a value experimentally noted for several α-fibrous proteins.

LONGLEY REPLIES—In calculating an example of his model of the coiled coil, Crick[1] started with a straight α helix having 18 units in 5 turns, giving a coiled coil with 126 residues in a pitch of 186 Å. If, instead one starts with the very similar helix of 11 units in 3 turns, the resulting coiled coil has 77 residues in a pitch of 114 Å. (The 11/3 helix is one of the alternatives considered by Pauling and Corey[2] and is the structure automatically formed when an α helix is constructed of CPK molecular models.) Thus, large variations in the pitch of a double helix can result from small changes in the α helix from which it is derived, and there is no reason why the pitch of tropomyosin (TM) should be the same as that of paramyosin, keratin or bee silk. The main resistance to bending the α helix into a tighter coiled coil is in stretching and compressing the H bonds[3]. To bend it into a helix of pitch 114 Å would require 0.1–0.2 kcalorie mol^{-1} which is not large, and would strain the H bonds by only 2 or 3%. The observed spread in H-bond lengths is about 8% (ref. 4).

Now, 77 is an odd number so that each

alternate half-turn of such a double α helix would have a different pattern of side groups from the next. This, together with the 14-residue stagger, could be accommodated in the thin filament of muscle if the pattern of contacts between TM and actin alternated (and perhaps commutated) along the length of the TM molecules. In the 'tactoids' likewise, cross linking (by divalent cations) would be simpler if the chemical repeat were compatible with the helix pitch.

Number counts of γ-ray bursts

STRONG and Klebesadel[1] suggest that most of the 23 γ-ray bursts detected by the Vela satellites are of galactic origin. I question their arguments, which are based on the distribution in galactic latitude and longitude of those bursts for which coordinates have been determined, as well as on the source counts. They admit that the latitude distribution is not significantly galactic. Similarly, the longitude distribution is of low significance. If, *a priori*, the local spiral arm had been predicted to dominate this distribution, then the observations have a chance probability of $\sim 1.5\%$. This probability rises above 6% if the observations in any way suggest the correlation. Further, the location of the event of April 27, 1972 (ref. 2) (which was not used in the reported analysis) does not easily fit into the simple local spiral arm hypothesis.

The source counts as presented give the number of events of time-integrated flux density, S, exceeding some level S_0. As S_0 decreases, the source counts flatten out below the three-halves dependence expected from a uniform source distribution. This seems to indicate a scarcity of weak sources, which is consistent with a galactic origin for the bursts. Such a flattening could perhaps also be caused by the first trigger of the event as well as by the method by which the end of the event is determined. The first trigger effects have been partially eliminated by Strong and Klebesadel and it is evident from their figure caption that the second has been noted, although it is not discussed in the text.

I consider this effect in more detail and assume an abrupt rise and gradual fall-off for the burst represented by:

$$I = 0 \qquad \rbrace t < 0$$
$$I = Ke^{-t/\tau} \qquad \rbrace t \geqslant 0$$

The time-integrated flux S is given by

$$S = K\tau(1 - e^{-t/\tau})$$

where t is the apparent duration of the burst. This will be determined by the detector noise level, which I assume to be constant and to imply a lowest sensitivity of L erg cm^{-2} s^{-1}. Now $t = \tau \ln(K/L)$, therefore $S = (K-L)\tau$.

If the sources are distributed uniformly,

$$N(>K) = CK^{-3/2}$$

and then, $N(>S) = \tau^{-2}C (S/\tau + L)^{-3/2}$

or

$$N(>S) \propto (S + L\tau)^{-3/2} \quad (1)$$

So when $S \gg L\tau$, a three-halves dependence is expected, but when $S \ll L\tau$, $N(>S)$ is independent of S. This is because the events rapidly seem to weaken as K approaches L. The dependence given by equation (1) is of a reasonable form to fit the source counts and implies

$$L\tau \simeq 5 \times 10^{-5} \text{ erg cm}^{-2}$$

τ is not necessarily a constant from event to event and is only representative of the time scale of event decay.

I conclude that the arguments for a galactic origin for γ-ray bursts are by no means sound, and that the distance estimates are extremely uncertain. Number counts of γ-ray bursts, or any other transient phenomena, of time-integrated fluxes less than about $2L\tau$ may merely reflect the average time structure of the events rather than inhomogeneities in source distribution. Many more observations over a much wider range of sensitivity are required if source distances are to be inferred from the number counts. Sensitive γ-ray detectors carried whenever possible in satellite, space-probes or long-duration balloon flights would be invaluable in this respect.

I thank the SRC for support.

A. C. FABIAN

Institute of Astronomy,
Cambridge CB3 OHA, UK

[1] Strong, I. B., and Klebesadel, R. W., *Nature*, 251, 396–397, (1974).
[2] Trombka, J. I., et al., *Astrophys. J. Lett.*, 194, L27–L33 (1974).

STRONG AND KLEBESADEL REPLY—
The arguments used in our letter[1] may be questioned on several grounds, but not those considered by Fabian[2], who makes two principal assumptions. These are the flux as a function of time may be represented adequately by a form having an abrupt rise to maximum followed by exponential decay, and the apparent duration of the bursts is limited by the detector noise level. Given that these were valid we would agree with his analysis. But both assumptions, although seemingly reasonable, are incorrect. The event of April 27, 1972 is an excellent counter-example[3,4]. Our paper did not include this case as it was written before the papers by Metzger et al.[3] and Trombka et al.[4] were published. Further examples may be found in ref. 5.

The actual time profiles of γ-ray bursts are very variable, ranging from single, very intense spikes to complex structures with one or more precursor pulses, a main burst comprising a number of sub-bursts lasting about a second each, and with pronounced substructure, and often a resurgence of weaker, but similar activity a few seconds to a minute later. If a decaying exponential were even an approximately correct model one would expect a strong correlation between S and the apparent duration, t. For values greater than $S = 3 \times 10^{-5}$ erg cm^{-2}, where we have noted that we expect trigger-threshold effects, this is not the case[6]. The Vela detectors can provide reliable values of S well below those of most of the measured events, if we assume the time profiles are similar to the stronger ones. We do not record these events because they fail to trigger the system. In other words, in dealing with low values of S we are trigger-limited rather than limited by the detector noise level.

Although Fabian's detailed argument is therefore not relevant this does not mean that we are still satisfied with our interpretation of the log N–log S plot. We had assumed, like Fabian, that the system would trigger only near the start of an event, and that trigger-threshold effects would appear as an increasing trigger-failure rate with weaker signals. Our threshold figure of 3×10^{-5} erg cm^{-2} meant that we would fail to detect a significant fraction of events with measured $S \lesssim 3 \times 10^{-5}$ erg cm^{-2}. What can happen is that even for $S > 3 \times 10^{-5}$ erg cm^{-2} the instantaneous flux may be low and a trigger, if it occurs at all, can take place after the start of the event. The event[3] of April 27, 1972 illustrates this. The Vela 6A system recorded only the last third of the event, giving 3×10^{-5} erg cm^{-2} instead of $\sim 10^{-4}$ erg cm^{-2}. Putting it simply, we had considered only failures to trigger which gives rise to errors in N. We did not consider errors in S caused by late triggering. The range over which the log N–log S relationship is reliable therefore lies at $S > 10^{-4}$ erg cm^{-2}. This contains too few events to be significant. (We note that the reported values of S from Vela data[6], and those used here, are low by a factor of about two compared with accurate simultaneous measurements made on some other spacecraft, and are probably all underestimated by this amount.)

Turning to the directional distributions, Fabian agrees with our assessment of their significance as being low. They are not therefore to be ignored. The point of our letter was to draw attention to the possibility that the data contained information relevant to the problem of determining the source distances, and not that there was conclusive evidence for a galactic distribution. We also intended to show how future data could be incorporated for this purpose. Work carried
Fig. 1 Integral galactic latitude distribution for 16 gamma-ray burst sources. —, Observed distribution; - - -, isotropic distribution.

out by many people over the past year has provided additional source directions. This has had the effect of largely removing the original anisotropy in longitude, and of further emphasising the preference for low latitudes (Fig. 1). We note that two of the high-latitude sources have large errors ($\sim \pm 15°$) and that one additional source on the Galactic Equator should probably be added.

This is again suggestive of a galactic association, but we accept the possibility that in a few cases we may be witnessing repeats from the same source. If this turns out to be true it is extremely important, but would mean that the distribution of sources as opposed to events would follow more closely the curve for an isotropic distribution.

reviews

THE value and dangers of drawing analogies between organism and societies have been debated at least since Herbert Spencer; part of their appeal is that they seem to provide a scientific language for talking about society and social organisation, which are prickly subjects of which scientists and doctors usually know little. Dr Salk is open and unashamed about it: "I believe in the usefulness of biological analogies in thinking about men." He calls it "a theoretical–experimental way of thought", to be distinguished from "a 'philosophical speculative way of thought' for dealing with questions in the human realm." He doesn't think much of philosophers, and we hear no more about them, not even those who have studied these problems through the ages. Instead he provides a long series of analogies. Racial intolerance may follow laws similar to immunological intolerance, and "then patterns of possible interest in psychological phenomena, could be observed through quantitative studies in immunology". The phenomena of enzyme induction are held to show something of the environmental forces that are needed to nurture and encourage the fulfilment of our potentialities. He takes the analogies very seriously, but can one really hope that they will, as he suggests, help in adjusting the relationships "between parent and child, teacher and student, lovers,

Biology and man

J. Z. Young

How Like an Angel: Biology and the Nature of Man. By Jonas Salk. Planned and edited by Ruth Nanda Anshen. Pp. 118. (David and Charles: Newton Abbot, London and Vancouver, April 1975.) £3.50.

peers, or between groups or nations"?

The general aim of the book is to show that biological knowledge is increasingly relevant to human affairs, and though this is indeed true perhaps the continual stressing of analogies is not the best way to make the point. Those who actually have to manage social, educational and political affairs are not very likely to pay attention to such generalities, and will ask for more concrete examples. Dr Salk is continually emphasising that we "must" change our ways "What is needed is a change of perspective . . . new values and new ethics are required . . . it will be necessary to establish patterns in the young child that will help him to develop to his fullest." He does not show any understanding that questions as to how these things can be done have occupied men for centuries and are at present being studied intensively.

Those who work in such fields may be annoyed to read that "a beginning must somehow be made". Perhaps more sociology for medical students might be a good start.

In view of Dr Salk's own contributions to infantile paralysis it is natural to look especially carefully at the social analogies he draws with this disease. He indeed believes that there is "a new form of crippling": Man's mind, which has "developed dinosaurian qualities (and) threatens to overpower his body", now apparently "faces uselessness". And our "socially and economically advantaged youths", because of their easy upbringing, are not immunised against this new disorder in the way that they have been immunised against polio. It is not clear whether the conclusion from this analogy is that we should inflict greater hardships upon children of the rich to immunise them against this disease.

It would be unfair to ridicule all of Salk's analogies. He is well up-to-date with studies of the development of the brain and its need for stimulation at appropriate stages of development. Not unexpectedly, he draws an analogy between learning and selective theories of antibody formation. But this is more than an analogy, and it is disappointing that he does not tell us about the evidence that the brain does actually begin with a library of possibilities from which selection is made.   □

PROFESSOR LURIA has produced a very interesting book from the edited transcript of the general biology course he taught at MIT. Its theme is the central place of the genetic programme in biology. In my opinion he succeeds very well in presenting his material (primarily on cell biology) in a logical self-sustaining and interesting manner. Although he provides references to other books he accommodates within his own the essential argument and examples. There are concise appendices on chemical topics such as kinetics, free energy and the structures of biological molecules, and other appendices on discussion topics and examination questions.

The first part of the book (four lecture-chapters) introduces the characteristics of living matter and gives a good account of the cellular components The section on biochemistry

(nine lectures) proceeds from enzymes through energetics and the generation of ATP to the biosynthesis of amino acids, nucleic acids and proteins, but not of carbohydrates and lipids. That on genetics (eight lectures) starts with

---

Lectures in Biology. By S. E. Luria. Pp. xvii+439. (MIT Press : Cambridge, Massachusetts, and London, 1975.) n.p.

Mendel, and deals, in order, with cell cycles and life cycles, bacterial and phage genetics, eukaryotic genetics (almost entirely *Drosophila* and Man) and population genetics and evolution An excellent feature here, and indeed throughout the book, is the way in which Luria demonstrates the value of particular systems in illuminating particular problems without making his treatment seem fragmented. Thus, in the section on developmental biology

(seven lectures) bacterial sporulation, slime moulds, plant gametogenesis and meristems, insects, sponges, *Hydra*, snails, *Amphioxus*, chickens and mice are all used as illustrations. The entry into the discussion of (vertebrate) physiology (eight lectures) is through hormones; there are then chapters on muscle, blood and ionic balance, immunity and neurobiology.

Given the area covered, it is not surprising that the treatment is dogmatic, and that the amount of attention given to how actual experiments were done (and who did them) is generally scant. This is an excellent book for those seeking an exposition of how living systems function. It will be particularly valuable for the more junior university student, physical scientists in search of biology and teachers of biology wanting to keep abreast of cell biology.   **Paul Broda**

Elementary particle theories and phenomena

Particle Interactions at Very High Energies. Edited by David Speiser, Francis Halzen and Jaques Weyers. Part A: Pp. xii+398. $33.60. Part B: Pp. xiii+366. $30.00. (NATO Advanced Study Institutes Series.) (Plenum: London, 1974.)

THESE two volumes cover the main lectures given at the Summer Institute on Elementary Particle Physics held at Louvain in August 1973. Looking back over the years it is probably fair to say that almost every summer school volume that has appeared has contained at least one noteworthy set of lectures, and the present volumes are no exception. Although both books shelter under the umbrella of general elementary particle physics, they are really very different in content and subject matter, and it is, therefore, best to deal with them separately.

Part A is concerned with hadronic interactions at very high energies, and concentrates mainly upon the phenomenological results that have been flowing in such profusion from the CERN Intersecting Storage Rings (ISR) and,

more recently, from the Fermi National Accelerator Laboratory near Chicago. It touches, too, upon the theories and models that have been conjured up to try to interpret the vast amount of data. But if there is a single overwhelming impression left by the reading of this volume it is simply one of amazement and awe; amazement at the absolutely prodigious flow of data from the new machines and awe in the face of the fascinating and complex behaviour of nature at these energies.

There is considerable overlap between several of the lecturers. The most interesting article is Sens', which covers the shadowy area of physics lying between the domain of the high energy physicist and that of the machine engineer: namely the design and structure of the ISR, its beam characteristics, its performance level, its instabilities and their cures, and the connection between the raw measurements and the quantities of physical interest. It is particularly exciting to read of Sens' optimism about the possibility of storing antiprotons in the ISR, using 400-GeV protons from the new CERN Super Proton Synchrotron (SPS) as a source of 25-GeV antiprotons. One awaits with great expectation and some trepidation the results of proton antiproton collisions at ISR energies— many a theory will surely topple.

All three authors concentrate on proton-proton collisions at very high energies, with coverage of elastic reactions, total cross-sections and many body production, the latter in the guise of 'inclusive' reactions. Jacob's treatment of the data is detailed and very wide ranging. Horn applies himself more to "general trends", that is, to the approximate phenomenological rules that seem to summarise the data. Both Jacob and Horn discuss the theoretical background, but neither does so in a sufficiently comprehensive manner to allow the non-expert to follow. Horn does succeed, though, in giving one a taste of the remarkable success enjoyed by Regge theory, in its extension to many body reactions by Mueller, at least in explaining the gross features of the data.

Finally, there are the notes of Halzen (Model Independent Features of Diffraction) which provide a rather pedantic, and sometimes careless, list of theoretical results that can be derived from 'deep' principles, that is, from axiomatic field theory. Some discussion of their relevance, or lack of relevance, to present day experiments is given.

All in all this is an interesting, though not distinguished, collection of notes the value of which is not a little diminished by the outrageous presence of 18 blank pages.

Part B reminds one of how much easier it is to write elegantly on a purely theoretical topic than on a phenomenological one. All the lectures are

clear; arguments are logically developed; examples reinforce one's understanding, and one emerges feeling that one has been subjected to a valuable pedagogical experience.

Gilman (Deep Inelastic Scattering and Final State Hadrons) gives a good summary of the theory of electron-proton and neutrino-proton collisions at large momentum transfer, with a judicious blend of ideas about scaling, partons, the structure of the produced hadrons, and just enough of experiment to motivate the treatment. The article by Weyers (Constituent Quarks and Current Quarks) tackles one of the most tantalising problems in elementary particle theory, namely the relationship between those quarks out of which the hadrons seem to be built, and the quarks in terms of which the weak and electromagnetic currents are simply expressed. There is a useful summary of the pros and cons of the group U(6) as a classification group for the hadrons, and a good pedagogical introduction to the Melosh transformation. Carlitz (Chiral Symmetry and the Hadron Spectrum) repeats much of the material of Weyers, but less adequately. It is hard to justify the duplication. A united effort by the two authors would surely have been more successful

The great mystery about quarks is their non-appearance as identifiable, individual particles in the real world. Models have been blithely advocated in which the quarks are permanently bound inside the hadrons which they constitute. In his article (Permanently Bound Quarks) Mandula presents a fascinating speculative study of a 'field theory' in which the fundamental quanta cannot materialise as free particles. The picture, though a little contrived does expose the basic and somewhat frightening difficulties.

The other principal article in this volume, a major *tour de force* that was originally issued as a CERN Yellow Report, is the evocatively titled "Diagrammar" of 't Hooft and Veltman. Inspired by the difficulties of applying the canonical rules of field theory to gauge theories, they have tried to re-formulate all the essential rules in terms of a diagrammatic calculus (essentially a sophisticated form of Feynman's propagator approach) and to de-emphasise completely both the role of the field and the Lagrangian. Many of the derivations of standard results, for example, of the Cutkosky rules for discontinuities of Feynman diagrams, are far clearer and simpler than in the conventional treatments. The *n*-dimensional regularisation method invented by the authors, is also discussed in some detail. This is a long article and, generally, is very clear, but it leaves one with the feeling that just a little more effort would have ironed out the few irritating sections in which the reasoning is difficult to follow.

Growing crystals

Crystal Growth: Theory and Techniques, vol. 1. Edited by C. H. L. Goodman. Pp. ix + 300. (Plenum : New York and London, 1974.) $33.60.

A FEW years ago essentially only one textbook on crystal growth existed. Today we have a wide choice, particularly as the assembly of a few miscellaneous articles between hard covers frequently masquerades as a textbook. An addition to both categories might be expected to cause only a slight shudder; in fact I found the present volume to be interesting and rewarding.

The articles, ably selected and edited, cover two subjects that have received little previous attention, and two that are both topical and important. The rapid development in crystal growth in recent years has forced redundancy on some of the earlier books on the subject and the appearance of comprehensive reviews aimed at a suitably high level is not only desirable, but perhaps essential if a new generation of crystal growers is to evolve.

The first section, dealing with 'Mechanisms in Vapor Epitaxy of Semiconductors' is adequate but pedestrian. This is compensated for by the excellent content and range of the section entitled 'Principles of Vapour Growth', by E. Kaldis. His *tour-de-force* includes recent work on transport theory, practical techniques and growth data. Kaldis has assembled much useful and interesting information which makes the purchase of the book worthwhile for this section alone.

Travelling solvent techniques are dealt with by two workers who have pioneered these processes and who have achieved some remarkable successes. Although many of the materials dealt with can be grown by other methods, the preparation of large crystals of calcite has demonstrated the possibilities of the technique for a production process. Its wide applicability makes it useful as a research tool for both bulk and thin layer single crystals.

The final article deals with refractory metal crystals. Although specialised, useful information is given on techniques which are possibly not familar to many crystal growers; the section is worth reading by all.

The book has restored my faith in current publications. I await the appearance of further volumes in this series without trepidation.

Reproductive aspects

Physiology and Genetics of Reproduction. Parts A and B. (Basic Life Sciences, vol. 4.) Edited by Elsimar M. Coutinho and Fritz Fuchs. Part A: Pp. xxi + 417. Part B: Pp. ix + 454. (Plenum: New York and London, 1974.) $38.50 each.

THESE volumes report the proceedings of an International Symposium on "Physiological and Genetic Aspects of Reproduction", held during December 1973 in Salvador, Brazil, to integrate knowledge of genetics and reproductive biology.

The books contain more than 50 articles covering a wide range of topics. Part A begins with a review on changes in reproductive life-span, the relationship between parity and breast cancer, and the thought-provoking concept that women in 'primitive' societies would normally have been pregnant or lactating and that, therefore, menstruation may be a 'disease' of modern society. The remainder of this volume is subdivided into four sections. The first deals with chromosomal structure and function, sex chromosome activity in germ cells, and chromosomal errors related to gonadal dysgenesis. The second section is concerned with the molecular basis of hormone action, and the third section reviews the control and inhibition of spermatogenesis, the effects of γ rays, and sperm structure and biochemistry. Finally, there are considerations of the role of the central nervous system; releasing hormones; protein synthesis in the egg; follicular growth, ovulation induction, luteinisation and steroidogenesis; and control of the menstrual cycle.

The second volume also contains four sections, the first of which examines structural and biochemical changes in spermatozoa, eggs and oviducts; species specificity in egg-sperm interaction; and inhibition of fertilisation with specific antibodies. Section 2 considers control of contractility in male and female reproductive ducts (ejaculation, tubal transport, uterine movements, and so on), and Section 3 reviews implantation, decidualisation, embryonic development, and chromosomal abnormalities in human abortuses. The final section discusses the control of luteal function, foetal and maternal hormones in pregnancy, uterine activity, and parturition.

The broad scope of these books ensures that they will be of interest to a wide audience, especially as a high proportion of the chapters consist of reviews. The main criticisms apply generally to conference proceedings: some topics are omitted or inadequately covered (oogenesis; contraception) whereas others are repeated in various sections (such as uterine activity). Furthermore, some of the contributions are remarkably similar to others by the same authors published elsewhere. By far the most serious criticism is that the discussions which followed each paper at the symposium have been omitted from the proceedings: such comments are sometimes more useful and thought-provoking than the articles themselves. In spite of these criticisms, however, the books provide a clear insight into a wide variety of fields. **T. G. Baker**
Hunters engraved in rock. From *Rock-Art in Central Arabia.* Vol. 4: *Corpus of the Rock Engravings,* Parts III and IV. Pp. 262. (Institut Orientaliste de l'Université Catholique de Louvain: Louvain-la-Neuve, 1974.) n.p.

Dealing with poisoned patients

The Poisoned Patient : The Role of the Laboratory. (Ciba Foundation Symposium 26, New Series.) Pp. viii+325. (Associated Scientific: Amsterdam, Oxford and New York, 1974.) Dfl. 55; $21.20.

THIS volume comprises 17 papers devoted to various aspects of poisoning; each is accompanied by a very full and frequently thought-provoking discussion.

Almost one third of the papers deal with drug detection and assay techniques, such as gas chromatography linked with mass spectometry, radio immunoassay and associated methodological problems. The controversy over the place of the laboratory in the management of patients who have taken overdoses is covered by Newton and Prescott of Edinburgh who argue spiritedly against Goulding of London and the North American contingent. My impressions are that all of the participants advocate conservative management of the majority of patients and that differences in emphasis of active treatment and demands for drug profile results would disappear if all specialists saw a similar spectrum of patients.

The least well covered aspect in the symposium concerns the role of the laboratory in detecting and preventing drug induced disease. Leach's paper on this subject is mainly concerned with refinement in existing drug assay techniques. The tantalising problem of converting present methods which are mainly concerned with single 'once off' assays into systems capable of dealing with many samples is barely touched on, and no mention is made of the claims of improvement in patient management that have followed the introduction of procedures such as the immunoassay of digoxin. It is estimated that between 5 and 10% of hospital beds are filled by patients suffering from drug-induced diseases. Presumably, that figure indicates the tip of the iceberg with respect to the total quantity of drug-induced ill health.

Dole contributes a stimulating paper on the role of the laboratory in the treatment of narcotic poisoning. In the US it is a federal requirement that the urine of those patients receiving maintenance methadone be tested weekly. That, however, has been found to be positively detrimental to the rehabilitation of patients, as it fosters non-cooperative attitudes.

Repeatedly during the discussions it is claimed that doctors are not sufficiently trained in clinical pharma-cology, so that no matter how sophisticated and accurate are the assay techniques used, the data obtained will be wasted. This book should stimulate interest in clinicians, thus going some way towards overcoming this very real gap in medical education and helping towards the establishment of useful collaboration between clinical and laboratory workers. **Noel Wright**

Biological interface

Biological Interfaces : An Introduction to the Surface and Colloid Science of Biochemical and Biological Systems. By Malcolm N. Jones. Pp. ix+240. (Elsevier Scientific: Amsterdam, Oxford and New York, 1975.) Dfl.34; $13.25.

THERE is no question that some knowledge of surface and colloid chemistry can be a valuable aid to the understanding of a range of biological problems. To date, however, there have been no serious attempts to present in a systematic manner those aspects of surface chemistry which are particularly relevant to biology. Dr Jones has undertaken this quite difficult task and, though he has not produced a definitive work on the subject, he has certainly produced a very readable little volume which should be useful to everyone from undergraduates upwards.

There are eight chapters on topics including surface and interfacial tension, monolayers, micelles, protein–surfactant interactions, electrical double layers, cell surfaces and cell contacts and artificial membranes. In each instance the surface chemical principles are discussed with special regard for biological systems and numerous references are given to the original literature. Herein lies the first of my criticisms, that is, that the references are not, in some cases, as up-to-date as they might be. It may be that this is difficult to avoid in a book on a relatively fast-moving field but, even so, this point should be appreciated. My second concern is that in one or two instances I should like to have seen a more critical presentation of the material. For example, it is not reassuring to find the author putting in a good word for the Pauling–Miller anaesthesia hypothesis, or to see Clements' theory of alveolar stability presented as established fact, or to find that the evidence on the water permeability of bilayers has been inadequately summed up. On most topics, however, the discussion and assessment of the present situation are refreshingly good and, for those starting out in the field, this is a book well worth reading. **D. A. Haydon**

announcements

Appointment

F. R. Jevons has been appointed the first vice-chancellor of Deakin University at Geelong, Victoria, Australia.

Award

A. M. Weinberg has been awarded the first **Heinrich Hertz Prize** for contributions to the science and technology of nuclear energy.

Miscellaneous

Johann–Georg–Zimmermann Prize. Intended to encourage cancer research, the prize (50,000 DM) will be awarded to one or more scientists who have earned special recognition in this field. Part of the prize will be awarded in acknowledgement of outstanding work by young scientists (under 40). For this section of the prize, the subject for 1976 will be 'Surgical and radiological treatment of cancer'. Closing date: January 15, 1976. Information: Freunde der Medizinischen Hochschule Hannover e.V, 3000 Hannover 1, Am Hofen Ufer 6, FRG.

International meetings

September 8–12, **Rhythmic functions in biological systems**, Vienna, Austria (Dr G. Lassmann, c/o Wiener Medizinische Akademie, Alser Strasse 4, 1090 Vienna, Austria).

September 8–12, **Mathematical models for environmental problems**, Southampton, UK (Dr C. A. Brebbia, University of Southampton SO9 5NH, UK).

September 8–12, **Europe from crust to core**, Reading (Mrs D. M. Powell, Local Organising Secretary of MEGS, Department of Geology, The University, Whiteknights, Reading RG6 2AB, UK).

September 8–12, **Applications of ion beams to materials**, Warwick, UK (Professor G. Carter, Department of Electrical Engineering, University of Salford, Salford M5 4WT, Lancashire, UK).

September 8–13, **Carboniferous stratigraphy and geology**, Moscow (Secretary General, Dr Sci Sergei, Viktorovich Meyen, Geological Institute of the USSR Academy of Sciences Carboniferous Organising Committee, Pyzhevsky per 7, Moscow 109017, USSR).

September 9–10, **Proton transfer**, Stirling, UK (Mrs Y. A. Fish, Faraday Division, The Chemical Society, Burlington House, Piccadilly, London W1V 0LQ, UK).

September 9–10, **Morphology and biology of living and fossil reptiles**, London (The Linnean Society of London, Burlington House, Piccadilly, London W1V 0LQ, UK).

September 9–12, **Energy and physics**, Bucharest, Rumania (European Physical Society, PO Box 39, 1213 Petit-Lancy 2, Switzerland).

September 9–12, **Pulsed high beta plasmas**, Abingdon (Mr J. H. C. Maple, Conference Secretary, UKAEA, Culham Laboratory, Abingdon, Oxfordshire ON4 3DB, UK).

September 9–12, **Calcium in biological systems**, Egham, UK (Professor C. J. Duncan, Department of Zoology, The University, PO Box 147, Liverpool L69 3BX, UK).

September 9–13, **Neurosciences**, Munich (Professor D. Ploog, Max-Planck-Institut für Psychiatric, Kraepelin strasse 10, München 40, FRG).

September 10–12, **Reproductive physiology of invertebrates**, Kerala, India (Dr K. G. Adiyodi, Department of Zoology, Calicut University, Kerala 673635, India).

September 10–12, **Thin-layer chromatography and associated techniques**, London, UK (Laboratory News Europe, 78 Wigmore Street, London W1, UK).

September 10–17, **Virology**, Madrid (Dr. R. Najera, Centro Nacional de Virologia y Ecologia, Sanitarias, Majadahonda, Madrid, Spain).

September 11–12, **Computers in laboratory use**, London (The Meetings Officer, Institute of Physics, 47 Belgrave Square, London SW1X 8QX, UK).

September 11–18, **Neurology**, Amsterdam (Preliminary Congress Secretariat, University Clinic of Neurology, Paviljoen 2, Wilhelmina Gasthuis, Amsterdam, The Netherlands).

September 12–21, **Surface membrane receptors**, Bellagio, Italy (Dr R. A. Bradshaw, Director, Department of Biological Chemistry, Washington University School of Medicine, 660 South Euclid Avenue, St Louis, Missouri 63110).

September 13–17, **Transplutonium**, Baden-Baden, German Federal Republic (Professor W. Muller, European Institute of Transuranium Elements, Kernforschungzentrum Karlsruhe, Pöstfach 22600, 7500 Karlsruhe, German Federal Republic).

September 14–19, **Environmental monitoring**, Las Vegas, Nevada (E. A. Schuck, National Environmental Research Center, US Environmental Protection Agency, PO Box 15027, Las Vegas, Nevada 89114).

September 15–16, **Prostaglandin**, Halle/Saale, DDR (Professor W. Forster, Institut fur Pharmakologie und Toxikologie der Universitat, 402 Halle/Saale, Leninallee 4, DDR).

September 15–19, **Beam-foil spectro-scopy**, Gatlinburg (Professor W. W. Havens, Jr, American Physical Society, 335 East 45th Street, New York, New York 10017).

September 15–19, **Liquid scintillation counting**, Bath, UK (Mr M. A. Crook, The Society for Analytical Chemistry, 9–10 Savile Row, London W1X 1AF, UK).

September 15–20, **Cnidarian fossils**, Paris (Dr J. P. Chevalier, Institut de Paleontologie, 8 rue de Buffon, 75005 Paris, France).

September 16–17, **Fluidised combustion**, London (Dr P. Eisenklam, Department of Chemical Engineering, Imperial College, London SW7 2AZ, UK).

September 16–18, **Neurohypophysial hormones**, Liblice, Czechoslovakia (Dr M. Zaoral, Institute of Organic Chemistry and Biochemistry, Czechoslovak Academy of Sciences, Praha 6, Felmingovonam 2, Czechoslovakia).

September 16–19, **Optical fibre communications**, London (The Conference Department, The Institution of Electrical Engineers, Savoy Place, London WC2R 0BL, UK).

September 16–19, **Offshore Europe**, Aberdeen (Exhibition Administration Limited, 4 Pine Walk, Surbiton, Surrey, UK).

September 17–19, **Growth hormone and related peptides**, Siena, Italy (Mrs M. L. Pecile, Department of Pharmacology, School of Medicine, University of Milano (SM-UM), 32 Via Vanvitelli, 120129 Milano, Italy).

September 17–19, **Clinical biochemistry**, Bratislava (R. Muller, Congress Office, Slovak Medical Society, Mickiewiczova 18, 88322 Bratislava, Czechoslovakia).

September 17–20, **Kinetics and biopolymers**, Jena, DDR (Professor H. Berg, Zentralinstitut fur Mikrobiologie und Experimentelle Therapie der AdW, 69 Jena, Beuthenbergstrasse 11, DDR).

September 21–24, **Electromyography**, Rochester, Minnesota (W. C. Wiederholt, Secretary Treasurer, 7010 Via Valverde, La Jolla, California 92037).

September 21–25, **Immunology of reproduction**, Varna, Bulgaria (Third Symposium on Immunology of Reproduction, 73 Lenin Avenue, Sofia 13, Bulgaria).

Oh, New Delhi; oh, Geneva

HAS the presence of the World Health Organisation (WHO) in India at the Research Unit on Genetic Control of Mosquitoes, New Delhi been a serious attempt to raise the health standards of the Indian people—or has WHO been, perhaps unwittingly, a vehicle for the United States to extend its knowledge of biological warfare procedures? That question has led to some appalling misunderstandings on the international science scene, the publication of a report by the Indian government strongly condemnatory of the operation and now the entire withdrawal of the WHO from the unit. There are some harsh lessons for all concerned in the extraordinary, and little publicised, events of the last year.

The programme

Three species of mosquitoes were earmarked for attention when the unit was established in 1970; *Culex fatigans*, *Aedes aegypti* and *Anopheles stephensi*. *C. fatigans* was the first to be studied in detail; it is the most ubiquitous nuisance mosquito and the vector of filariasis in many parts of India. *A. aegypti* is less widely distributed; it is virtually absent in villages and not common in most towns. It is the only proved natural vector of urban yellow fever; it is also a vector of dengue and chikungunya. *A. stephensi* is the principal vector of malaria.

It is widely accepted that since a mosquito control programme must take note of a much wider ecosystem than simply that of the mosquito in question, it is bound to contain elements of many different control techniques. Genetic control, the most recently promising technique, started to be widely discussed in India in the early 1960s.

Genetic control may be by one of several methods, amongst which are:
● sterile male techniques; males are sterilised by radiation or chemical treatment;
● chromosomal translocations: the normal chromosome arrangement can be broken by radiation or chemical treatment—the abnormal rearrangement or translocation does not normally cause sterility, but the offspring carry the translocations and are more likely to be sterile.
● cytoplasmic incompatibility: some strains of a given species show mutual incompatibility, and the eggs of such matings are infertile; the introduction of an alien strain thus promotes suppression of a population.

First moves to establish a joint WHO/Indian Council of Medical Research (ICMR) unit to study genetic control were made in 1969. An agreement between the WHO and the Government of India was signed in June 1969 and authorised research on the three species mentioned above.

Progress would be reviewed by the representatives of ICMR, WHO, the US Public Health Service (USPHS) and the (Indian) National Institute of Communicable Diseases (NICD). PL-480 funds from the US government would be made available, and in addition WHO would support a Project Leader, 2 other professional staff and underwrite various other expenses. The agreement was to run for six years in the first instance. Staff levels early in 1975 were: 2 foreign scientists (WHO staff), 13 Indian scientists, and 139 other Indian staff.

In the first four years, work was concentrated on *C. fatigans* partly because there had already been some success in genetic control of this species by chemosterilisation in the United States and by cytoplasmic incompatibility in Burma. Twelve villages in the vicinity of Delhi were singled out for attention, and it was hoped that they could be treated as islands with trivial migration over the kilometre or two that typically separates villages. A variety of sterilisation techniques were employed and mosquitoes were released either as pupae or adults.

Unfortunately it was soon discovered that breeding grounds for *C. fatigans* were not confined to drains and pits in the villages but were fairly uniformly distributed over the countryside in irrigation wells. Further, *C. fatigans* proved to be a good traveller; sometimes as much as 85% of the adult population of a village were immigrants from up to ten kilometres away.

Thus the field experiments, although they showed maximum sterilities on egg rafts of well over 50 per cent were somewhat disappointing.

First criticism

All was not well, however, in the public understanding of these experiments. On the one hand, it was neces-

sary to work hard at the local level to convince villagers that the release of vast numbers of mosquitoes and the associated operations might ultimately be beneficial. On the other there was evidence of some hostility to the programme at a scientific level when the *National Herald* for February 11, 1972 published an article 'Science or Neo-imperialism' by 'A Scientific Worker'. The writer declared that international cooperation in science could often degenerate into a donor-recipient relationship with little opportunity for the recipient to evaluate and influence the work, especially if the recipient nation's scientific elite "is so brain-washed that they are at ease only in the donor nation's social outlook and science programmes". This was to be exemplified by the mosquito programme, run for the benefit only of the US Department of Agriculture (USDA) which could use India as a test-bed for chemosterilisation experiments too dangerous to be permitted in the United States. For, the argument ran, the unit should have tried the three sterilisation methods of irradiation, incompatibility and chemicals and chosen the most appropriate, but it had not purchased a cobalt-60 source necessary for irradiation, nor had it pursued much research on incompatibility. The emphasis on chemosterilisation was inevitable, continued the article, since the first two project leaders were from the USDA with long experience of and a continuing enthusiasm for chemical methods.

This was slightly odd, as two of the five field experiments already performed had used irradiation techniques and a large experiment just about to be performed was to use the incompatibility technique.

The newspaper report went on to describe the chemical used (thiotepa) as a modification of mustard gas, producing 'mutations, cancer and foetal deformities in experimental animals." In one experiment "50,000 mosquito pupae, dipped in the dangerous chemical for 3 h and washed with water, were placed in all the wells of a small village. No one bothered how much residue of the dangerous chemical absorbed or sticking to the insects could directly pollute the drinking water." This is at variance with the unit's own version of these experi-

ments. They claim that drinking water wells were never used, only between six and ten disused irrigation wells; cans of the sterilised pupae were floated in the experiment in question, and in later experiments suspended above the water level. They further claim that chromatographic analysis showed an extremely rapid breakdown of thiotepa residues in the body of the mosquito (half-life, 6 hours).

The unit's recently issued version of these experiments should not go entirely unchallenged. Dr R. Pal who was with the unit during the experiments and is now at WHO headquarters wrote in a review book 'The Use of Genetics in Insect Control' of the same experiment described in the *National Herald*, 'Initially mortality of the released pupae was heavy due to release into the village well water' (so containers of laboratory water were used). Nonetheless, the implication behind the article was that this was the way things were always being done whereas it is clear that the unit's techniques evolved quite rapidly; indeed by the beginning of 1972 pupae were to be used no more.

Even though the article could be faulted as erroneous scaremongering with a touch of anti-Americanism added in, it carried one clear message—that someone close to, perhaps even within the unit was seriously dissatisfied. No doubt it put the unit on its toes to ensure that its future operations could not be faulted; this was to have unfortunate consequences.

More recent work

Work on *Aedes aegypti* at the unit started much later and never reached anything like the intensity of work on *C fatigans*. After two preliminary studies in Delhi in which laboratory strains were successfully incorporated into the normal population, a more extensive study was done in Sonepat City in 1973 along the same lines. There had been considerable optimism that *A. aegypti* would yield definitive results more quickly on the feasibility of genetic control methods since the densities of the mosquito are generally lower than those of *C. fatigans*, and *A. aegypti* has more limited ability to migrate. Genetic control experiments were planned for February 1975 but, as we shall see, were not caried out.

Work on *Anopheles stephensi* was even less advanced; it was only in 1973 that a scientist was hired specifically to work on *A. stephensi*, but the intentions since then have been to increase emphasis on the species in the unit. First field trials were planned for 1975.

New criticism

Work at the unit was struck a major blow by the appearance of a newspaper article on July 29, 1974 entitled 'WHO works for US secret research in India' and written by Dr K. S. Jayaraman, Science Correspondent of the Press Trust of India. The report was fiercely critical of three operations; the other two were the Bombay Natural History Society's bird migration study and a malaria eradication programme in Jodhpur. Dr Jayaraman wrote of tight secrecy in the mosquito project. Some experts, he claimed, believed data could be useful in germ warfare, or that India was being used as a guinea pig "for chemicals or methods not permitted in sponsoring countries." The experiments "appear to have no relevance to malaria and filariasis." Instead the unit was collecting data on *A. aegypti*, a vector of yellow fever—of which "there had not been a single case in India for ages." *Aedes aegypti* could be very useful in transmitting viruses "because its eggs (unlike those of other mosquitoes) can be dried, put on a piece of paper in an envelope and mailed to any part of the country where they can hatch." Yellow fever was believed to be absent in India because of natural cross protection from another virus. "Experts ask if genetic mosquito experiments would affect or remove this natural cross protection. If it does, yellow fever would strike India."

The story had evolved in an interesting way. When Dr Jayaraman first started to enquire about the unit in April 1973 he met with some reluctance from its then project leader to speak in other than generalities, owing to the unfavourable publicity received in 1972. A new project leader, Dr G. Brooks, said in December 1973 that he would get clearance from WHO in Geneva for a more detailed briefing, but clearance never came. Meanwhile the West German embassy in Delhi published, in February 1974, a magazine *German News* in which were printed the views of Professor H. Laven, an insect geneticist from Mainz and regular consultant to the unit. Laven who had worked for many years on incompatibility techniques, was critical of the chemosterilisation experiments which, he declared, had left the mosquito population unaffected. Jayaraman confronted Brooks with Laven's statement and as a result the Press Trust of India carried both Laven's article and Brooks' short rejoinder. But Brooks was still unable to get WHO clearance for more detailed information to be given to Jayaraman.

Jayaraman then contacted Dr R. Pal the Indian malariologist who was responsible for the unit's programme at WHO's headquarters. Pal told Jayaraman that he could give no more details of the operation as it was 'sensitive to the Indian press', presumably as a result of the earlier *National Herald* article. At about this time, Jayaraman alleges, he was indirectly sounded out for a job as an information officer at WHO headquarters.

Response

There were two major consequences of the publication of Jayaraman's article—scientists rapidly reviewed the programme, and a rather slower political investigation was set up. The scientific and administrative review was conducted under the auspices of ICMR. There was obvious concern that the WHO/ICMR agreement needed some tidying up to strengthen Indian involvement in the management of the unit. In particular the consultative role of the Indian counterpart originally provided for in the agreement to assist the project leader needed to be taken more seriously. The scientific review committee, consisting of twenty-one members, could find little wrong with the unit's operations, however, and congratulated the unit on its achievements. Its only recommendation of substance was that an independent monitoring body should be established to oversee future releases of genetically manipulated mosquitoes.

The perspicacious reader of this complicated saga will recognise at this stage all the ingredients to ensure that the political investigation would be explosive:
● a complex scientific investigation with, like all such, its failures and blind alleys as well as its successes
● genuine and sincere disagreement amongst scientists about the correct procedures
● a journalist kept at arms length
● an agency in Geneva suspicious of the Indian press
● US involvement both through money and personnel
● a scientific review that seemed to close ranks.

The consequence was almost inevitable.

It was helped by the way that the Public Accounts Committee went about its business; it indulged in what the Americans would call a fishing expedition. Everything that could possibly be found against the project or those involved in it was brought out —from a contravention of the Registration of Books Act, in not printing the publisher's name on leaflets distributed to villagers, to doubts on Dr Brooks' abilities as project leader (he had only obtained his PhD in 197 (though by then he had worked as a public health entomologist for 1 years).

In January 1975 the committee heard representatives of ICMR and NICI and of the Ministries of Health and Family Planning, Defence and Agriculture, of whom technical and administrative questions were asked. The com

mittee then examined Dr T. Rama-chandra Rao, a distinguished entomo-logist who had worked closely with the unit since his retirement as director of the Virus Research Centre, Poona. Finally, the committee in March 1975 took evidence from Dr Jayaraman and his Editor-in-Chief Mr C. Raghavan. The report was published in late April.

Were they fair?

It is perhaps not insignificant that nowhere in the report is the unit given its correct title by the committee or the journalists—it is always referred to as the Genetic Control of Mosqui-toes Unit, the word 'Research' some-how being lost; perhaps also lost at the same time was some understanding of the complex, frustrating, and often illogical nature of research. It is per-haps also not insignificant that Mr J. Bosu, chairman of the committee had already sufficiently made up his own mind, even before hearing the journa-lists (who were the only witnesses to level accusations of biological warfare), to write to Mrs Gandhi in late January accusing the US of using the pro-gramme, first, to carry out harmful experiments in India which would not be permitted in the US, second, to make preparations in case the US ever wished to wage chemical, bacterio-logical and virus warfare against India, and third, to prepare for such warfare using India as a base.

It also seems unfortunate that the committee should have delayed hearing the journalists who were presenting, as it were, the case for the prosecution until after they had heard all other witnesses. Dr Jayaraman and Mr Rag-havan presented an imposing and detailed case but no-one was then asked to review this case scientifically.

One is forced to the inevitable con-clusion in reading the committee's report and particularly its recommen-dations that its mind was clearly made up that the unit was involved in nefari-ous activities, and that the testimony of the journalists was only needed to provide confirmation. But the journa-lists' evidence needed the most detailed point-by-point investigation. For ex-ample although the journalists took a swipe at almost everything in sight, their central argument could probably be summarised as that the unit was devoting an unreasonable amount of its effort to *A. aegypti* which could be used as a vector of yellow fever. For instance, Mr Raghavan said 'An analy-sis of GCMU's (*sic*) activities in the last five years suggests that GCMU is primarily interested in the collection of data on the ecology and dispersal of Indian mosquitoes, particularly *Aedes aegypti* which is a vector of yellow fever.' The remark necessarily went unchallenged and in its conclu-sions the committee spoke of the unit's

'preoccupation' with *A. aegypti*. But if the committee had even bothered to do a simple thing like count up the num-ber of papers published by the unit in its past five years, it would have seen the *C. fatigans* papers outnumbered *A. aegypti* papers by a ratio of four to one.

Likewise assertions that India's im-munity to yellow fever might be weak-ened by experiments eliminating *A. aegypti* were not confronted with elementary arguments such as that *A. aegypti* already does not exist at all in many Indian cities and nearly all villages—indeed it was eliminated from Poona in 1953 without any incidence of yellow fever.

Biological warfare

Since the committee preferred the journalists' views to those of Dr Rao and the Ministries on all matters of dispute it was easy for it to follow them in the step from believing that the unit was preoccupied with *A. aegypti* to believing that preoccupation with *A. aegypti* meant preparation for biological warfare. It is not clear that the committee believed that any of the foreign scientists working at the unit were witting tools of the US Depart-ment of Defense, but it was certainly convinced that evil purposes lay behind it all. After all, the committee was told that the US Public Health Service (which releases PL-480 funds to WHO) had been known to receive money from the US Biological Warfare Research Centre at Fort Detrick (for a study of a fungal disease in 1967) and there were other links including 'efforts to avoid duplication'.

The committee were also told that the Stockholm International Peace Re-search Institute (SIPRI) had reported that biological warfare could be con-ducted through infected mosquitoes. (It was not told that it is only the females that pick up and transmit viruses, whereas the unit's field work has been exclusively concerned with males.) The committee concluded 'it is likely that the ultimate and only beneficiary of the GCMU (*sic*) experiments is the US military machine . . . The benefits, if any, that are likely to occur to India are not immediate but only potential.' The last sentence needs no comment. WHO has now pulled out.

We would be the first to admit that the thought of the US government using an intermediate organisation to learn how to infect Indians with yellow fever is utterly revolting. We would also admit that in military matters, particularly those of espionage, the standards of proof of involvement have, of necessity, to be lower than a judge, or a scientific referee, would deem adequate. But in this case the chain of logic is tenuous in the ex-treme: Fort Detrick has been known to collaborate with the US Public

Health Service; the USPHS represents the United States in dealing with WHO; WHO does some research in India on *A. aegypti* males; *A. aegypti* females could transmit yellow fever; yellow fever could be a biological weapon against India; therefore Fort Detrick is using the WHO to study the possibility of biological warfare in India. Perhaps the committee have more compelling evidence than they have printed. If so they should publish it at once.

That an enquiry could be conducted in this way should be a matter of con-cern to Indian scientists. For not only did the committee seem prepared to look for the worst in everything, but also if a spirit is abroad which looks with suspicion on anything with the remotest possible military connection, then India will find few opportunities to collaborate with the rest of the scientific world. Almost everything has its military aspect, and for good measure the committee suggested in-tense scrutiny headed by the Scientific Adviser to the Ministry of Defence on collaboration in

● oceanography
● meteorology
● remote sensing
● microbiology, epidemiology, ecology and virology
● toxicology
● propagation of radio waves
● science in border areas, such as Himalayan geology.

But WHO equally responsible

If one cannot but deplore the way in which WHO has had to pull out of such an important project and leave it to ICMR as best it can afford to carry on, the blame is really WHO's as much as anyone's. If it had not been for the totally leaden-footed way that the organisation has behaved, the unit would still be alive and well. It has shown itself completely incapable of handling public relations in a way to prevent a relatively small matter in-flating to gigantic dimensions. In 1973 it should have pursued a policy of being open with the Indian press—open about failures as well as successes; once-bitten-twice-shy is not a philosophy to adopt towards the press. And yet even in late 1974, when *Nature* carried a report of the fuss that had been created by Dr Jayaraman's article, we received no spirited defence of the unit from Geneva. Only now is it likely that WHO will defend the unit publicly. Did WHO believe that it shouldn't get involved in squabbles in the press? Obviously WHO has politi-cal problems in dealing on a country-by-country basis with controversy. But if it cannot be more nimble in dealing with criticism, the organisation's influ-ence is bound to diminish. ☐

international news

THIS has been a long, hot summer for the National Science Foundation (NSF), the agency chiefly responsible for supporting basic research in the United States.

For several months, NSF has been the target of mounting criticism from some members of congress, who have accused it of, among other things, wasting taxpayers' money on trivial research projects and of corrupting children's minds by supporting the development and marketing of controversial school science curricula. Such attacks are nothing new—in fact, they have been breaking out sporadically since the mid–1960s. But this time, instead of petering out, the criticism has lately turned into a broad assault on the entire process by which NSF determines which research grants to support, and which to turn down. Some issues of vital importance to university scientists are involved.

The matter finally came to a head during the past two weeks when NSF officials were called before a sub committee of the House of Representatives to listen to, and answer, a string of complaints about the manner in which NSF operates the so-called peer review system. Peer reviews, the process in which grant proposals are assessed for scientific merit by scientists outside the NSF, is used in some shape or form by virtually every government agency which supports academic research. It has never lacked critics, but the system has always been stoutly defended as the best, and probably the fairest method available for judging the relative merits of competing grant proposals.

NSF itself handles some 21,000 grant proposals each year, less than half of which are funded. Nearly three quarters of the proposals are sent out by mail to several scientists to review, and about a third of those are also reviewed by a panel of scientists at a meeting. The rest are reviewed by a panel only, frequently with the grant applicant along to explain and discuss his proposal. In 1974, each proposal on which NSF took action received an average of 6.4 reviews by scientists outside the agency.

Peer review will undoubtedly survive this latest assault, but it is already clear that some important changes will be made by NSF in the next few months. The nub of the matter is how secret the system should be. NSF's critics have been arguing for complete

NSF grants system under attack

by Colin Norman, Washington

Conlan : chipping away

openness by insisting that peer review reports and the reviewers' names should be made public, while NSF officials maintain that the system will break down unless some degree of anonymity can be guaranteed to the reviewers. The arguments have a familiar ring to the editors of learned journals.

At present, it is NSF policy that grant applicants can be given only paraphrases of the reports of scientists who review their proposals, but, at a meeting last month, the National Sciences' Board, NSF's governing council, decided that beginning next year, verbatim copies of the entire peer review reports will be made available to grant applicants on request. The board suggested, however, at least for the time being, that the names of the reviewers should be kept secret, and that the reports should not be given to a third party.

The new policy should at least

ensure that unsuccessful grant applicants will be informed of the chief reasons why their grant proposals were turned down, but the move certainly hasn't stifled the criticism. That was plainly evident when NSF officials and their critics met at the witness table during the congressional hearings last week.

The hearings began with a long, vituperative attack on NSF by John B. Conlan, a Conservative Republican from Arizona who has been chipping away at NSF for months because of its sponsorship of a few controversial school science courses. Calling the peer review process "an incestuous buddy system that frequently stifles new ideas and scientific breakthroughs, while carving up the multi-million dollar federal research and education pie in a monopoly game of grantsmanship," Conlan argued that the secrecy of the system makes it prone to abuse. It is a "completely arbitrary system that is closed and unaccountable to the scientific community and to the Congress," he said.

His line of attack was that NSF officials have too much power in deciding which projects should be funded, and that unless peer review reports are made available outside NSF, their decisions cannot properly be checked. "It is common knowledge in the scientific community that NSF programme managers can get whatever decision they want out of the peer review system to justify their decision to reject or fund a particular proposal," he said.

Citing some of his now unsuccessful attempts to obtain peer review documents relating to a science education course which he called "a new height in science porno literature," Conlan argued that the peer review process is "a sick system crying out for reform." His suggested reform is simple enough: "reviews and reviewers' names must be available to principal investigators and to the Congress. And a credible system must be devised for selecting peer reviewers that will completely divorce programme managers from the suspicion — sometimes warranted — that their own biases, prejudices, and special relationships dominate grant award decisions."

The demand for total openness in the system didn't go down all that well with members of the sub-committee, and it was strongly resisted by NSF witnesses. Apart from the traditional

argument that if reviewers cannot be guaranteed anonymity, they will either be reluctant to participate in the review process, or they will mute their criticisms, James Symington, the sub-committee chairman, suggested that such an open system would be potentially subject to political manipulation. "I believe that you would have a near 100 per cent adversary process generated by what you are suggesting," he told Conlan, and he pointed out that if the reviewers' names are made public, they could be subject to pressures, perhaps even from congressmen representing grant applicants in their districts.

The next critic of NSF to take the witness stand was Robert E. Bauman, a Conservative Republican congressman from Maryland, who earlier this year succeeded in persuading the House to pass an amendment to an NSF Budget Bill, which would enable Congress to review all NSF grants before they are awarded, and veto those it doesn't like. Though the fate of that amendment was uncertain at the end of last week—it was passed by the House but not by the Senate, and no compromise has been reached on the matter—the fact that it was approved by the House is a fair measure of the hostility toward NSF which has been building up in that august body.

Bauman last week argued that NSF's granting system is open to several criticisms. First, NSF has been supporting some trivial research projects which are a waste of taxpayers' money. Second, its work often overlaps with that of other agencies, and there could well be wasted money on duplicated studies. And, perhaps most important, it tends to stifle creative, but unorthodox views. Bauman claimed that he has received several letters which suggest that "the availability of NSF grants gives the stand-pat scientific establishment much more money and power to suppress unorthodox ideas than has ever been the case before." He suggested that more Congressional review of the agency is in order, and that "the peer review system must be opened up to the light of day."

Symington asked Bauman if he would provide the committee with copies of the letters containing criticisms of NSF. Bauman said he would be happy to do so, but he had some reservations about putting his correspondents' names in the public record. The irony was not lost on the committee.

NSF director H Guyford Stever and deputy director Richard C. Atkinson then took up NSF's side of the case They came armed with reams of computer information about how NSF's peer review system operates (see box), and argued that the process "is working with a considerable degree

One of the central complaints about NSF's Peer Review system, which has been raised in the past few months, is that the system is simply an "old boy" network which is strongly biased in favour of the large, elite universities. The suspicion, raised chiefly by Senator William Proxmire, is that the prestigious institutions not only get more than their fair share of grants, but they also provide more than their fair share of grant reviewers.

In anticipation that such complaints would inevitably surface during the hearings on Peer Review which have been taking place before a House sub-committee during the past two weeks, NSF deputy director Richard Atkinson arrived at the hearings armed with a computer analysis of NSF's granting decisions in 1974. The figures both support and refute the critics' assertions, depending on how they are interpreted.

They show, for example, that grant applicants from institutions ranked in the top 20 by the American Council on Education stand a better chance of success than their colleagues in less star-studded universities. But that is not too surprising since the institutions are considered prestigious because they supposedly have a more innovative and distinguished faculty. Atkinson noted, moreover, that "the NSF data clearly indicate that proposals submitted by scientists from the top 20 departments have the same distribution of reviewers as proposals from other schools. The assignment of reviewers in terms of the eminence of the university with which they are affiliated is not statistically correlated

with the eminence of the school from which the proposal originates." Similarly, there is no correlation between the geographic locations of reviewers and the scientist submitting the proposal.

NSF also took a look at the distribution of its funds between the states, to see whether the spread of funds is correlated with such measures as population, numbers of scientists, average income and so on. It found that three States—California, Massachusetts and New York—get more than their fair share of NSF funds, according to those criteria. Since those States contain such elite institutions as the University of California, Stanford, Harvard, MIT and Columbia, it can be argued that there is obvious bias in the system.

But, if the distribution of funds and reviewers is assessed against traditional measures of scientific excellence, such as the number of members of the National Academy of Sciences, or the numbers of former NSF graduate award holders in each State, then California and Massachusetts can argue that they are being discriminated against.

"Obviously NSF's distribution of funds turns out to be something of a compromise between a state's population and its collection of scientific talent," Atkinson noted last week. He added however that NSF has no precise formula for making this compromise—rather the various forces operating on NSF have defined this policy.

The policy will, of course, be viewed differently by different people.

of effectiveness." Stever conceded, however, that "it is true that it is possible to find specific cases where there are problems."

Stever noted that one reason why the peer review process is now coming in for considerable criticism is that "the absolute level of basic research activity supported by the federal government is inexorably declining" as the research budget is eroded by inflation. The upshot is that good grants are being turned down. "Let me ask you rhetorically," Stever said, "what is the reaction of a highly competent scientist, who intuitively knows that the proposal he submitted would produce well done, imaginative research, the results of which almost certainly would be a useful contribution to an advance in his discipline, when he subsequently is declined? True, he knows that the competition is rougher than it used to be, but he still cannot help but harbour the suspicion that somthing went wrong in the decision-making process."

NSF's new policy of making peer review reports available to grant applicants should help to remove some of that suspicion, particularly if unsuccessful applicants are given a chance to rebut criticism which they feel is either biased or invalid. But NSF will clearly find that it will be difficult to explain why grant applications with generally favourable reviews have been turned down. Atkinson noted that "NSF will have to document its decisions more carefully in order to explain to the scientific community why high quality proposals are not funded. This will be costly and will bureaucratise the decision process," he suggested, "but it may be unavoidable given the attitudes of suspicion and distrust that exists in the country today."

Be that as it may, there's clearly going to be a continuing debate about whether or not NSF should take the next step in opening up its proceedings, by making the names of peer reviewers public as well.   □

ENVIRONMENT minister Anthony Crosland cancelled the Channel Tunnel project last winter, yet an advisory group headed by Sir Alec Cairncross (Master of St. Peter's, Oxford) and originally briefed in April 1974 reported on the economic prospects of the Chunnel only last week ("The Channel Tunnel and alternative cross Channel services"). The expense of completing the assessment and publishing the report so many months after the horse had bolted would be justified if there were anything conclusive about its findings—its remit was amended to provide guidelines for assessing cost benefit if the project was revived, but Mr Crosland in the Commons on publication day turned that down emphatically.

The report, however, cannot say "indisputably" that a Chunnel would be "better than the expansion of existing services" to meet the certain growth of traffic, especially passengers and cars. This is partly through the lack of reliable data on the Tunnel-London rail-link, and British Rail is further criticised for lack of imagination both in planning with Continental partners a high-speed alternative to the air-linking of London and Paris and over devising connections with the inter-city services within Britain. In addition, it has failed fully to exploit its cross-Channel ferry services—both conventional and hovercraft, the two profit-makers on BR's otherwise red balance sheet.

Previous studies have been unbalanced through ignoring the hovercraft factor. Hovercraft now handle 30% of the passenger traffic on the short sea routes and their potential both there and on the Channel more widely is nowhere near fully developed. The British hovercraft industry should make capital out of the report since it is currently pressing for some firm orders from British Rail (Seaspeed) for a second generation of cross-Channel hovercraft to meet the needs of the 1980s onwards. Moreover if this move is turned down there may be a permanent loss of lead in hovercraft technology (and ultimately manufacture) abroad. In other words, British Rail may be operating a Channel hover-ferry service with either French or American craft in five years' time. Chauvinism has no part in the argument but good sense and timely investment have, and at the present time Britain's hovercraft industry and expertise is recognised as a European even a Western asset and brings in good export money from Iran and other OPEC areas. Big hovercraft for open sea performance is where the technological growth and profits reside, so a good deal more than an alternative to a nineteenth century engineering

fantasy hangs on the £5 million decision sought this summer.

● The Rothschild customer-contractor principle consecrated in the Government's 1972 Policy paper "A Framework for Government R & D" removed substantial sums from the direct control of the research councils to 'contractor' departments as commissioned research. Inevitably the research councils most affected—ARC, MRC and NERC are being obliged to hawk

Round Britain

their wares now to attract commissions for the work they want to do or even to complete research programmes half done. A bold example was the recent attempt by the director of the MRC Blood Pressure Unit (Glasgow) to pressurise the Department of Health through press promotion to set up a massive screening programme for people at risk from heart attacks in middle life. A two-hour MRC press briefing the day before the MRC specialist panel met to extend the current MRC funded pilot screening project for a final year described the programme and its achievements in great detail, and discussed the possibilities of a nation-wide screening programme costed at £6 million over 5–6 years. It turned out that it was not in MRC's power to take up this programme but the Department of Health could, when the pilot project was complete. If and when they do, they are likely to lean heavily on the Glasgow Blood Pressure Units' unique expertise.
● The year ending in March 1975 was one of adaptation to altered circumstances rather than of any great progress for the Medical Research Council. That is the main message of the MRC Annual Report which has just been published by HMSO. Adaptations have consisted of the post-Rothschild administrative variety, internal changes necessitated by the Council's recent reorganisation and, perhaps most importantly, changes imposed by the financial difficulties of the universities.

Total expenditure by the MRC last year, including £5.5 million coming by way of the Health Departments and the Department of Employment, amounted to £36 million This represented a reduction of 1.7% in real terms compared with the previous year. An oddity of the financial outgoings of the MRC was that less was spent

on grants last year than expected. That was due partly to unusually late applications and partly to a growth in unfilled positions for research assistants in universities. The dual-support system of funding university research has been under great pressure with the universities increasingly unable to provide their share, namely the salary of the principal investigators, laboratory space and ordinary departmental overheads. Sir John Gray, secretary of the MRC, stated his recognition that the situation was bound to deteriorate further but added that he felt the MRC had sufficient flexibility to cope, partly by implementing a modest capital development programme for university research.

The MRC Research Groups are one casualty of the present stringencies. In the past they were set up when a university wished to pursue a particular line of research and agreed to assume financial responsibility for the Group after a limited initial period of MRC support. Universities can no longer afford to give undertakings like that and no new Research Groups were established last year.

The past year has also seen a new career structure for the scientific staff of the MRC With less numerous and flexible careers available in universities, the MRC has been persuaded to offer far greater opportunities of tenure within its own establishments, whilst regretting the consequent reduction in the mobility of its scientists. The Cell Biology and Disorders Board of the MRC has set up two sub-committees to review specific fields of research. One, under Professor W. F. Bodmer, will be looking at the field of clinical genetics including the possibilities for screening programmes. The other, under Professor D. C. Phillips, will review molecular biology with particular emphasis on the role of the Laboratory of Molecular Biology in Cambridge. And the Council is continuing to evaluate last year's Neuberger report on Food and Nutrition Research.

● THE Committee of Vice-Chancellors and Principals introduced the first report of a study group on postgraduate education—more in the nature of a Green Paper than a White one, floating ideas for discussion in the universities in place of a hardcore of recommendations intended as policy. Nothing highly controversial in the group's findings, except perhaps a suggestion that overseas students should be asked to pay more for education at British universities than native scholars. When the government first introduced differential fees in 1966, most universities were reluctant to make the charges, and some flatly refused, but there have been changes in the status

INDIA has forced her way out of the exclusive smallpox club. From June 30, there was not a single indigenous case of smallpox in the country, according to figures received from the field from all sources including the World Health Organisation (WHO). This has been hailed as a remarkable feat. Only last year, nearly 200,000 cases with more than 30,000 deaths were reported from all over the country. Six states—Bihar, Uttar Pradesh, West Bengal, Assam, Orissa and Madhya Pradesh—accounted for nearly 99% of the cases, with Bihar leading them all with a staggering 68% of the total.

Starting in October 1973, concerted and intensive efforts were undertaken jointly by the government of India, the state governments, and the WHO to tackle the disease. Health workers literally visited each and every village in the endemic areas to inquire about smallpox cases, and as a result of hard and dedicated work, in less than two years, the disease has been wiped out.

Congratulating the workers and agencies whose efforts made this achievement possible the Union Health Minister, Dr Karan Singh, also announced that the vaccination programme would be continued for another two years to ensure against recurrence of the disease. Unfortunately, smallpox has not yet been controlled completely in neighbouring Bangladesh and there is always the danger of its importation from across the border. The government, Dr Karan Singh emphasised, was well aware of this and had already stepped up vigilance arrangements on the border with Bangladesh, so that no smallpox cases entered the country undetected. India is self-sufficient in the production of the preventative smallpox vaccine and has already donated 275,000 ampoules to Bangladesh; more will be made available to that country, if necessary.

Meanwhile, the Health Minister also announced that the award for reporting of any fresh incidence of smallpox from July 1, 1975 would be Rs.1,000—ten times what it used to be.

● India's first satellite, Aryabhata, has been orbiting the Earth for over three months now. The data being received indicate that all systems and instru-

Indian diary

from Narendar K. Sehgal

ments of the satellite are healthy and functioning normally. The three scientific experiments on board had to be switched off, however, after the first five days, following detection of a fault in one of the four lines delivering power to the experimental packages.

Scientists at the Indian Scientific Satellite Project at Peenya (near Bangalore) say they have good data from two of the three experiments— the one looking for X rays in space and the other aimed at detecting high-energy neutrons and gamma rays at times of intense solar activity— received during the first five days, but none from the aeronomy experiment which was to look for electrons in the ionosphere and ultraviolet radiation in the night sky.

As soon as the fault was detected, all scientific experiments were turned off for fear that the trouble might spread to the remaining three power lines as well. Using simulation techniques, the scientists have been working overtime to determine and pinpoint exactly what went wrong. So far, they have not succeeded. Redundant instrument capacity was not built into the experimental packages for several reasons. The principal one was that the experiments were only a secondary objective of the Aryabhata mission. The primary aim was to establish satellite fabrication capability and to see if the various systems and components aboard functioned and performed as planned.

Indian space scientists have not given up all hope yet; they are planning to turn on the experiments again, hoping that the fault—possibly due to some stuck relay which prevents power flow in one of the lines—may have corrected itself. They do admit, however, that chances of this happening are rather slim. In the meantime, studies will continue unabated to determine the exact cause of the failure.

As if to counter this hitch, there has been an unexpectedly happy development too. The operational life of Aryabhata was originally estimated to be about six months. That was how long the inert gas supply on board (used in the satellite's stablisation mechanism) was expected to last. But fresh calculations, based on actual data being received, show that the gas supply would last much longer, possibly more than 18 months. This will give scientists extra time in which to determine and, if possible, correct the fault and revive the experiments.

Encouraged · by the success of the first attempt, the Indian Space Research Organisation has already signed an agreement with the Soviet Union to launch India's second satellite, Aryabhata-2, in 1977–78. The second satellite is expected to be a lot more sophisticated and it will carry television camera systems to survey mineral deposits and agricultural crops, among other things. The flight model for Aryabhata-2 will actually be a modified version of the back-up model of the one now in orbit.

and capabilities of countries sending students to Britain in the interim which are likely to ensure a milder response to the Vice-Chancellors' proposal.

Ten years ago the majority of overseas students came from relatively poor countries which were in no position to provide postgraduate education themselves and the facilities provided in Britain were seen as a relatively inexpensive form of aid. But these days, says the study group, many students come from countries which in terms of national income per head of population are better off than we are, and it is clearly arguable that in these cases the fee payable should be at least a significant proportion of the cost of providing the course.

The fee would not have to be so high that it was out of proportion with similar charges in Western Europe or the US (which would leave plenty of leeway with MIT charges running at $4,000 to $5,000 a year), and the needs of the countries which are still underdeveloped could be met by a system of postgraduate scholarships, continuing the notion of offering development aid in the form of education. Even so, the first effect of any increase in charges would almost certainly be a fall in the number of overseas students arriving in Britain.

The universities want to keep the door open to foreign students not only because of the idea of a world academic community, visiting and returning visits internationally, but also because there is a theory that scientists and technologists trained in Britain will one day be ordering British goods when they're sitting at the biggest desk in the headquarters of the Zambian State Uranium Corporation, or Burundi Rubber. An unfortunate flaw in the theory is that British industry doesn't seem to recognise the value of postgraduate education, with the result that in certain fields it doesn't achieve the sophistication which can be managed by countries (like Germany) which automatically look for masters degrees and doctorates in recruits to their engineering industries. A member of the Vice-Chancellors' group confessed, privately, that at CERN, for example, British loyalists were wringing their

hands and looking elsewhere for equipment, simply because we don't have the calibre of engineer to produce the sort of equipment they require.

Not surprisingly then, the study group is recommending that steps should be taken to see that British industry becomes acquainted with the meaning and value of the masters degree. Also they suggest a tightening up of the admission procedures to a PhD course, in view of justified criticism to the effect that less than ideal candidates are being accepted, and in some cases are receiving the degree. To weed out the stragglers before they have gone too far, the Vice-Chancellors will be asking universities to consider the introduction of a more formal and rigorous assessment of progress, possibly in the form of a written examination or preliminary dissertation, at the end of the first year of a PhD course. And by way of consolation for

the candidates who get over this additional hurdle in the education race, there is a recommendation that a special mark of distinction might be considered for outstanding theses. So if all goes well it will only be a matter of time before the plushest jobs are reserved for thinkers with an upper second PhD or better.

Perhaps by way of a reply to Lord Crowther-Hunt, the report steered clear of making recommendations about the relation between student places and manpower requirements. Apart from areas like medicine and law, where there is a clear connection between the number of career openings and university places, the Vice-Chancellors suggest that in general, progress to postgraduate education should be on the principle that any student who is "qualified, suitable and keen to proceed" beyond first degree level should be able to do so.   □

This week we're running the first in a series of competitions designed to allow scientific minds a flight of literary fancy. Two or three weeks' leeway will be allowed for overseas entrants, but UK competitors are asked to submit their efforts within a week of publication. £10 is available for the best entry or entries

No. 1: Dissident scientists in the Soviet Union are forced to confine their activities to the meetings of the famous Sunday seminars A prize for the minutes (not more than 150 words) of an illicit seminar somewhere in the Western world.   □

correspondence

Sulphones for leprosy

Sir,—If Drs. Browne and Davey (*Nature*, May 15) agree with my statement (March 20) that "sulphones provide a cheap and practical form of treatment", why are most of the World's leprosy patients not receiving it? In countries or areas adopting the outpatient approach, the percentage on treatment is very high; for example, in an area of Northern Nigeria where I worked about 90%; in a remote area of New Guinea 100% (*Med J. Anat.*, **1**, 1262, 1971) and in an area of India, 60% after only three years of starting outpatient clinics (*Dan. Med. Bull.*, **20**, 198, 1973). In countries persisting with institutional care, such as Tanzania, only 33% receive treatment, and some patients have to travel up to 250 miles to receive it. Rehabilitation, including reconstructive surgery, prostheses, physiotherapy and occupational therapy, has greatly magnified the cost of institutional care. Vast sums have been spent on a rehabilitation centre (ALERT) in Ethiopia for crippled patients, yet only 40% of patients are receiving dapsone. Thus, it is the strategy employed which determines the number on treatment and not economic reasons or social aspects of the disease. Will Mr Van Den Wijngaert (May 22) tell us how much of the £4 million collected by the European anti-leprosy Association (ILEP) in 1973 was spent on institutional care, including rehabilitation, and how much

on outpatient treatment?

The figures I quoted showing the rapid fall in leprosy incidence in areas where sulphones have been used, have been ignored by Drs. Browne and Davey. LEPRA have not published any incidence figures in their Malawi project, which started nine years ago, and ILEP have not used money for this purpose. Thus, it is a failure of evaluation, rather than a failure of sulphones to rapidly interrupt transmission, which is the problem. A proved and practicable method of prevention is available and no more time should be wasted on BCG or chemoprophylaxis. Immunoprophylaxis using dead M. leprae from infected armadillos, as suggested by Drs Browne and Davey, has no proven preventive effect.

If government are informed of these facts, if voluntary agencies spend the money on treating patients before they become crippled and if WHO arranges for proper evaluation, then all leprosy patients can be treated and the disease could probably be eradicated within the next ten years.

North to Alaska

Sir,—In her correspondence "North to Alaska" (May 29) Angela Croome states that no ship got through the North

West passage until 1944. This is not quite correct. During the years 1903–06 the Norwegian explorer Roald Amundsen succeeded in getting his little ship Gjøa through. Thus he is rightly credited with the "discovery" of the North West passage.

Yours faithfully,
                    K. STENSTADVOLD
University of Trondheim, Norway

A hundred years ago

THE recent French inundations have recalled to memory an experiment which was tried twelve years ago before Napoleon III. The design was to manufacture mattresses of cork, so that any one on board a ship or in a house which could be flooded would have in his bed a ready-made raft capable of floating under a weight of more than 1 cwt. for any length of time. Cork is a material so soft that mattresses made of it are not inferior to any other for comfort.

news and views

Rhizobium as a free-living nitrogen fixer

from John Postgate

SCIENTISTS interested in biological nitrogen fixation have for many years been perplexed by the apparently complete dependence of Rhizobium, the bacterial partner in the well-known legume symbiosis, on its host plant. Despite frequent attempts nobody, until about six months ago, had successfully obtained growth and fixation by rhizobia in the absence of living plant material (either as a nodulated plant or an association between rhizobium and a tissue culture of plant callus). The plant, indeed, contributes genetic information important to the nodule symbiosis, so Dilworth and Parker (J. theoret. Biol., 25, 208; 1969) earlier suggested that some of the genes determining rhizobium's ability to fix nitrogen (nif genes in geneticists' shorthand) were actually 'banked' with the host plant. More recently evidence had been accumulating to support the contrary view: that rhizobia possess the complete quota of nif genes themselves but that the genes are silent in free-living cells.

One line of evidence stemmed from the work of Dunican and Tierney (Biochem. biophys. Res. Commun., 57, 62; 1974) who took a strain of Klebsiella aerogenes which did not normally fix nitrogen, transferred genetic material from Rhizobium trifolii to it, and obtained progeny which fixed. The presumption was that the K. aerogenes Nif$^+$ progeny were using rhizobial nif genes but, as the authors recognised, ability to fix nitrogen is common among klebsiellae and the possibility that K. aerogenes possessed cryptic (latent) nif genes, and that some activator had been transferred, was not excluded Circumstantial evidence came also from H. J. Evans's group, who showed that R. japonicum grown in conventional laboratory culture, in the absence of plant material, possess not only the electron transport factor associated with nitrogenase (Plant Physiol., 51, 136; 1973) but also a protein immunologically similar to the molybdenum-iron protein of nitrogenase (Biochim. biophys. Acta, 381, 248; 1975). Even stronger evidence was provided by the experiments published in Nature a few months ago (see Nature, 253, 305; 1975) in which

strains of the slow-growing cowpea type of rhizobium were shown not only to fix nitrogen in the presence of callus from non-leguminous plants, but also to continue fixing nitrogen for up to twelve hours after the callus was removed. Callus was clearly providing a diffusible material which permitted nitrogen fixation by the rhizobia; it might be a genetic activator, but actual gene transfer was hardly likely, particularly since non-leguminous callus functioned as well as legume callus in the artificial symbioses.

In the event, the situation has proved remarkably simple. In this issue of Nature three groups, two from Australia and one from Canada (pages 406, 407 and 409) simultaneously report successful cultivation of nitrogen-fixing rhizobia in the complete absence of plant material. As with the earlier experiments using callus culture associations, the possibility that the rhizobial cultures might be contaminated by free-living nitrogen-fixing bacteria had to be rigidly excluded, because rhizobia are difficult to sustain as pure cultures, and the slow growth of the cowpea group makes them even more awkward in this respect. In addition, positive acetylene tests needed to be backed up with $^{15}N_2$.

These things have been done and the key to the question proves to be the carbon source: for fixation, a pentose such as arabinose or xylose as well as a dicarboxylic acid such as succinate seem to be essential Note that both classes of carbon source are common plant constituents. A relatively small amount of fixed nitrogen (such as glutamine, glutamate or nitrate) seems to be helpful; in this respect the cowpea rhizobia seem to resemble free-living aerobic nitrogen-fixing bacteria such as Derxia gummosa or Mycobacterium flavum which also fix nitrogen best when 'kicked off' with a little pre-fixed nitrogen. In D. gummosa, the need for fixed nitrogen can be simply interpreted: nitrogen fixation is an oxygen-sensitive process, so a little pre-fixed nitrogen permits colonies or cultures to grow to a density such that, within the colony, the cooperative respiration of the bacteria lowers the oxygen tension to a level at which fixa-

tion can occur (Hill, J. gen. Microbiol, 67, 77; 1971).

So far, all the successful experiments with rhizobia have made use of media set with agar, on the surface of which the colonies of rhizobia grow and within which colonies the oxygen tension may range from zero to atmospheric. Since fixation by rhizobia has long been known to involve aerobic metabolism, it is tempting to assume that the cowpea rhizobia, like D. gummosa and M. flavum, are bacteria which become microaerophilic when fixing nitrogen. There is an apparent paradox, brought out by the Canadian group, that nitrate or ammonia, which repress nitrogen fixation in liquid cultures of ordinary fixers such as clostridia, azotobacters or klebsiellae, actually promote fixation by free-living rhizobia, but the local ammonia or nitrate concentration near an agar colony cannot readily be assessed and it would be premature to conclude that regulation of nif in these rhizobia is unusual. Resolution of both of these problems must await the successful culture of nitrogen-fixing rhizobia in homogenous liquid media, where both oxygen and fixed nitrogen concentrations can be measured. No doubt this is only a matter of time.

The substantial advance represented by this work is not only the final proof that cowpea and some other rhizobia carry the complete complement of nif genes; it is also the fact that many strains and species of rhizobia now join the ranks of free-living nitrogen-fixing bacteria, with revolutionary consequences for the study of their biochemistry and genetics—for one thing, the host plant can be by-passed in the laboratory. A well established obligate symbiosis is crumbling; in what does the host specificity of the traditional legume symbioses reside? And is the nodule nothing more than a compartment to restrict access of oxygen to rhizobia? If only a pentose and a dicarboxyclic acid are needed for rhizobial fixation, how readily can this information be used to set up new associations with plants and forage crops? And how many other free-living nitrogen-fixing bacteria have been missed by microbiologists because two carbon sources are needed?

Degrees of antiquity

from Peter D. Moore

PRIMITIVE things have a fascination all of their own; and when those primitive things, are, in addition, both rare and attractive, it is natural that they should become a source of attention. All of these things are true of the cycads, which, being the sole survivors of a group that was widespread and successful during the Mesozoic era, were romantically termed 'living fossils' by Chamberlain in 1935. Although they are not considered to be in the direct line of Angiosperm evolution, they probably represent an offshoot from it and it is natural that modern taxonomic techniques should be brought to bear upon the problems of their internal and external relationships.

There are three extant families of cycads, the Cycadaceae, Stangeriaceae and Zamiaceae, and views have differed regarding their relative primitiveness. Sporne (*Morphology of Gymnosperms*, Hutchinson, London; 1965) considered *Stangeria* to be most primitive in that it possesses the largest number of fernlike characters, whereas Marchant (*Chromosoma*, 24, 100; 1968) preferred to regard *Cycas* and *Microcycas* as primitive, both on morphological and cytological grounds. In his cytotaxonomic work on cycads, Marchant examined chromosome number and form in 35 species belonging to eight of the ten extant cycad genera. He found that many species possess telocentric chromosomes (that is, having a terminal centromere), a character which he regarded as primitive. High chromosome number he also considered a primitive feature. On this basis *Microcycas* (Zamiaceae; 2n=26,. 22 telocentric) and *Cycas* (Cycadaceae; 2n= 22, 20 telocentric) emerge as particularly primitive. *Stangeria* (Stangeriaceae) has a chromosome complement in which 2n=16, two only of which are telocentric. Marchant, however, admitted that it was impossible to refute the reverse argument, that telocentric chromosomes represented a derived, or advanced condition. The extreme antiquity of the genome, of course, makes interpretation difficult since there has been ample time for complex evolutionary processes.

Dossaji, Mabry and Bell (*Biochem. System Ecol.*, 2, 171, 1975) have now made a chemotaxonomic approach to the problem of evolutionary relationships among the cycads by analysing biflavonoids from their leaves. Fourteen of these compounds, which are restricted mainly to gymnosperms, were identified in the 82 species studied. Ten species of *Cycas* were uniform in their biflavonoid patterns and contained some biflavonoids, such as hinokifla-

vone, which are not found in the other two families. Within the Zamiaceae, the pattern is slightly more diverse, and both of these families have biflavonoids in common with *Ginkgo biloba*, another surviving member of a primitive group of gymnosperms. Perhaps the most striking result, however, is the complete absence of biflavonoids from the leaves of *Stangeria*. Dossaji *et al.* regard this as a derived condition in which the capacity for biflavonoid synthesis has been lost as has happened in the Pinaceae. Thus, in spite of its primitive morphology, *Stangeria* is beginning to achieve the status of an advanced cycad.

It would have pleased Chamberlain to know that it was plants collected by himself and now cherished by Professor Bold in Texas which provided the incentive for these studies.

Mapping viral integration sites with somatic cell hybrids

from J. K. McDougall

CELLS transformed by viruses into a potential or actual malignant state can usually be shown by molecular hybridisation techniques to retain at least part of the viral DNA molecule covalently linked to cellular DNA. One of the phenotypic changes which these altered cells exhibit is the expression of antigens which are virus specific, for example the tumour antigens (T-ag) and transplantation antigens (TSTA) found in cells transformed by Simian Virus 40 (SV40) and adenoviruses. The progress made in the identification of sequences of viral DNA which persist in single or multiple copies has been spectacular since the restriction endonucleases became available Having reached a point where the viral DNA integrated into a particular cell line can be accurately described, the tumour virologist is that much closer to analysing the role of viral genes in inducing and maintaining transformation. The location(s) at which viral sequences are integrated into host chromosomes may be of prime importance in this analysis.

Croce and his co-workers (Croce, Girardi and Koprowski, *Proc. natn Acad. Sci. U.S.A.*, 70, 3617; 1973) made an encouraging start to answering the question of whether specific integration sites exist, by making use of gene mapping techniques in somatic cell hybrids (Weiss and Green, *Proc. natn Acad. Sci. U.S A.*, 58, 1104; 1967). Hybridisation of SV40-transformed human cells with thymidine kinase negative mouse cells resulted in selection of hybrid cells in which reten-

tion of human chromosome C7 and expression of SV40 T-antigen, TSTA and rescue of defective virus were concordant (Croce, Huebner, Girardi and Koprowski, *Virology*, 60, 276, 1974). Fusion of mouse peritoneal macrophages, which do not divide in these *in vitro* conditions, with the virus-transformed human cells resulted in cell lines which were all transformed and which all contained C7 (Croce and Koprowski, *J. exp. Med.*, 140, 1221; 1974).

Thus the criteria for gene assignments to chromosomes (Ruddle, *Nature*, 242, 165; 1973) appear to be satisfied, allowing Croce and Koprowski (*Proc natn. Acad. Sci. U.S.A.*, 72, 1658; 1975) to conclude that the gene(s) responsible for transformation and the integrated SV40 genome are located on C7.

The study has been taken a step further (Croce, Aden and Koprowski, *Proc. natn. Acad. Sci. U.S.A.*, 72, 1397; 1975) by injecting the transformed hybrid cells into nude mice, which act as convenient culture hosts for heterotransplants (Rygaard and Povlsen, *Acta Pathol. Microbiol. Scand*, 77, 758; 1969) Inoculation of an uncloned population of hybrid cells, which all contained chromosome C7 together with different frequencies of 13 other human chromosomes, resulted in the development of tumours. Analysis of the tumour cells showed 100% retention of C7 and expression of SV40 T-antigen, but a reduction, often complete, in the frequency of all other human chromosomes. Although most cloned hybrid cells and the tumours derived from them were near tetraploid for the mouse and contained on average three C7 chromosomes, more recent studies (Croce, Aden and Koprowski, *Science*, in the press) have shown that hybrids with a near diploid complement of mouse chromosomes and only one C7 are tumorigenic and have the SV40-transformed phenotype.

The hybrids derived by Croce do not follow any pattern which would be compatible with the hypothesis of chromosomal balance and suppression of malignancy (see Jones, *Nature*, 252, 525; 1974) Neither the transformed phenotype *in vitro* nor tumour induction is associated with the loss of specific mouse chromosomes in the man–mouse hybrids or of human chromosomes in hybrids between normal human and SV40-transformed human cells (Croce, Huebner, Girardi and Koprowski, *Cold Spring Harb. Symp. quant Biol.*, 39, 335; 1975) In these experiments it would seem therefore that the transformed phenotype and malignancy are under positive control.

The results from Croce's studies all show that SV40 DNA integrates into

only one chromosome, in the two bio-chemically abnormal human cell lines examined. No SV40 DNA sequences could be detected using the sensitive DNA–DNA reassociation kinetics method, in any hybrid lacking C7. Results from molecular hybridisation studies on SV40-transformed mouse cells (Botchan, Ozanne, Sudgen, Sharp and Sambrook, *Proc. natn. Acad. Sci. U.S.A.*, **71**, 4183; 1974) show that the pattern of viral DNA sequences integrated in transformed cells can be very complex, in that different regions of the virus genome may be present at different frequencies. The situation with adenovirus-transformed cells is similar (Gallimore, Sharp and Sambrook, *J. molec. Biol.*, **89**, 49; 1974). Kelly and Sambrook (*Cold Spring Harb. Symp. quant. Biol.*, **39**, 345; 1975) suggest an integration of SV40 DNA sequences in more than one chromosome although expression, in terms of T-antigen and cytochalasin B susceptibility, is associated with specific chromosomes. Many SV40-transformed cell lines have been shown to contain multiple copies of the viral genome (Ozanne, Sharp and Sambrook, *J. Virol.*, **12**, 90; 1973). This is again true of adenovirus-transformed cells, although the whole adenovirus genome is not found.

Before the generalisation that SV40 integrates only into chromosome C7 in human cells can be made, it will be necessary to examine other SV40-transformed human cell lines and in particular, those containing multiple copies. Weiss (*Proc. natn. Acad. Sci. U.S.A.*, **66**, 79; 1970) has previously suggested a random association of SV40 T-antigen expression with human chromosomes. A crucial question is the role of chromosome C7 in the somatic cell hybrids and whether there may not be some growth advantage conferred by host genes located on this chromosome. These might nevertheless be under the control of viral genes. Croce has been unable to obtain hybrid lines by fusion of mouse macrophages with untransformed human cells.

Somatic cell hybridisation techniques, which have accelerated the mapping of genetic loci in mammalian genomes, must now be a method of choice for localising integrated viral sequences. The results from current studies on adenovirus-transformed human and rodent cell lines, in which the viral sequences have been quantitated, will be of great interest. Croce and his colleagues have demonstrated the power of this approach, the implications of which extend beyond the experimental situation. The recognition of transforming genes, whether of viral origin or not, should be possible using these methods.

Structure and functions of an early T7 promoter

from Maria Szekely

THE nature of promoter sites, defined originally as regions of DNA required for initiation of transcription, has attracted the interest of many laboratories Attempts to isolate these sites and to determine their structure were made as early as 1972, when Heyden, Nüsslein and Schaller (*Nature new Biol.*, **96**, 9) isolated a fragment from fd DNA, the binding site of RNA polymerase. Polymerase binding sites have since been isolated from a number of different DNAs, making use of the fact that the binding of this enzyme protects the corresponding DNA fragment from nuclease digestion. The length of the fragments obtained was in most cases around 40 base pairs, although Giacomoni *et al* (*Proc. natn Acad. Sci. U S.A.*, **71**, 3091; 1974) found binding sites 14 base pairs long on T5, T7 and λ DNA by using somewhat different conditions for nuclease digestion. Recent improved techniques for DNA sequencing made it possible to establish the nucleotide sequence of polymerase binding sites in fd (Schaller *et al*, *Proc. natn. Acad. Sci. U.S.A.*, **72**, 737; 1975), SV40 (Dhar *et al.*, *Nucleic Acids Res.*, **1**, 595; 1974), lambda P$_L$ (Maniatis *et al*, *Nature*, **250**, 394; 1974), tyr-tRNA (Sekiya and Khorana, *Proc. natn. Acad. Sci. U.S.A.*, **71**, 2978; 1974) and lac DNA (Dickson *et al*, *Science*, **187**, 27; 1975).

The function of the promoter is, however, more complex than the simple binding of RNA polymerase. The functional definition of a promoter site is in fact somewhat vague, as it is not clear whether the same DNA region is responsible for the different stages in the initiation of transcription. The functions of the promoter include providing a recognition site for the polymerase, and providing an entry site where a stable 'closed complex' can be formed (Chamberlin, *A. rev. Biochem*, **43**, 721; 1974) which is converted into an 'open complex' in which a short stretch of the DNA strands has been separated. Only the open complex is able to start RNA synthesis. The starting point of the actual transcription process is also part of the promoter. There are, however, contradictory data and hypotheses in the literature as to whether the binding and starting sites are overlapping, or whether they are far apart, thus requiring a migration of the enzyme along the DNA. The finding of Schaller *et al* (see above) that the sequence of a strong polymerase binding site on the replicative form of fd DNA includes the 5'-

terminal sequence of the corresponding mRNA (determined by Heyden) suggested that the binding and starting sites probably overlap. Dickson *et al.* established the sequence of the whole control region of the lac operon (*Science*, **187**, 27; 1975) and determined the site of interaction with RNA polymerase by locating the nucleotide changes produced by different promoter mutants. They came to the conclusion that this interaction site does not coincide with the starting point for transcription. They propose a scheme for initiation of lac transcription according to which the enzyme moves 35 base pairs from the entry site to the start site.

The disagreement may probably be ascribed to the fact that very different approaches and some indirect methods have been applied in both the above studies. It is therefore of great interest that a direct comparison of binding and initiation sites produced more conclusive data.

A recent article by Pribnow (*Proc. natn. Acad. Sci. U.S.A.*, **72**, 784; 1975) elucidates these problems by identifying the binding sites of RNA polymerase at an early promoter site of T7 DNA under conditions of initiated or non-initiated complex formation and by comparing the nucleotide sequence of this site with the 5'-terminal sequence of the mRNA transcribed from this promoter. Pribnow finds that the polymerase binding site is the same whether transcription is initiated or not, and that the starting point of transcription is around the centre of the binding site.

He uses specific dinucleotides to direct initiation of transcription to one or other of three early promoter sites. Specific initiation at promoter site A3 can be achieved in the presence of CpA and a very low concentration of CTP (Minkley and Pribnow, *J molec. Biol.*, **77**, 255; 1973). Under these conditions only the first three nucleotides of the mRNA are joined together, CpApC-OH is formed, and the polymerase is 'locked' into this site. The binding site of the enzyme—the fragment of DNA protected by the polymerase—can be isolated and sequenced. If, after the formation of this complex, transcription is allowed to proceed for 10 min, RNA fragments up to 80 nucleotides long can be obtained, the first 19 nucleotides of which have been sequenced. This sequence corresponds exactly to the 3'-half of the 43 base pair long DNA fragment which binds the polymerase. The sequencing of the DNA fragment itself was done by an indirect method: a stretch of RNA complementary to the DNA fragment was synthesised by read-through transcription and isolated by hybridisation techniques and its nucleotide sequence

was determined. Essentially the same technique was used to establish the structure of the non-initiated polymerase binding site. Tight, non-initiated binary complexes of DNA and RNA polymerase were obtained in low salt media in the absence of dinucleotides or nucleoside triphosphates. The protected DNA fragment was isolated and its sequence was found to be identical to that of the initiated binding site.

It is thus clear that the binding site of the polymerase does not change when transcription is initiated and that this binding site overlaps with the starting site of transcription. Further data show that the same DNA region does not fulfil the function of a polymerase recognition site. The protected DNA fragment is unable to rebind the enzyme (in agreement with the findings of Schaller *et al.*, see above), probably because some further information, not contained in the 43 base pairs, is required for recognition of the promoter site. Still, even in this known sequence, striking homologies are found with polymerase binding sequences in other DNAs, suggesting either that this DNA stretch may also play a part in the recognition process or that the stable binding of polymerase requires the presence of a short specific sequence in all promoter sites.

Very similar conclusions have recently been reached by Heyden, Nüsslein and Schaller (*Eur. J. Biochem.*, **55**, 147; 1975).

Protein conformation and α-complementation

from Roger Pain

RESTORATION of activity to an inactive mutant enzyme is always intriguing. When a purified system is developed such that the phenomenon can be translated from the realm of genetics into solid protein chemistry then one can expect interesting advances, both to the cell biologist and the protein conformation–activity industry.

Attention was first drawn to a particularly interesting example of mutant reactivation by Ullman, Jacob and Monod (*J. molec. Biol.*, **24**, 339–343; 1967) involving β-galactosidase, the enzyme specified by the *z* gene of the lactose operon in *E. coli*. Inactive mutants of this enzyme bearing mutations in a particular region of the *z* gene can have their activity restored by non-covalent binding of the gene product from *z* genes bearing mutations outside this same region. On the map of the *z* gene (see figure) both the operator-proximal α region and the
The *z* gene for β-galactosidase: figures and letters above the solid line indicate the position of point mutations in the *z* gene; *o*, operator; *p*, promoter; *y*, structural gene of β-galactosidase permease. From Ullman, Jacob, and Monod, *J. molec. Biol.*, **24**, 339; 1967.

operator-distal region specifying the N-terminal and C-terminal regions respectively of the β-galactosidase subunit can act as 'acceptors', if mutated, or as 'donors', if intact, in the reactivation or complementation 'process. As an example of α-complementation, the protein specified by the deletion mutant M15 can be restored to wild-type β-galactosidase activity by binding proteins arising from point mutations such as z^{-1}, B200 or X90 or deletions such as A238 or X2, but not by mutants such as 131 or E65. M15 is termed an α-acceptor while z^-1, A238, and so on exhibit α-donor activity. Finally, wild-type β-galactosidase consists of four identical subunits, each of molecular weight 135,000. α-complementation involves the binding of a polypeptide donor to the individual subunit, enabling it to form an active enzyme, rather than the association of different subunits; it is intra- rather than inter-cistronic in character.

A significant step forward in this fascinating phenomenon has been taken by Zabin and his colleagues who have purified the M15 protein, shown how it differs in sequence from the wild-type enzyme and also purified a sequenced peptide with α-donor activity (Langley *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **72**, 1254–1257; 1975). Cyanogen bromide cleavage of β-galactosidase yields peptides with α-donor activity; peptide CB2, residues 3–92, has been purified and found to complement purified M15 protein, giving a specific activity close to that of pure β-galactosidase. This confirms the genetic analysis that α-complementation involves the N-terminal region of the enzyme. The single CNBr peptide peculiar to M15 protein as compared with wild type β-galactosidase was found to correspond to CB2 and has been purified by an ingenious double labelling procedure and shown to differ from CB2 in that residues 11–41 are missing. It is therefore these 31 deleted residues in M15 protein whose function is supplied by the α-donor peptide CB2 in α-complementation.

An · interesting model for such systems already exists in the work of Anfinsen on staphylococcal nuclease (*Science*, **181**, 223–230; 1973). In this

single subunit enzyme of 149 residues, the tryptic fragment (1 to 126)—a protein chemist's deletion mutant—can be complemented by peptide 99 to 149 with partial restoration of enzyme activity. Further, the overlapping regions may be 'trimmed' by proteolysis in the same way that certain complemented β-galactosidase mutants have been trimmed (Ullman and Perrin in *The Lactose Operon*, edit. by Zipser and Beckwith; Cold Spring Harbor, 1970). Anfinsen's well characterised model would act as a precedent for suggesting that the peptide CB2 provides residues 1–41 in the wild-type conformation with the remainder 42–92 and residues 1–10 of M15 going spare, yet without interfering with the structural features essential for activity.

The fact that M15 protein possesses a strong substrate binding site, together with the observation of Langley *et al.* that it behaves in solution as a dimer rather than a tetramer, suggests that α-complementation may be concerned with inter-subunit binding sites. The sharp delineation of the α-region shown by genetic analysis may well reflect the boundary of a protein domain such as are now known to exist in several larger enzymes. Immunological evidence in favour of this hypothesis has recently been published by Celada, Ullman and Monod (*Biochemistry*, **13**, 5543–5547; 1974).

With the ability now to study the phenomenon of complementation on purified systems it is perhaps worthwhile speculating on one or two implications for protein conformation of the original results of Ullman *et al.* Treatment with guanidinium chloride (GuCl) was found to destroy α-acceptor activity in all mutants examined, while α-donor activity was unaffected. This suggests that the N-terminal α region must be free from deletions for refolding to occur from GuCl but not presumably *in vivo*. Further, mutants having α-donor activity can be divided into two classes: mutants in the operator-distal ω region whose α-donor activity is only revealed after exposure to 6 M GuCl and subsequent return to aqueous solution and mutants in the central region between the α and ω regions whose α-donor activity is evi-

dent both before and after GuCl treatment. Consideration of the unfolding and refolding processes involved suggests that even a minimally altered ω region may affect the *in vitro* folding of other regions or domains of the enzyme in a way different from the *in vivo* situation. It must be acknowledged that these experiments were carried out on crude extracts of enzymes and mutants. If, however, they were reproduced using purified systems like those of Langley *et al.*, they would pose most interesting and potentially productive questions about the kinetic pathways along which large polypeptide chains fold in the test tube on the one hand and off the ribosome on the other.

Mössbauer effect and order–disorder transitions in alloys

from G. Longworth

To study the mechanisms involved in order–disorder reactions in alloys, the functional dependence of some physical quantity (for example resistance, magnetisation or X-ray diffraction pattern) must be measured. An ordered alloy is one whose structure may be divided into sublattices each of which is occupied predominantly by one type of atom, whereas after disordering the various atoms are arranged at random on each sublattice. Such reactions are divided into those of first or second order (degree) involving either a discontinuous or continuous change in long-range order parameter with temperature. At a first order transition, usually associated with closely packed lattices such as in Cu_3Au or Ni_3Fe, two phases of different composition may coexist, whose transformation is governed by a latent heat. The highly monochromatic gamma rays emitted by certain (Mössbauer) nuclides may be used to study order–disorder reactions by measuring the hyperfine interactions, which are a function of local atomic order.

Thus the complex ordering in Fe_3Al has been studied by Cser *et al.* (*Phys. Stat. Sol.*, **20**, 581; 1967) by determining the changes in magnetic hyperfine field (H_{hf}) at the ^{57}Fe sites. In iron alloys, H_{hf} is determined essentially by the magnetic moment on the iron atom and by the conduction electron polarisation, both of which may be a function of local atomic order. Erickson and Roberts (*Phys. Rev.*, **B9**, 9; 1974) have measured the change on ordering in the electron charge density at the gold nuclei, and in the vibrational motion of the gold atoms in Cu_3Au.

Drijver *et al.* (*J. Phys., Paris*, **35**, C6–465; 1974) have used an analysis of the hyperfine fields in Ni_3Fe to determine the long range order parameter, and more recently (*Phys. Rev. Lett.*, **34**, 16; 1975) have extended this technique to follow the time evolution of the phase transition in this alloy 'at temperature'. A detailed analysis of the Mössbauer lineshapes confirmed that the transition was first order, proceeding by way of a nucleation and growth mechanism.

In this latest work, a sharp drop in mean field $\bar{H}_{hf}$ at the iron sites at about 771 K on heating indicates a first order transition, while during cooling, the reverse path is followed with a hysteresis of about 10 K. The linewidths (Γ) at the transition were much greater than the theoretical value (0.20 mm s^{-1}), mainly due to the presence of both ordered and disordered regions having values of H_{hf} which differed by a small amount (≈20 koersted). The amount of ordered material at 770.9 K roughly follows the increase in the mean field $\bar{H}_{hf}$ with time, along an S-shaped curve, consistent with nucleation and growth, taking about 200 hours to complete. By comparison with model calculated spectra, it was suggested that: (1) during the ordering reaction the first nuclei present have a long range order parameter of only about 0.6. There is then a homogenous growth of order within these ordered segregates. (2) During the disordering reaction there is in addition composition segregation involving iron-rich ordered material and iron-poor disordered material consistent with a two-phase region about 4 K wide similar to that observed by Calvayrac *et al.* (*Mater. Res. Bull.*, **7**, 891; 1972) using electron microscopy. While disordering starts at a temperature at or above the two-phase region, ordering is suppressed as shown by the hysteresis and starts about 10 K below.

The disadvantage of the Mössbauer technique is that for detailed measurements above room temperature it is really restricted to iron and possibly tin alloys, since for most other Mössbauer nuclides the size of the Mössbauer effect is too small. In the case of Ni_3Fe the amount of information available from the spectra is limited by the relatively small difference in H_{hf} between the ordered and disordered phase. One might expect a larger difference when a change in crystal structure is also involved. The use of small amounts of the Mössbauer nuclide ^{119}Sn as a probe in magnetic alloys might lead to a greater change in H_{hf}, since the tin atoms carry no magnetic moment and derive their field entirely from their neighbours. Thus the Mössbauer technique is restricted in its application in this field. But the advantage of being able to measure the changes in local properties at the temperatures concerned is considerable, and this technique, combined ideally with electron microscopy, could add greatly to our knowledge of order–disorder transitions in alloys.

Analysis of membrane noise

from Shin-Ho Chung

A NUMBER of researchers are using a powerful new technique to study electrical properties of nerve and muscle membranes. This technique, known as membrane noise analysis, is based on the fact that spontaneous perturbations of the mechanisms underlying membrane permeability give rise to random fluctuations in membrane conductance, and the statistical structure of these fluctuations provides, in turn, information about the microscopic events generating such noise.

On the basis of physical theory, electrical noise arising from several different sources is expected to be present in nerve and muscle membranes. First, the thermal agitation of charge carriers will produce thermal, or Nyquist, noise. In addition, when the flow of current is due to only a relatively small number of the total available carriers (as it is in the membrane), flicker noise is shown to be present. Superimposed on these two sources, there will be random fluctuations of membrane conductance resulting from microscopic perturbation of ionic channels. For example, single ionic channels in a membrane at an equilibrium state may spontaneously open and close, although the average number of open channels remains constant. The membrane conductance will then fluctuate around its mean value. Because each of these noise sources has a different physical basis, their analysis, in principle at least, will provide answers to different sets of questions which have not previously been amenable to experimental attack. An experiment by Conti, De Felice and Wanke (*J. Physiol., Lond.*, **248**, 45–82; 1975) was aimed at elucidating some of these questions.

Two physical models for ionic channels follow from Hodgkin and Huxley's description of current flows in membranes. The first of these, a probabilistic version of the Hodgkin–Huxley equations, envisages a channel gate, guarded by four macromolecules, either in an open or closed conformation. The channel is open when all these macromolecules are in their open conformation. An alternative class of

models, based on a literal interpretation of the Hodgkin–Huxley equations, predicts that channel conduction can occur even if the molecules of the gate are not all in the open conformation This condition allows the channel conduction to have more than just two (open and closed) states; rather, perhaps, a sufficient number of intermediate states to approach a continuum. Hill and Chen (*Biophys. J.*, **12**, 948, 1972, *ibid.* **13**, 1276; 1973) and Stevens (*Biophys. J.*, **12**, 1028; 1972) have independently derived that the spectral density for conduction fluctuations in the Hodgkin–Huxley axon (obtained from a Fourier analysis of the experimental records) obeys a mathematical form which, though not identical, resembles a simple Lorentzian function. The predicted spectrum is constant in the low frequencies and decreases according to $1/f^2$ in the high frequency limit. This holds true for both physical interpretations of the Hodgkin–Huxley equations, but the frequency at which the extrapolated $1/f^2$ decline intersects the low frequency limit is different in the two models.

Earlier measurements of voltage and current fluctuations in nerve membranes (Verveen and Dirksen, *Proc. IEEE*, **56**, 906; 1968; Poussart, *Biophys J*, **11**, 211; 1971) were dominated by the presence of flicker noise, and the most interesting noise, namely, that arising from ionic channels, went unnoticed. The expected Lorentzian noise from the squid axon was first detected by Fishman (*Proc. natn. Acad. Sci. U S.A.*, **70**, 876; 1973; *Fedn Proc.*, **34**, 1330, 1975) in his power spectrum of membrane voltage fluctuations. When tetraethylammonium ions (which are known to block potassium channels) were added to the bathing solution, the Lorentzian component disappeared, thus indicating that the detected noise arose from microscopic events associated with potassium permeability Because the voltage noise is related to conductance fluctuations by the membrane impedance, the elementary processes of nerve excitation can be revealed more directly through measurements of current noise. Conti *et al.* (also De Fecile *et al.*, *Fedn Proc.*, **34**, 1338; 1975) have now obtained two Lorentzian components, associated with the open–close kinetics of potassium and sodium channels (see figure). From the measurements, they also derived the number of sodium and potassium channels present per unit membrane, and, from it, they calculated the absolute conductance of individual channels. Their estimate of the number of sodium channels, 330 per square micrometre, agrees well with those derived from other lines of argument (see Hodgkin, *Phil. Trans. R. Soc.*, **B270**, 297; 1975; Keynes *et al.*, *ibid.*, 365). Available data, however, are not refined enough to distinguish between the two possible physical interpretations of the Hodgkin–Huxley equations, but with luck they soon will be, as a number of laboratories are now making measurements of axon conductance fluctuations.
Components of current noise spectral density from squid axons When sodium channels were blocked with tetrodotoxin, the spectrum consisted of the two separate components (flicker + K Lorentzian). Similarly, in an axon with its potassium channels blocked, the sum of the two components (flicker + Na Lorentzian) could adequately describe the obtained spectrum. (Modified from Conti *et al.*, *J. Physiol*, *Lond.*, **248**, 45; 1975.)

Analysis of noise in the muscle membrane has also provided important sets of data. One of the possible physical models emerging from such measurements is that two acetylcholine molecules binding on a receptor induce a conformational change in a gating macromolecule (Stevens, *Fedn Proc.*, **34**, 1364; 1975). The channel then allows the transmembrane flux of sodium and potassium ions The length of time a channel stays open depends exponentially on membrane potential; for each -100 mV change in membrane potential, the lifetime of open channels doubles. At $8°C$ and 0 mV, for instance, a channel remains open, with a conductance of 20 to 30 $p\Omega^{-1}$, for about 6.5 ms. These conclusions could have been derived directly, were it possible to activate a known number of channels by iontophoretically applying acetylcholine at the endplate and, instantaneously, to cause the relaxation of the receptors back to their normal, closed, conformation. Because such an experiment is not technically feasible, quantitative information such as that obtained by Stevens can only be acquired by membrane noise analysis.

Katz and Miledi (*Nature*, **226**, 962; 1970) first discovered that a constant dose of acetylcholine applied to the frog neuromuscular junction gives rise to a substantial increase in membrane noise. In a subsequent analysis (*Nature new Biol.*, **232**, 124; 1971; *J. Physiol.*, *Lond.*, **224**, 665; 1972), they showed that this increased noise results from endplate gating mechanisms, and calculated the size and time course of the elementary event. The technique of noise analysis was further exploited by Anderson and Stevens (*J. Physiol.*, *Lond.*, **235**, 655; 1973) Making the assumption that the receptor molecule exists either in open or closed conformation, Stevens and his associates (see also Magleby and Stevens, *J. Physiol*, *Lond.*, **223**, 151; 1971; *ibid.*, 173) made a number of predictions about the behaviour of conductance fluctuations, making use of the fluctuation-dissipation theorem The measurements of acetylcholine-induced conductance fluctuations, obtained under voltage clamp conditions, agreed well with the theoretical predictions. The striking agreement between theory and experiment does not, however, constitute final proof of the theory proposed by Stevens. In fact, a slightly different version of microscopic events, in which a channel opens instantaneously and its conductance then decreases exponentially (Katz and Miledi, 1971), will lead to the same prediction about the behaviour of conductance fluctuations. There is, furthermore, an additional observation, for which Stevens's model. in its simplest form. cannot account without making additional assumptions. This is the observation that the mean lifetime in the open state, and the absolute conductance of a single channel, can each vary when different drugs are used to open the channel (Katz and Miledi, *J. Physiol.*, *Lond.*, **230**, 707: 1973; Colquhoun *et al*. *Nature*, **253**, 204; 1975). The model would have predicted that a channel, once it is open. will have the same conductance whichever drug caused it to open. Nevertheless. theoretical predictions of the type Stevens has made, along with the quantitative data extracted from membrane noise analysis, will place a severe constraint on a number of tenable physical models for endplate gating mechanisms.

In the closing chapter of his classic book. *Membranes. Ions and Impulses* (University of California, Berkeley, 1968), Cole suggested that a sequel of his volume should be written in a decade or so under the title of *Membranes, Ions and Impulses: A Chapter of Molecular Biophysics*. When that chapter is finally written, we will have witnessed the final act of a long drama, staged by some of the intellectual giants

of the past and present It is toward this goal that a group of neurophysiologists are making steady progress; and analysis of membrane noise is but one of the many tools at their disposal.

Ordered disorder?

from P. V. E McClintock

A NEW theory of the dilute magnetic alloys known as spin glasses has been proposed by Edwards and Anderson. The burden of their argument, published in *J. Phys.* (**F5**, 965; 1975), is that an apparently random arrangement of magnetic spins may, in reality, sometimes be regarded as being highly ordered.

An example of the type of alloy to which their theory applies is formed when a few per cent of manganese is added to copper: the copper, being non-magnetic, serves as a relatively inert medium in which the manganese atoms are held fixed in random spatial positions. The unpaired electron spins responsible for their magnetism are, however, free to point in different directions. At high temperatures the spins will be randomly orientated with their directions changing with time, but the intriguing question arises· what will happen as the temperature is reduced?

In order to try and guess the answer it is instructive, first, to consider what happens in a pure magnetic material, for example pure manganese, where the spins are all equally spaced from each other In such a case the mutual interactions between nearest neighbour pairs of spins would all be the same, and the system would either become ferromagnetic (all spins pointing in the same direction) or antiferromagnetic (neighbouring spins pointing in opposite directions). Which of these two types of ordered state is the one actually adopted is a sensitive function of the spacing between the atoms Measurements of the magnetic susceptibility χ as the temperature T is reduced show that the change from the disordered to the ordered state occurs as a so-called cooperative transition, with $\chi(T)$ passing through a sharp anomaly at a critical temperature T_o. This behaviour can be understood if one postulates a critical temperature T_c. This behaviour spins: the larger the number of ordered spins, the larger the molecular field becomes, thus accounting for the sharpness of the anomaly and also, of course, for the description of the transition as cooperative.

On the other hand, when the manganese is diluted with copper, the magnetic atoms will no longer be spaced equally from each other, and the whole situation becomes very much more complicated. The simple molecular field approach is no longer applicable because some pairs of spins will be attempting to align while others, with different mutual separations, will be tending to take up antiparallel orientations. Moreover, the different spin spacings will tend to give rise to different values of the temperature T_o at which the ordering transition occurs. Thus, common sense would seem to suggest that any peak in $\chi(T)$ must be greatly broadened. Experiments, however, have demonstrated quite otherwise: Canella and Mydosh (*Phys Rev.*, **B6**, 4220; 1972) for example, working on the somewhat similar iron–gold system, found that for an alloy containing 5% of iron there was a very sharp cusp in $\chi(T)$ at about 20 K.

To try to account for this, Edwards and Anderson have pointed out that, despite their random positioning, there must be some configuration of the orientations of the spins which minimises their potential energy. Considering the spins' positions in space to be fixed and permanent, this configuration can then properly be regarded as the ground state of the system (in fact, one of many such states, each corresponding to a local minimum in potential energy). The authors argue that the mere existence of such a state is sufficient to give rise to a well-defined magnetic ordering transition, and hence to account for the observed sharp cusp in $\chi(T)$. Thus, as T is reduced, there must eventually come a temperature at which the spins 'notice the existence' of this ground state; and, as $T \rightarrow 0$, the system will then settle into that state. Of course, if one were able to examine the material in its ground state, it would seem, superficially at least, still to be in total disarray with the spins arranged quite randomly. The randomness would be more apparent than real, however, because the system would be in the particular state which minimised its potential energy. It thus could reasonably be regarded as being, in actual fact, highly ordered.

These ideas are by no means original, other workers having previously arrived at broadly similar conclusions. The great contribution which Edwards and Anderson make in this paper is that of devising a theoretical framework within which the magnetic behaviour of such systems may be treated quantitatively. They describe the degree of order in the spin system by a parameter q which represents the probability that a spin pointing in a particular direction at one moment will be pointing in that same direction when viewed again a long time later. Thus at $T=0$, where the system is magnetically in a state of perfect order, $q=1$; while for $T \geqslant T_o$, there is no long-range order, and $q=0$. The order parameter q therefore be-

haves rather like the molecular field of the familiar Curie–Weiss theory. The authors have, in fact, worked out these ideas at a similar level of accuracy to that of the Curie–Weiss theory, and they suspect that their conclusions must be inaccurate in similar ways, notably in a wrong prediction of the detailed shape of the cusp in $\chi(T)$· they are generously leaving the application of quantum mechanical refinements to other workers.

Their main conclusion, however, is the important one: that, even though the alloy may be neither ferromagnetic nor antiferromagnetic, it will nevertheless undergo a magnetic ordering transition which should manifest itself as sharp peaks in properties such as the magnetic susceptibility, and at a temperature which can in principle be predicted. This is a remarkable theoretical result, but one which is in excellent accord with reality as revealed by the experiments.

Mutating and mapping SV40

from Lois K. Miller

NUCLEIC acid biochemists are now able to manipulate the DNA genome of small animal tumour viruses with remarkable skill as illustrated by two papers from Paul Berg's laboratory (Shenk *et al*, *Proc. natn Acad. Sci. U.S A*, **72**, 989, 1975; and Carbon *et al*, *Proc. natn. Acad. Sci U.S.A.*, **72**, 1392, 1975). These workers have exploited the known specificities of several types of DNA nuclease to produce viral deletion mutants and map those mutants with astounding ease, accuracy, and rapidity.

Mutations in small animal viruses are difficult to map by the more conventional genetic methods because of their size, low recombination frequencies, and lack of different mutant types for three-factor genetic crosses. A technique, originally developed for ΦX174 (Weisbeek *et al*, *Biochim. Biophys. Acta*, **224**, 328; 1970; Hutchison and Edgell, *J Virol.*, **8**, 181; 1971), was modified by Lai and Nathans (*Virology*, **60**, 466; 1974), and utilised to map temperature sensitive (ts) mutations of SV40. The technique relies on the ability of wild-type DNA fragments to rescue a mutant DNA genome when the two are properly annealed together and introduced to an appropriate cell. When wild-type restriction endonuclease fragments are employed, the mutation can be localised within a single fragment and the relative position within the genome is known since restriction nuclease fragments can be ordered by independent means. Al-

though it is known from the ΦX174 studies that fragments 30–50 nucleotides long can rescue mutant genomes, the achievement of such accuracy in mapping with this technique would require a tour de force on the part of the investigator Nevertheless, marker rescue is a rapid direct approach to mapping ts mutations within a region of the genome 300–500 nucleotides in length.

Shenk *et al*. have developed a purely biochemical mapping technique which is based on the ability of S_1 nuclease, an endonuclease from *Aspergillus oryzae* which recognises regions of single-stranded DNA, to produce double-stranded cleavages at the mismatched region of a wild type–mutant heteroduplex The technique is ideal for mapping small deletion mutations (too small to map by electron microscopy heteroduplex techniques) due to its rapidity and accuracy. Although Shenk *et al*. have also mapped ts mutations using this technique, it is apparent from their results that single-base mutations are not easily recognised by the S_1 activity. In mapping ts mutations, Shenk *et al*. observe very high backgrounds due to non-specific cleavage of the DNA and the 'nibbling' of the breathing ends of the double-stranded DNA by the S_1 nuclease. It would be interesting to scan the presently known repair endonucleases for an enzyme with higher specificity for single-base mismatched regions and couple such an enzyme with the S_1 nuclease technique.

There are several advantages the S_1 mapping technique has over the marker rescue technique. The S_1 technique, according to Shenk *et al*., is accurate to 1% of the SV40 genome or approximately 55 nucleotides and thus gives ten times more accuracy with approximately equal ease. Since the S_1 technique is purely biochemical, it does not rely on infectivity and is potentially useful for mapping non-viral DNA (including eukaryotic DNA) or viral DNAs having low plaque forming units/µg DNA ratios (for example adenovirus 2). But since it is purely biochemical, caution must be taken that a second-site, silent mutation is not mistaken as the true mutation.

Carbon *et al*. have developed an excellent technique for producing deletion mutants of SV40. By digesting 25 to 30 nucleotides from the ends of a linear double-stranded DNA with the 5′-end specific lambda exonuclease, they produce shortened DNAs which, when introduced into monkey cells, yield circular deleted genomes in a manner similar to that previously reported by Lai and Nathans (*J. molec. Biol*., **89**, 179; 1974) at a high frequency. By using appropriate combinations of DNA nucleases, it is

apparent that Carbon *et al*. will be able to produce deletion mutants not only at restriction nuclease sites but also at essentially random sites throughout the SV40 genome. Since these deletion mutations can be mapped readily by the procedure of Shenk *et al*., such mutants should be most helpful in defining essential regions of the genome and the limits of the various genes.

Previous reports on isolating deletion mutants (Mertz and Berg, *Proc. natn. Acad. Sci. U.S.A.*, **71**, 4879; 1974); Lai and Nathans, *J molec. Biol*.) have shown that certain deletion mutants are viable whereas other mutants are non-viable and must be carried with helper virus. The latter case presents problems in obtaining pure stocks of deletion mutants. It would be useful in this respect to develop stocks of helper virus which could contribute functions lacking in the non-viable deletion mutants yet be easily separable from the deletion mutant itself. It would also be useful to develop *in vitro* techniques for the production of specific conditional lethal mutants (such as ts mutants) at high frequencies.

Lipid
on the run

from A G. Lee

THE nightmare of anyone using probe molecules to study membranes is of awakening to find that all that has in fact been studied is the probe. Hence the tendency to seek confirmation of previous results using new probes and new physical techniques, on the principle that a nightmare shared is a nightmare halved.

The latest example of this concerns the measurement of the diffusion rates of lipids within the plane of a lipid bilayer These measurements have generally been based on studies of the magnetic interactions between molecules in the membrane. If a spin-labelled steroid or lipid is incorporated into the membrane at high concentrations, then magnetic interactions occur between the unpaired electrons of the spin-labelled molecules, and this interaction is reflected in the shape of the electron spin resonance spectrum. If the spin labels are moving in the plane of the membrane, then the movement will modulate the magnetic interactions, the exact effect of the motion on the shape of the spectrum depending on the rate of the motion. In this way, Träuble and Sackmann were able to estimate a rate of lateral diffusion for spin-labelled androstan of about $1-2 \times 10^{-8}$ cm^2 s^{-1} (*J Am. Chem. Soc*., **94**, 4499; 1972). Devaux and McConnell

(*J. Am. Chem. Soc*., **94**, 4475; 1972) obtained similar results, also with spin-labelled molecules, but using a kinetic technique to detect diffusion. A diffusion rate of this magnitude is of considerable interest since if the lipids in a real biological membrane were moving as fast, it would mean that a lipid could move from one end of a 1 µm long bacterium to the other in the order of a second.

An alternative approach was to look at the magnetic interactions between the protons of the lipid fatty acid chains which are reflected in the proton nuclear magnetic resonance line shapes. This has the advantage that it is possible to use natural phospholipids, with no perturbing spin-label, but it has the disadvantage that it is rather difficult to separate contributions to the linewidth from the diffusive motion and from other sources. However, the self-diffusion coefficients obtained in this way were identical to those obtained by electron spin resonance (Lee *et al*, *Biochemistry*, **12**, 1650; 1973).

In the latest paper (*Proc natn. Acad. Sci. U S A.*, **72**, 1451; 1975) on lateral diffusion Brulet and McConnell have extended the theory of time-dependent magnetic interactions to the case of two-dimensional diffusion This has enabled them to look in detail at the effect that a spin-labelled molecule incorporated into a lipid bilayer will have on the relaxation times of ^{13}C or ^{1}H nuclei of the lipids of the bilayer. Unfortunately, for the calculations to be at all tractable it was necessary to assume that the two-dimensional lateral diffusion of the spin label was confined to one single plane, at some fixed depth within the lipid bilayer. Similarly it had to be assumed that the nucleus of interest was also forced to diffuse laterally within a fixed plane. Neither of these assumptions is strictly valid, since it is known that phospholipids undergo extensive vibrational motion, so that positions in a direction perpendicular to the bilayer surface are constantly changing. Although it is not known what effect this will have on the results, it is more than a little comforting that what emerges at the end of the calculations is once again the magic number obtained by the other techniques—2×10^{-8} cm^2 s^{-1}.

It now seems very unlikely that these results for lipids in simple lipid bilayers will be overturned. When we turn to the intact biological membrane, however, an interesting problem emerges. If all the lipids in biological membranes were to have such high diffusion rates, then there could be no persistent interactions between specific proteins and lipids in the membrane, and the environment of the membrane proteins would be a weighted average of that provided by the heterogenous mixture

Superconducting regions in lysozyme

from a Correspondent

GREAT interest was aroused at the Dielectrics Society annual meeting by Herbert Fröhlich's report of some experiments which show that an aqueous solution of the enzyme lysozyme contains regions which are superconducting. The report (now published: Ahmed, Calderwood, Fröhlich and Smith, *Phys. Lett.*, **53A**, 129; 1975) can be summarised thus.

Magnetic fields of order 600 Gauss were found to bring about very large changes in the dielectric constant of aqueous lysozyme solutions. Since for this to happen the magnetic field must be able to overcome ionic thermal fluctuations, the magnetic energy must act over a volume of the order of a million lysozyme molecules, which indicates the existence of a cooperative phenomenon capable of increasing the magnetic susceptibility in a

magnetic field.

This measurement was therefore made, and a 1% increment in bulk susceptibility was found on application of the 600 Gauss field. This is ten thousand times larger than the effect for an ordinary diamagnetic material and its disappearance about 800 Gauss indicates that it represents a Meissner effect in superconduction. Complicated temperature and concentration effects were found, including temperature hysteresis. It was postulated that in solution the ions form a layer structure, giving rise to an a.c. Josephson effect, that is, to the electric vibrations in biomolecules recently proposed by Fröhlich and reported in the Soviet literature. Physiological effects of magnetic fields would seem to be given physical respectability if a Meissner effect exists in a biomolecular solution.

---

of chemically distinct lipids present in that membrane. That goes against the considerable weight of experimental evidence suggesting specific interactions between particular proteins and lipid classes, with at least a ring of lipid bound relatively tightly to the protein in a long-lived interaction. So it seems that whereas the bulk of the lipid could be diffusing as fast as lipid in simple lipid bilayers, there might also be some lipid in contact with protein and exchanging only slowly with the bulk lipid.

In a recent paper, Warren *et al.* (*Nature*, **255**, 684; 1975) explore this possibility of relatively long-lived lipid–protein interactions with their simplified lipid–protein system, containing the (Ca^{2+}–Mg^{2+}) ATPase from sarcoplasmic reticulum. They have found that the activity of the protein is maintained as long as there are 30 or more phospholipid molecules for each protein molecule: with a smaller proportion of phospholipid there is an irreversible loss of activity. It has been suggested therefore that these 30 lipid molecules form a single shell of phospholipid bilayer around the protein, protecting it from denaturation. Further experiments have then shown that cholesterol, which on its own leads to a reversible loss of activity, cannot normally penetrate this lipid annulus. If, as seems likely, this proves to be a general property of membrane proteins, then the organisation of lipids within the membrane will be by no mean homogeneous. Each protein will be surounded by a lipid microenvironment, the structure of the

protein and the nature of the microenvironment together determining the functioning of the protein. Only the bulk lipid will be free to diffuse within the membrane, and around each protein there will be an immobilised lipid annulus, whose composition will be determined by the structure of the protein. Even in the transitory world of membranology, not everything is in a state of flux.

Mammalian development, with chicks and newts

from Gillian M. Morriss

The Ciba Foundation held a symposium on "Embryogenesis in Mammals" on June 16–19. The proceedings will be published by Associated Scientific Publishers.

THE symposium was held just ten years after the symposium on preimplantation states of pregnancy—ten years which have seen a tremendous creative surge in the field of vertebrate experimental embryology. With congenital anomalies an increasing medical problem, much of this creative energy has been applied to studying normal and abnormal postimplantation mammalian development. Whole embryo and organ culture techniques have contributed ~atly to the accessibility and ma⁣ ⁣ity of the systems under

investigation; however, in comparison with the work on other vertebrates, mammalian embryology appears to have embarked on an obstacle course beset with many frustrations. Thus it was fitting that two presentations on recent advances in avian and amphibian development were included in the symposium, and that four additional non-mammalian embryologists were present as discussants.

Death of a germ layer

More than one established dogma was challenged by the participants. The first was the demonstration by R. L. Gardner (University of Oxford) that the early differentiation of inner cell mass into 'endoderm' (hypoblast) and 'ectoderm' (epiblast) does not signify the establishment of cell lineages loyal to the historical concept of germ layers. The most important determinative factor in the differentiation of preimplantation and implanting embryos is cell position; thus chimaeras can be constructed whose primary endoderm-derived cells are detectably different from the rest of the embryo. Examination of such embryos at 15½ days showed that the whole embryo is derived from the so-called ectoderm. Other experiments demonstrated that even the germ cells are ectodermal in origin.

N. Skreb (Faculty of Medicine, Zagreb), describing a study carried out in collaboration with B. Levak-Svajger and A. Svajger (see *J. Embryol. exp. Morph.*, **32**, 445–467; 1975), showed that, when transplanted to a site under the adult kidney capsule, embryonic ectoderm retains the capacity to differentiate into all embryonic structures (including gut) up to the primitive streak stage, though not later. Endoderm alone was always resorbed, but this may simply be a further demonstration of the essential interactive role of adjacent mesenchyme and intercellular matrix in epithelial differentiation. Nicole Le Douarin (Université de Nantes), for instance, showed that grafts of portions of avian pharyngeal endoderm will not differentiate in the absence of mesoderm. The major part of her paper concerned that unique piece of ectoderm, the neural crest. Her elegant studies on quail–chick transfers are too well known to need description here (see, for instance, *Devl Biol.*, **41**, 162–184; 1975); as the chairman, Anne McLaren (University College, London) remarked, they are a source of envy to mammalian embryologists. A further characteristic of the primitive endoderm is its slow proliferation: M. Snow (University College, London) calculated that in the primitive streak stage mouse embryo, the cell cycle time in the endoderm is more than 15 h, compared to 6½ and

8 h in the other two layers.

The question of the developmental capacity of the primitive (or primary) endoderm is clearly as yet unresolved. But does the term 'germ layer' remain meaningful or useful? Small wonder that by the end of the symposium there was general agreement that the products of the first differentiation of the inner cell mass be designated 'epiblast' and 'hypoblast', in common with avian terminology.

A day of consideration of genetic aspects began with the questions: "How early do genes begin to function in mouse embryos?" and "Is there a genetic programme for the timing of gene expression?" Using β-glucuronidase as a specific product of gene expression in two strains of mice whose rate of synthesis of the enzyme differs, V. M. Chapman (Roswell Park Memorial Institute, Buffalo) suggested that the gene involved is expressed as early as the two-cell stage.

Postimplantation developmental abnormalities were described in a variety of trisomies in mice by A. Gropp (Lubeck Medical School). Like human trisomies, these are all associated with abnormal facial morphogenesis, but the mechanisms are unknown.

Gene action in abnormal preimplantation development of mouse embryos homozygous for the yellow allele of the agouti locus was demonstrated by R. A. Pedersen (University of California, San Francisco) by means of timelapse cinemicrography of cultured embryos. The abnormalities culminating in preimplantation loss consisted of delayed or arrested cell division during cleavage stages, and failure of extension and adhesion of trophoblast cells to the culture dish at the implantation period. One may speculate that the lethal gene affects the synthesis of one of the proteins which are involved in both spindle formation and cell motility or adhesion.

Abnormalities of cell motility and cell–cell interaction are characteristics of abnormal gene expression in T-locus mutant mice. In an ultrastructural study of the lethal t^9-homozygote, Martha Spiegelman (Cornell University Medical College) showed that newly formed primary mesenchyme cells lack subsurface microfilaments, do not make organised cell contacts, and fail to migrate away from the primitive streak. In T-homozygotes the abnormality involves defective development of the basement lamina of the neuroepithelial cells, which are consequently able to make close associations with underlying notochord and somite cells. Thus alterations in the cell surface are of major importance in the changing interactions between cell and environment. In this context, M.

Edidin (Johns Hopkins University) examined three types of antigen, and changes in the concanavalin A binding pattern, as indicators of alterations in cell surface components. The results confirmed that new antigens are expressed during the course of differentiation, and that their quantity alters. Con A receptors come and go on mouse embryonic cells: they increase up to the blastocyst stage, but in the blastocyst itself they disappear from trophoblast cells and are localised exclusively in the inner cell mass.

W. J. Rutter (University of California, San Francisco) showed that actual cell contact may not be necessary for differentiation of the pancreas. The epithelium will develop its characteristic glandular structure when in contact with sepharose beads coated with a factor derived from mesenchyme. The cell surface receptors influence the synthetic abilities of the cell, under appropriate external stimulation. In the context of the cell–cell interactions, the cell surface must be taken to include the surface coat. This was clearly demonstrated by R. O. Kelley (University of New Mexico, Albuquerque), using the epithelial–mesenchymal interaction during human limb morphogenesis as a model system, and an impressive armoury of techniques. The mesenchymal cells have both receptor and catalytic components of the adenylate cyclase system, and the receptivity of this system to exogenous stimulation is potentiated by diminishing or removing the cell surface glycosaminoglycans (GAGs). The fact that trypsin reduces the thickness of cell surface GAGs should be borne in mind by all experimenters using this enzyme.

Although the stability of the differentiated state is still acceptable as a general rule, studies on transdifferentiation (well established in connection with regeneration in amphibia) have now been extended to avian embryos. G. Eguchi (University of Kyoto) showed that in the case of both chick and newt, cloned pigmented retinal epithelial cells will give rise to a few lens cells. The time period is about 90 days in the chick compared with less than 40 in the newt, but the process can be speeded up, *in vivo* as well as *in vitro*, by the use of a small crystal of nitrosoguanidine (a potent mutagen/carcinogen). The outcome of similar experiments on mammalian cell lines is awaited with interest.

Those present at the symposium spanned a great many of the component areas of this exciting field of research. The discussions were both wide-ranging and controversial. Such a stimulating symposium can only add to the accelerating impetus which all areas of developmental biology are undergoing at the present time.

A comet in the Plough

from Robin Scagell
THE first comparatively bright comet to appear since the ill-starred Kohoutek is in the evening sky at the moment, and is making up for its predecessor's fickleness by being readily observable with binoculars. It could well provide an interesting sight within the next few weeks.

Comet Kobayashi–Berger–Milon, named after its three independent discoverers, was first spotted from Japan on July 2, and has the designation 1975h. It has been moving through the evening sky towards the Sun, to which it makes its closest approach on September 5. Much to the delight of those who spent cold and fruitless vigils trying to glimpse Comet Kohoutek, 1975h has passed almost through the zenith for observers in Britain and America and was easily seen even on nights of full Moon. By July 24, although no tail was noticeable, the object appeared as a fairly large circular diffuse patch of light of about fifth magnitude—just visible to the naked eye.

Kobayashi–Berger–Milon represents a good run of the mill comet which is worth following. It has even had the good sense to appear to mingle with the stars of that best known of all northern constellations, Ursa Major—the Plough or Big Dipper. At the beginning of August it will pass close to the well known double star Mizar, the middle star in the handle of the Plough or Dipper, and should be easily visible with even the smallest pair of binoculars.

Throughout August it will move steadily south-eastwards until it reaches perihelion on September 5 in Leo Minor, where it will best be seen in northerly latitudes at twilight. After perihelion it will become less readily visible.

Three-dimensional structure, function and genetic control of immunoglobulins

Roberto J. Poljak*

Recent crystallographic analyses of the three-dimensional structure of immunoglobulins have shown how it is related to their binding affinities. Considered with evidence from sequencing, it is beginning to cast some light on how the genetics of immunoglobulins could have evolved to maximise binding diversity with a minimal genetic load.

SERUM antibodies are glycoproteins generically denominated immunoglobulins. Although in recent years much progress has been made in analysing experimentally induced antibodies[1], the structure of immunoglobulins has been most intensively studied using human and murine myeloma proteins which provide homogeneous material in the quantity required for structural analysis. It is now widely accepted that antibodies and myeloma immunoglobulins are closely related molecules. The antibody response against a specific antigen (or hapten) is usually degenerate, consisting of a heterogeneous population of molecules, a fact which complicates structural analyses. In contrast, myeloma immunoglobulins are homogeneous but the elucidation of their hapten binding specificity may require an intensive search.

Several classes (or isotypes) of immunoglobulins (Ig) are present in normal or pathological sera and of these the IgG (or γ globulin) class is the most abundant and has been most intensively studied. A diagrammatic representation of a human IgG immunoglobulin is shown in Fig. 1. The comparison of the amino acid sequences of internal segments of the heavy (H) and light (L) polypeptide chains have led to the recognition of homology regions about 110 amino acid residues long[2]. The homology region designated as C_L (Fig. 1) is constant in amino acid sequence and characteristic of a given subclass (κ or λ) of L chains which are present in all immunoglobulin classes. C_H 1, 2, 3 are also constant in sequence and characteristic of a given class or isotype of immunoglobulin defined by its H chain. When the amino acid sequences of different immunoglobulins are compared, the regions designated as V_L, V_H (Fig. 1) show variability, in particular around positions 25–30, 50 and 95–100 in V_L and 30, 55–60 and 105–110 in V_H, positions which are called "hypervariable"[3]. These hypervariable regions have been postulated by many workers to be the determinants of the conformation and specificity ("complementarity") of an antibody combining site, and to be closely related to the "idiotypic"[4,5] antigenic markers which are unique to immunoglobulins secreted by a clone of cells.

Three-dimensional structure of immunoglobulins

Models of Fab' New obtained by X-ray crystallographic analyses at 6 Å, (ref. 6), 2.8 Å (ref. 7) and 2.0 Å (ref. 8) resolution showed that Fab' consists of two globular domains, V and C, separated by an internal space accessible to solvent. Each domain consists of two globular subunits corresponding to the V_L and V_H homology regions in the V domain, and to C_L and C_H1 in the C domain. V_L and C_L as well as V_H and C_H1 are

joined by narrow, linear regions by which the L and H polypeptide chains cross from the V to the C domain. These regions are exposed, accessible to solvent and to attack by agents such as proteolytic enzymes. The overall structure is that of four "homology subunits" in tetrahedral arrangement. In agreement with their sequence homology and the ensuing postulate that they arose from a common ancestral gene[2], V_L, V_H, C_L and C_H1 share a basic pattern of polypeptide chain folding although V_L and V_H include an additional loop of polypeptide chain (Fig. 2). In each homology subunit two irregular, roughly parallel β sheets consisting of strands of antiparallel polypeptide chain surround a tightly packed interior of hydrophobic side chains including the intrachain disulphide bond. In the variable homology subunits V_L and V_H, the hydrophobic interior consists of invariant or semi-invariant amino acid side chains. The same overall pattern of polypeptide chain folding was observed in the 3.5-Å resolution structure of the Mcg L-chain dimer[9]. Different arrangements of interchain disulphide bonds which occur in other immunoglobulin molecules could be explained on the basis of the Fab' New model. Since these different disulphide bonds occur in macroglobulins (IgM), in
Fig. 1 Diagrammatic structure of a human IgG1 molecule. The light chains are divided into two homology regions, V_L and C_L. The thicker lines in the heavy chains correspond to the "hinge" region. The four homology regions (V_H, C_H1, C_H2, and C_H3) of the heavy chains, the interchain and intrachain disulphide bonds, the N-terminal region of both chains, and the major fragments (Fab, Fab', Fc) are indicated. Reproduced from Poljak[33].

*Department of Biophysics, Johns Hopkins University School of Medicine, Baltimore, Maryland 21205.

secretory immunoglobulins (IgA) and in other immunoglobulin isotypes, it was postulated[7] that the basic immunoglobulin fold (Fig. 2) is present in all classes of immunoglobulins. This postulate was given substantial support by the results of the crystallographic analysis[10] of the Fab fragment from the McPC 603 IgA, a murine immunoglobulin secreted by cells of an experimentally induced mouse myeloma tumour. The H (α) and L (κ) polypeptide chains present in this immunoglobulin are of different isotype from the corresponding chains of the human Fab′ but the overall three-dimensional structure is similar. Further, the high resolution structure of the variable part of a human κ chain (a Vκ dimer) indicated the same folding of the polypeptide chain[11]. At the present stage of the structural analysis of immunoglobulins the postulate that they all share a common pattern of three-dimensional structure (Fig. 2) can be accepted with reasonable confidence. The "hinge" region connecting Fab to Fc is not included in this pattern; different isotypes of immunoglobulins differ in this region which determines a segmental flexibility[12]. Within one isotype of immunoglobulin, the region that determines the antigen combining site (or active centre) makes for variability in structure and function.

The combining site

The atomic resolution model of the human Fab′ fragment[7] showed that the hypervariable regions of both L and H chains occur at one end of the molecule, in spatial proximity and fully exposed to solvent with all the characteristics of a combining site. A similar observation was made in the structure of Fab from the McPC 603 IgA (ref. 10). Thus, different immunoglobulins will present a unique, idiotypic structure at this end of the molecule. In the L chain dimers Mcg[9] and Rei[11] there is a cavity surrounded by the hypervariable regions of both chains which resembles the combining site of the Fab fragments, although it is wider and symmetrical around a central twofold rotation axis. The combining site of IgG New consists of a shallow groove, about 15 × 6 Å, with a depth of about 6 Å. The active centre of McPC 603 is deeper (about 12 Å) than that observed in IgG New. This increased depth can be attributed in part to the fact that the first hypervariable region of the κ (L) chain of McPC 603 is six amino acids longer (by an "insertion" of the type shown in Fig. 3 for human Vκ_III sequences) than other murine and human κ and λ chains. This inserted sequence protrudes to form a "deeper" active site. It follows that the pattern of insertions and/or deletions, characteristic of the hypervariable regions (in particular around residue 105 in human H chains) will be the major determinant of the dimensions of the active site. Variations in sequence or amino acid replacements which are also a characteristic of those regions will determine the chemical environment of the site. Thus, different antibodies may display unique antigen complementarity sites although they share a common three-dimensional structure. A vast number of recognition specificities can be incorporated in this design, although a constant, compact immunoglobulin fold is maintained. A further consideration is that, since both H and L chains contribute to the combining site, random pairing could give rise to a large number of different combining sites (n^2) with a much smaller number (n) of H and L chains, further extending the economy of structural design. The number of germ line structural genes required to encode all necessary H and L chains in an immunologically mature animal would thus approach a reasonably small value ($n \leqslant 10^3$) when compared with the total number of structural genes in the genome of vertebrates. Evidence of recombination of H and L chains *in vitro* has been obtained in several laboratories (for reviews see refs 13 and 14); and the possibility that recombination is restricted to mutually compatible H and L chains has also been submitted to limited experimental tests[13,15]. Experimental tests of *in vitro* recombination of H and L chains would however have to cover all possible subgroup and isotype permutations (subgroup is used to designate a set of V_H or V_L sequences which are similar or more closely related to each

other than to those of another subgroup). A study of this problem by analysis of the interactions between V_L and V_H in the three-dimensional structure[16] reveals close interactions between amino acid side chains at positions 35, 37, 42, 43, 86 and 99 in V_L and at positions 37, 39, 43, 45, 47,95 and 108 in V_H. These positions are occupied by constant residues or by fairly conservative replacements in human V_L and V_H sequences as well as in V_L and V_H sequences that have been studied from other animal species. Furthermore the amino acid sequences of human κ and λ chains are very similar at these positions: almost all human L chains have Tyr (35), Gln (37), Ala (42), Pro (43), Tyr (86) and Phe (99). L chain positions 88 and 90 occur at the active site and also seem to provide for V_L–V_H interactions but the importance of these interactions is more difficult to assess because they could be affected to some degree by the conformation of the last hypervariable region of V_H; even so there are preferred residues at these positions: Gln (88) and Trp/Tyr (90). In the C_L region κ and λ chains share the sequence of residues which interact with C_H1. Thus, the interactions between V_H and V_L, which should provide the stereochemical basis for their association, seem to be independent of H and L chain subgroups or even L chain class. Although preferred associations could occur under genetic control there is no apparent structural basis for restricted pairing. Different H, L chain associations could be expressed under selective stimulation by antigens, thus making use of all the structural information contained in the genome.

Fig. 2 Diagramm of the basic 'immunoglobulin fold'. Solid trace shows the folding of the polypeptide chain in the constant subunits (C_L and C_H1). Numbers designate L (λ)-chain residues, beginning at "NH_3+" which corresponds to residue 110 for the L chain. Broken lines indicate the additional loop of polypeptide chain characteristic of the V_L and V_H subunits.

Fig. 3 Amino acid sequences of the N-terminal region of human κ chains arranged in subgroups, Vκ$_I$, Vκ$_{II}$ and Vκ$_{III}$. Reproduced from Gally and Edelman[34].

In human L chains, subgroups can be defined by (or correlated with) the presence of insertions (or deletions) in the first hypervariable region (Vκ, Vλ) and also in the third hypervariable region (Vλ). Consequently, these subgroups define different conformations of the active site, as discussed above. For example, human κ chains of subgroup III (Vκ$_{III}$, see Fig. 3) will delineate a "deeper" active site such as that observed in the murine myeloma protein McPC 603 (ref. 10) than will a κI or a λ chain. Since murine λ chains seem to lack the pattern of deletions and/or insertions at the hypervariable regions characteristic of murine κ and human κ and λ chains, they should be expected to make a smaller contribution to the diversity of antibodies. Thus the number of genes encoding λ chains or their expression in mice would be limited relative to κ chains as reflected in the κ/λ serum ratio[17].

Hapten binding, cross reaction and multispecificity

An increasing number of human and murine myeloma proteins has been shown to bind ligands in a reaction that closely resembles that of a specific hapten–antibody system[18,19]. A number of mice myeloma proteins that bind phosphorylcholine share idiotypic determinants with induced anti-phosphorylcholine antibodies indicating the antibody function of these immunoglobulins[18]. Although McPC 603 IgA does not share this idiotypic specificity it binds phosphorylcholine. Crystallographic analysis of the Fab–phosphorylcholine complex revealed that phosphorylcholine binds close to heavy chain residues, occupying a relatively small region of the combining site. No major conformational change was observed in the Fab structure after ligand binding. IgG New binds a number of ligands such as menadione, orceine, uridine and others with a low affinity constant ($K_0 = 1 \times 10^3$ L/M), and a γ-hydroxy derivative of vitamin K_1 (vitamin K_1OH) with a higher affinity constant ($K_0 = 1.7 \times 10^5$ L/M)[20]. Crystallographic studies[21] of the complexes between these ligands and Fab' New showed that vitamin K_1OH binds at the combining site, making contact with a number of amino acid chains of the hypervariable regions of the L and H chains; the other ligands bind at the same site occupied by the naphthoquinone moiety in the vitamin K_1OH–Fab' New complex. Since the affinity constants for these compounds are lower than that observed for vitamin K_1OH it was concluded that the total binding energy in the Fab' New–vitamin K_1OH complex is derived from contacts made by the naphthoquinone moiety and by the phytyl chain with the side chains at the active site. As in the case of the McPC 603 Fab, no major conformational change took place after binding of vitamin K_1OH to Fab' New. These studies provided firm experimental evidence for the concept that the hypervariable regions of H and L chains determine the conformation of the combining site and a preliminary structural model for the interactions between antigens and antibodies. Ligand binding studies have also been conducted with the Mcg L-chain dimer

which has been postulated to represent a primitive antibody molecule[22]. By crystallographic analysis a number of ligands were shown to bind in the vicinity of hypervariable and constant residues of the Mcg L chain.

Using the amino acid sequence and the three-dimensional structure of Fab' New as a basic structural model, a correlation between the structure and function of the well characterised MOPC 315 anti-2,4-dinitrophenyl (DNP) mouse myeloma protein has been made[8]. The L (λ) chains of IgG New and MOPC 315 IgA are highly homologous in their first and third hypervariable regions where they contain a similar number of amino acid residues; also, the sequences of V$_H$ New and V$_H$MOPC 315 are closely related in number of amino acid residues at their hypervariable regions. Therefore, the V$_L$ and V$_H$ sequences of MOPC 315 can be made to fit the basic structure of the active site of IgG New. In this tentative model, MOPC 315 IgA has a shallow combining site with a high density of Trp, Tyr and Phe residues in close correlation with the observed specificity of MOPC 315 IgA for DNP, menadione, flavin mononucleotide, vitamin K_1 and other haptens which include aromatic rings in their structure[23]. IgG New and IgA MOPC 315 have nearly equal avidities for vitamin K_1 and each binds additional ligands not bound by the other. This observation of two binding sites that partially overlap in their ligand-binding spectrum can be taken as support for the postulate that antibodies are multispecific[24,25]. Thus, different antibodies will cover a wide spectrum of antigens with partially overlapping domains of specificity, leading to degenerate immune responses. The mode of binding could be common to a group of chemically related ligands such as DNP, vitamin K_1, menadione, and so on, which share aromatic ring structures. Different affinity constants will be observed in these ligand–antibody complexes reflecting a different number of additional chemical contacts and interactions. A gene pool encoding these multispecific antibodies would be smaller than one encoding monospecific antibodies and each of its structural genes would naturally be subject to repeated induction and expression. The selective advantages of carrying such a genetic pool would ensure its maintenance against genetic drift and spontaneous deleterious mutations.

Three-dimensional structure and variation in immunoglobulin sequences

Variations in the amino acid sequences of the L and H chains can be analysed in terms of their three-dimensional structure. A striking example of the relationship between a deletion (or insertion) and the tertiary structure is observed at positions 27a, 27b and 27c in human L (λ) chains. These residues form part of a single turn helical loop which can be deleted without creating a gap or other major alteration in the path of the polypeptide chain[7]. Deletions also occur in segments of the polypeptide chains of immunoglobulins outside the hypervariable regions. Two examples with a clear structural correlation can be given

here. The first is that of the deletion of residues numbered 54 to 60 in the amino acid sequence of the L chain of IgG New[7]. These residues very nearly constitute the loop of polypeptide chain which is characteristic of the variable regions (V_L, V_{II}) of immunoglobulins and which does not occur in the constant regions C_L, C_H1 (Fig. 1). An integral deletion of this loop can be easily visualised in a three dimensional model of V_L (Fig. 2) and evidently results in a stable tertiary structure similar to that of C_L. A second example is that of the deletion of an entire homology region, which occurs in H chains synthesised by human tumour cells in the "heavy chain disease"[26] and in murine myeloma H chains[27,28], beginning at the start of the C_H1 region (position 119) or before, and ending at position 215, close to the beginning of the C_H2 region. In the three dimensional structure the sequence . . . Val-Ser-Ser shared by γ and μ chains[29], clearly constitutes the end of V_H, and after a sharp bend, position 119 marks the beginning of the C_H1 homology subunit. Complete deletion of C_H1 should not affect the molecular interactions of C_H2 and C_H3, leading to a compact, stable Fc-like molecule with an N-terminal appendix of variable length.

Variations in the amino acid sequences of V_L and V_H which do not affect the length of the polypeptide chains ("point mutations") also have structural correlations[8]. For example, invariable or semi-invariable glycine residues occur at bends (hairpin loops) of the polypeptide chains or at internal points of close contact between two strands of polypeptide chain where larger side chains could not be accommodated; other constant or nearly constant residues are involved in close contacts between V_H and V_L (discussed above), make intrachain hydrogen bonds, or occur in the tightly packed interior of the structure between two β sheets. Multiple mutations that alter these residues to other sequences compatible with an energetically stable, constant three-dimensional structure can best be explained by a process of evolutionary germ-line gene divergence rather than by selection of random somatic mutations. In contrast, the amino acid residues that constitute the hypervariable regions and the antigen complementarity site are not subject to visible structural constraints.

A comparison of the amino acid sequence of β_2-microglobulin with those of the constant regions of immunoglobulins reveals a striking homology[30] indicating that the overall polypeptide chain folding of β_2-microglobulin is similar to the folding of the C regions of immunoglobulins (Fig. 2). This homology includes the hydrophobic amino acid side chains by which C_L and C_H1 interact to form a compact C_1 structural domain. The extent of sequence homologies with the C regions of immunoglobulins further suggests that β_2-microglobulin interacts with another polypeptide chain that shares the basic immunoglobulin fold (Fig. 2). This common structural folding may be reflected in the amino acid sequences of the proteins bearing the murine H-2K, H-2D or the human HLA-K, HLA-D antigenic specificities and which interact with β_2-microglobulin in cell membranes. The structural similarities

between histocompatibility antigens and immunoglobulins suggest a common genetic origin and subsequent steps of translocation and duplication[31].

The basic polypeptide chain folding of immunoglobulins (Fig. 2) has recently been observed in the Cu, Zn enzyme superoxide dismutase from bovine erythrocytes[32]. A comparison of the structure of superoxide dismutase with that of the C and V regions of immunoglobulins indicates that the basic framework pattern of β sheets is present in all three; in superoxide dismutase and in the V regions there are insertions (such as in the hypervariable regions) which presumably have been positively selected through evolutionary events to optimally fulfil a specific biological function. Since the superoxide dismutase activity is present in many organisms including prokaryotes the "immunoglobulin-fold" may indeed turn out to be the expression of a widespread, ancient gene.

Signal-to-noise ratio of electron micrographs obtained by cross correlation

J. Frank & L. Al-Ali

Cavendish Laboratory, Cambridge, UK

The signal-to-noise ratio of electron micrographs can be determined by two-dimensional digital cross correlation even though neither signal nor noise can be analysed separately. Such measurements suggest how best to make use of the electron microscope.

HIGH resolution electron micrographs contain a large amount of detail that is not related to the object structure and is commonly referred to as noise. The relative amount of significant information compared with noise in the image can be expressed in terms of the ratio of signal variance to noise variance, or signal-to-noise (s/n) ratio. The s/n ratio is an important criterion for

the quality of the electron micrograph, and for the imaging process by which it is obtained. Unfortunately, no exactly defined electron microscopic model object is available from which the relative portion of the signal variance in the image could be inferred; hitherto, therefore, the s/n ratio has been a merely theoretical concept. Using a cross-correlation technique, we have studied the defocus dependence of the s/n ratio for a carbon film micrograph and found a characteristic behaviour which closely follows the predictions of linear contrast transfer theory, if one takes into account the effects of partial coherence and energy spread and assumes purely elastic scattering.

Our results support the view that, for thin biological objects and bright field illumination, elastic scattering plays the dominant role in contrast formation. They also stress the importance of the underfocus range for practical work and suggest a way of achieving accurate reproducible focusing of instrument with on-line image readout.

The technique

It has been suggested[1] that the sample cross-correlation coefficient could be used for estimating the s/n ratio of band-limited stochastic time functions, if two different versions of the desired signal disturbed by uncorrelated noise are available, each as a series of N time samples taken at a rate equal to twice the bandwidth. The sample cross-correlation coefficient of two series x_i, y_i with zero lag is defined as

$$r_N = \frac{\langle(x_i-\langle x_i\rangle)(y_i-\langle y_i\rangle)\rangle}{\{\langle(x_i-\langle x_i\rangle)^2\rangle\langle(y_i-\langle y_i\rangle)^2\rangle\}^{1/2}}$$

where the angle brackets denote averaging. Assuming stationary Gaussian zero-mean statistics for both signal and noise one obtains the s/n estimate

$$\alpha = \exp[-2/(N-3)](r_N/(1-r_N)+\tfrac{1}{2})-\tfrac{1}{2}$$
$$\approx r_N/(1-r_N) \quad \text{for large } N \qquad (1)$$

The formula for large N can be shown to be identical with the formula that generally relates the s/n ratio of two continuous series to their cross-correlation coefficient, irrespective of the statistical distribution of noise and signal. In image processing application where N is of the order of 10,000, the Gaussian assumption can therefore be dropped.

We have adopted this method of s/n measurement for the quantitative analysis of electron micrographs of a thin amorphous carbon film, and found excellent agreement between the defocus dependence of α obtained from two-dimensional digital correlation, and the theoretical behaviour expected for weakly elastically scattering objects ('weak phase objects').

In these conditions, the action of the electron microscope can be considered[2] as that of a linear system with transfer function $H(k)$ (k spatial frequency), with the projected potential of the object as 'input' and the image intensity recorded on the photographic plate as 'output'. The transfer function[3] describes the distorting and resolution limiting effects due to spherical aberration, defocusing, axial astigmatism, energy spread[4] and partial coherence [5,6]. Assuming an input with power spectrum $P(k)$ and additive signal-independent noise on the output side, the s/n ratio of the output becomes proportional to the signal variance[7].

$$\text{var}(s) = \int |H(k)|^2 P(k)\mathrm{d}k \qquad (2)$$

where the integration extends over the range of spatial frequencies within the bandlimit of the system.

Studies of carbon film

Pairs of electron micrographs of a thin (≈ 100 Å) carbon film were available, each pair taken with a different defocus but in otherwise identical conditions. Assuming a stable specimen, each pair contains the same signal portion distorted by the instrument in a characteristic way, with a superposed noise

portion that is due to the photographic grain and electron noise and is by first approximation additive to the signal. For the experiment, a JEM 100B electron microscope was used at 100 kV, ×200,000 magnification and large objective aperture (≈ 0.5 Å^{-1}). Defocus values and astigmatic focus difference (250 Å) were determined by optical diffraction using Thon's[8] method of evaluation, whereas the divergence of illumination (semiangle 2.7×10^{-4} rad) and the energy spread (1.8 eV) were obtained from bandlimit measurements (J.F., unpublished) using Young-type optical interference[9] for each micrograph pair. From these parameters, the transfer function can be constructed for any defocus value (Fig. 1). As power spectrum, the intensity curve for elastic scattering of thin amorphous carbon films as obtained by electron diffraction[10] was used. The overall behaviour of this function can be approximated in the interesting spatial frequency range by $P(k)\sim\exp(-|k|/\mathscr{H})$ with $\mathscr{H} = 0.18$ Å^{-1}. Since the highest bandlimit observed in the optical interference experiment was 0.38 Å^{-1}, the integration limit for the computation of the integral (2) was set at 0.4 Å^{-1}. For simplicity, the transfer functions were taken to be rotationally symmetric. As the astigmatism is very small, this approximation was expected to cause no appreciable error. The theoretical s/n ratio so obtained is shown in Fig. 2 as a function of defocus. For comparison, the case of a 'white' object spectrum $P(k) =$ constant was also considered (Fig. 3).

Broadly, the s/n ratio increases with increasing defocus and shows an oscillatory behaviour at positive defocus (that is, underfocus), with the maxima lying just above the defocus positions $[(2n+1)C_s\lambda]^{1/2}$; $n = 0, 1, 2...$ (C_s spherical aberration constant, λ electron wavelength) where large transfer intervals appear in the transfer function. For carbon scattering, the absolute maximum is assumed at $n = 0$ ('Scherzer focus'), whereas it appears at higher defocus values for 'white' scattering. Even if one ignores the oscillations, the curve is remarkably asymmetric about $\Delta z = 0$. Computations with different illumination and energy spread parameters show that this behaviour is typical for imaging conditions where the resolution is limited by illumination divergence rather than energy spread.

The electron micrographs were copied from plates (Ilford EM4) on to fine grain film (Ilford N4E.50). This process is linear within 4% in the interesting density range, as checked by calibration, and does not affect the s/n ratio appreciably. The images were scanned using a Joyce-Loebl Scandig densitometer, with a sampling distance of 25 µm, corresponding to optimum sampling[11] of data with a bandlimit at 0.4 Å^{-1}. The digital data were recorded on magnetic tape and processed using the IMPROC image processing software system[12]. The images were aligned using cross correlation[13], and the orientation checked by rotational correlation techniques[14]. For the computation of the cross-correlation coefficients, matrices of size 128×128 were selected from the scanned data. Since a sizeable portion of the full cross-correlation matrix had to be examined in the context of another study, the computation was done by using the Fourier relation, by forming the conjugate product of the respective discrete transforms, inverse transformation, and appropriate normalisation. As a check on the assumption of stationarity, the cross-correlation coefficient was computed for different areas of the scanned image field, and was found
Fig. 1 Electron microscopic phase contrast transfer function for defocus $\Delta z = 1,860$ Å, spherical aberration constant $C_s = 1.8$ mm, electron wavelength 0.037 Å, chromatic aberration constant $C_c = 1.4$ mm, energy spread halfwidth $\Delta E = 1.8$ eV, and Gaussian source distribution with halfwidth 5.4×10^{-4} rad. The transfer function is computed from the coherent transfer function by using the envelope representations [5,6].
Fig. 2 Theoretical s/n ratio of electron micrographs of carbon as a function of defocus, and experimental s/n ratios α and $\tilde{\alpha}$ of a defocus series obtained from cross correlation (error bars) and from variance measurements (dots), respectively. The theoretical curve was scaled to fit the α measurements at $\Delta z = 790, 1,320, 1,860$ and $2,390$ Å optimally. The sections of the theoretical curve which lie within the horizontal error margins of the α measurements are marked by dotting.

reproducible within 5%. The s/n ratio α was calculated using formula (1). The result was corrected for the decrease of the s/n ratio due to the densitometer. Detailed analysis leads to a correction formula of the form

$$1 + 1/\alpha_{true} = (1 + 1/\alpha)/(1 + 1/\alpha_d)$$

where the s/n ratio of densitometer measurement, α_d, is obtained from the cross correlation coefficient of two scans of the same image. For our measurements, α_d was found to be between 50 and 90. The resulting α_{true} values are plotted in Fig. 2, with the horizontal bars indicating the inaccuracy of defocus determination, estimated at ± 50 Å, and the vertical bars the error limits due to the α_d range and the fluctuation of r when measured in different areas. The scaling factor for the theoretical curve was chosen in such a way that optimum fit occurs for the measurements at $\Delta z = 790, 1,320, 1,860$ and $2,390$ Å.

Interpretation

Theoretically, we expect some deviation of the measured values from the theoretical curve because the latter does not account for the change of noise variance with the signal variance that can be expected for a Poisson process. The defocus dependence of the experimental values is nevertheless in excellent agreement with the predicted behaviour: the measured s/n values are low and follow a flat curve at negative defocus, they then jump to a high value between the Gaussian and the Scherzer focus, and follow the predicted variations at the sampled defocus positions. (Corroborating the detailed structure of the theoretical curve at positive defocus by experimental data would be a formidable task with the method used, involving the evaluation of dozens

Fig. 3 Theoretical s/n ratios of electron micrographs for 'white' object scattering with arbitrary scale.
of micrograph pairs. It would be more adequate for this purpose to analyse electron micrographs obtained with a tilted stage which contain the entire defocus range of interest at once[15]. Data of this type are being evaluated at present, so that results on the continuous defocus dependence of the s/n ratio will soon be available (Kübler and Downing, private communication).) As an independent check of the experimental values, we have computed the variances of all image pairs var(i) ,and the variance of an image obtained with free electron exposure in the same optical density range, var(n). From these variances we obtain again with the assumption of additive superposition and uncorrelated noise,

$$\tilde{\alpha} = (var(i) - var(n))/var(n)$$

(Strictly speaking, these s/n estimates should be closer to the theoretical curve than the ones obtained by correlation, since they are obtained with the assumption of signal-independent noise variance.) We found good agreement between α and $\tilde{\alpha}$ (dots in Fig. 2) in the range of small α, and general agreement for large α. The two measurements marked by arrows belong to images whose histograms show a sharp peak on top of a Gaussian appearance. The origin of this artefact, which is missing in the corresponding twin image histograms, is unknown but it is thought that it is responsible for the large deviation of $\tilde{\alpha}$. On the other hand, no reason could be found for deviations at $\Delta z = 1,860$ Å and $3,900$ Å. These discrepancies will be investigated further.

Several conclusions can be drawn from the results of our study: (1) the satisfactory agreement between experimental and theoretical defocus dependence suggests that the linear transfer theory gives an adequate description of contrast formation in the conditions prevailing in the experiment, which are typical for electron microscopy of thin biological specimens; (2) in particular, since the fit of the theoretical curve to the experimental data was achieved by using a scaling factor only, it can be concluded that all those scattering processes ignored in our treatment, which could produce an image with defocus-dependent variance, make only a negligible contribution to the image contrast, such as inelastic scattering[16]; (3) with regard to efforts to retrieve the original object function by restoration techniques, it is important to know that the amount of information is maximised at distinct defocus values. For our experimental conditions, the first four maxima have approximately the same height. On the other hand, it is known from the study of partially coherent transfer functions[17] that with increasing defocus the relative portion of high resolution information passed to the image increases. It may therefore be preferable, for the purpose of subsequent processing, to use defocus values larger than the Scherzer focus in the experiment, even though the electron micrographs may become less intelligible for direct interpretation; (4) as a practical conclusion, our measurements show that for the normal partially coherent illumination used, the gain in s/n ratio lies between two and three if one goes from overfocus to underfocus; (5) in the underfocus range, the positions of maxima and minima are fixed for a given instrument and may therefore be used as absolute focus references, possibly in connection with an objective current wobbler and on-line image readout, complementing methods recently proposed for controlled focusing[18].

The method of measuring the s/n ratio by cross correlation is not restricted to phase contrast electron microscopy, or electron microscopy for that matter; it could be used quite generally, as a performance criterion of electron optical and light optical systems as well as new imaging and recording techniques.

E. coli membrane lipid alteration affecting T4 capsid morphogenesis

Lee D. Simon, Thomas J. M. McLaughlin, Dale Snover*, Jonathan Ou, Charles Grisham† & Marilyn Loeb

The Institute for Cancer Research, The Fox Chase Center for Cancer and Medical Sciences, Philadelphia, Pennsylvania 19111

An Escherichia coli *mutant,* hd *B3-1, cold sensitive for* T4+ *capsid assembly is described. The* hd *B3-1 character seems to be caused by altered lipid components of the bacterial inner membrane. The genetic locus for the* hd *B3-1 phenotype is designated* fat A *and is closely linked to proline.*

THE *E. coli* B inner (cytoplasmic) membrane has been implicated in the assembly of bacteriophage T4+ heads. Electron micrographs of sections through cells fixed shortly after infection show amorphous lumps of viral head proteins associated with the bacterial inner membrane. These lumps form intermediate membrane-bound structures called τ particles which mature into empty phage heads that move from the inner membrane to the cytoplasm, where they are filled with DNA[1]. Host factors thus seem to be involved in T4+ head morphogenesis, and we, as well as other investigators, have been able to isolate host cell mutants which enable T4+ phage adsorption but not capsid assembly.

Three *E. coli* strains defective for T4+ capsid formation have been described[2–4]; in these host-defective (*hd*) cells, T4+ head production seems to be blocked at an early stage of assembly. Normal T4+ head precursor proteins are present but are not processed to the cleaved forms found in the mature capsid structures, and only lumps of head proteins are seen on the bacterial inner membrane. Until now, no direct evidence has been presented to indicate the nature of the host block. Specific T4 mutants in gene 31 are able to overcome this host defect in phage formation. In T431⁻ infection, the major capsid protein accumulates in 'lumps' on the *E. coli* inner membrane[5], indicating that the product of gene 31 (p31) may affect the association of T4 head proteins with the host cytoplasmic membrane.

The results presented here describe an *E. coli* mutant, *hd* B3-1, that is cold sensitive for T4+ head formation. Evidence is presented to show that the defect in *hd* B3-1 is associated with an altered lipid component of the cytoplasmic membrane.

Physiology of T4+ infection of *E. coli hd* B3–1

E. coli hd B3-1 is an N-methyl-N′-nitro-N-nitrosoguanidine derivative of *E. coli* B. Within 10 min after the addition of T4+ phage at a multiplicity of infection (m.o.i.) of five phage per cell to mid-log phase *hd* B3-1 bacteria at 30 °C, more than

90% of the cells lose their colony forming ability. *In vitro* complementation tests (data not shown) and electron microscopic studies (Fig. 1) indicate that at 27 °C no detectable T4+ capsids are produced in *hd* B3-1, although tails and tail fibres are made in approximately normal amounts. At 27 °C head assembly does not proceed beyond the stage of membrane-bound lumps; bands of detectable T4+ head proteins, however, are visible on SDS polyacrylamide gels (Fig. 2). At 41 °C, the infected cells produce an average of 50–80 phage per cell.
Fig. 1 Electron micrographs of negatively stained crude lysates from T4+-infected *E. coli* B3-1 bacteria. In these and in all subsequent experiments, T4+ refers to T4D phages and unless stated otherwise, mid-log phase bacteria growing in L-broth[1] were used. ×58,500 *a*, Bacteria were grown and infected at 41 °C with T4+ particles at m.o.i. four phages per cell; 5 min later the cells were superinfected with T4+ particles (m.o.i. = 4) to inhibit lysis. *b*, Prepared similarly to *a*, except temperature was 27 °C.

a b c d
Fig. 2 Autoradiograph of an SDS acrylamide gel showing the phage proteins in T4⁺-infected *hd* B3-1 cells. *E. coli hd* B3-1 and *E. coli* B were grown in LSTG medium (6.4 ml 0.1 M KH₂PO₄, 1.6 ml 0.1 M Na₂SO₄, 2.0 ml 0.5 M MgCl₂, 100 ml 10× low salts, 100 ml 1.0 M Tris, *p*H 7.4, 100 ml 20% glucose, H₂O to 1,000 ml; 10× low salts contains 5.4 g NaCl, 3.0 g KCl, 11.0 g NH₄Cl, 10 ml 0.1 M CaCl₂, 10 ml 0.1 M FeCl₃, H₂O to 1,000 ml). The cultures were then infected (m.o.i. = 3) and super-infected (m.o.i. = 3) 7 min later with T4⁺ particles or with T4*am*H11 (23⁻) mutants. A mixture of ¹⁴C-amino acids (20 μCi ml⁻¹) and ³⁵S-methionine (20 μCi ml⁻¹) was added to the cultures 12 min after infection. The bacteria were pelleted 35 min after infection; the pellets were heated to 100 °C for 2 min in 1% SDS and 1% β-mercaptoethanol. The denatured proteins were run on SDS acrylamide (10%) slab gels for 5.5 h at 80 V, after which the gels were dried. Autoradiographs were then made to enable visualisation of the protein bands. *a* and *b hd* B3-1 infected with T4⁺ phage at 27 and 41 °C, respectively; *c*, B infected with T4⁺ phage. *d*, B infected with T4*am*H11 mutant. p23 and p22 are unprocessed capsid proteins. p23ᶜ is the processed form of p23 found in normal T4 heads; p22 is degraded during capsid morphogenesis²². Following T4⁺ infection of *hd* B3-1 at 41 °C, p23ᶜ is formed and p22 is degraded, whereas at 27 °C, p23ᶜ does not appear and p22 accumulates.

Intermediate temperatures lead to the production of intermediate numbers of complete phage (Fig. 3). Thus, there is a cold-sensitive block in *hd* B3-1 which affects T4⁺ head assembly.

T4⁺ heads can be found soon after shifting a T4⁺-infected *E. coli hd* B3-1 culture from restrictive (30 °C) to permissive (41 °C) temperature 25 min after infection (Fig. 4). Complete phage appear within 4 min after the shift. Conversely, a temperature shift of T4⁺-infected *hd* B3-1 cells from 41 to 30 °C 25 min after infection causes a rapid decrease in phage production (Fig. 4). In other experiments (data not shown) shifting *hd* B3-1 cultures from 20 to 30 °C and from 20 to 41 °C at the time of T4⁺ infection, phage capsids were produced only in the cultures shifted to 41 °C. T4⁺ capsid assembly in *hd* B3-1, therefore, requires temperatures approaching 41° C, regardless of previous culture conditions.

In addition to *E. coli* strains B and *hd* B3-1, the results reported below include *E. coli* B3-1ʳᵉᵛ, a spontaneously arising mutant of *hd* B3-1 which plates T4⁺ phages as efficiently as B between 24 and 41 °C. For all experiments the bacteria were growing rapidly, approximately in mid-log phase (4.5 × 10⁸ cells ml⁻¹).

E. coli hd B3–1 inner membrane

As the host cell membrane seems to play a part in T4⁺ head assembly¹, and as changes in membrane fluidity as a function of temperature may relate to the temperature-dependent *hd* B3-1 block in capsid assembly, we suspected that *hd* B3-1 may possess an altered cytoplasmic membrane. SDS polyacrylamide gels of inner membranes from *hd* B3-1 and B showed identical protein bands. Therefore, we investigated the possible relationship between the host defect and altered inner membrane lipid components.

To determine whether the effect of temperature on T4⁺ capsid production in *hd* B3-1 is related to the mobility of the inner membrane lipids, we used electron spin resonance spectroscopy (ESR). Electron spin-labelled methyl esters of fatty acids

$$I_{m,n} = CH_3(CH_2)_m - \underset{\underset{\displaystyle N \to O}{O}}{C} - (CH_2)_n - COOCH_3$$
were used to examine the mobility of the lipids of purified⁶ bacterial inner membranes. The membranes were labelled with either 6-(4′,4′-dimethyloxazolidinyl-N-oxyl) heptadecanoate (I₁₀,₄) or 12-(4′,4′-dimethyloxazolidinyl-N-oxyl) stearate (I₅,₁₀); electron spin resonance (ESR) spectra were then
Fig. 3 Phage production following T4⁺ infection of *E. coli hd* B3-1 and *E. coli* B. Bacteria growing at various temperatures were infected with T4⁺ particles (m.o.i. = 5) and 5 min later they were superinfected (m.o.i. = 5). ▲, B 30 °C; ●, B3-1 27 °C; △, 30 °C; ×, 33 °C; ▽, 37 °C; ○, 41 °C. Anti-T4 serum was added 8 min after infection; 10 min after infection the bacteria were diluted × 10⁴ to prevent inactivation of progeny phages by the antiserum. At various times, samples were removed from the infected cultures, exposed to chloroform to lyse the bacteria, and assayed for plaque forming particles to determine phage production.
Fig. 4 Effects of temperature shifts 25 min after T4+ infection on phage production in *hd* B3-1. Conditions were similar to those described for Fig. 3, except that 25 min after infection the 30 (▼, △) and 41 °C (○,●) cultures were each divided into two equal parts; one part was maintained at the same temperature whereas the other part was shifted from the initial temperature of 30 to 41 °C (△) or from the initial temperature of 41 to 30 °C (●).

obtained over the temperature range 3–60 °C. The ratio (B/A) of the mid-field peak intensity to the low field peak intensity was taken as a measure of membrane fluidity. B/A values of nearly 1.0 are characteristic of very fluid, isotropic motion of the spin-labelled fatty acid ester, whereas values greater than 1 typically indicate more restricted motion of the spin-labelled molecule.

A discontinuity in a membrane fluidity profile indicates a transition in the physical state of the spin-labelled fatty acid esters. A discontinuity may indicate true phase transition, that is, a melting of the lipid chains where they are in a solid or ordered state below the transition temperature and are in a fluid or disordered state above the transition temperature[7]. Alternatively, a discontinuity may indicate lateral phase separations of the type described by Shimshick and McConnell[8] and Linden et al.[9], which involve the clustering of membrane lipids into solid phases, liquid phases and solid–liquid phase mixtures. Lateral phase separations require the occurrence of rapid lateral motion of lipids in the bilayer; this has been observed in several systems[8,10].

The data obtained with the $I_{10,4}$ label (Fig. 5a) and with the $I_{5,10}$ label (Fig. 5b) indicate that the purified *E. coli* B inner membranes are more fluid than the *hd* B3-1 or B3-1 rev membranes throughout most of the temperature range. Furthermore, discontinuities are observed in all of the fluidity profiles. With the $I_{10,4}$ label, the *E. coli* B and *hd* B3-1 membranes exhibited discontinuities at 38.4 and 48 °C, respectively; with $I_{5,10}$ label discontinuities were seen at 31.7 °C for B and at 47 °C for *hd* B3-1. The B3-1 rev membranes exhibited discontinuities at both 21 and 29 °C with $I_{10,4}$ and at both 19 and 27 °C with $I_{5,10}$. Thus, the temperature at which a discontinuity appears in the membrane fluidity profile is much higher for *hd* B3-1 than for either B or B3-1 rev.

To investigate the chemical bases for these observations, we examined inner membrane phospholipid compositions. Cells were grown for 12 h in medium containing inorganic[32]P-phosphate to label membrane phospholipids. Subsequently, inner membranes were purified from the bacteria; the phospholipids were extracted by the procedure of Bligh and Dyer[11], and the various phospholipid classes were separated by ascending one-dimensional thin-layer chromatography. Phospholipid spots were identified with iodine vapour, ninhydrin, and molybdate reageant[12].

After labelling for 12 h (Table 1) *hd* B3-1 inner membranes had 39% more cardiolipin and 27% less phosphatidylglycerol than B membranes. The B3-1 rev membranes showed only an 11% increase in cardiolipin and only a 19% decrease in phosphatidylglycerol. The other major phospholipid of the *E. coli* inner membrane, phosphatidylethanolamine, showed little if any change in the different membranes.

To characterise further the membrane lipid components, we investigated the fatty acid compositions of the purified inner membranes. As the fatty acids of the *E. coli* inner membrane are contained in phospholipids[13], we prepared free fatty acids from the phospholipids by alkaline hydrolysis. Free fatty acids were methylated with diazomethane and separated by gas–
Fig. 5 Temperature dependence of the fluidity (B/A) of spin-labelled fatty acid esters in cytoplasmic membranes from *E. coli* B, *hd* B3-1 and B3-1 rev. Arrows indicate discontinuities in the ESR fluidity profiles. a, Spin-labelled fatty acid ester, methyl 6-(4',4'-dimethyloxazolidinyl-N-oxyl) heptadecanoate $(I_{10,4})$ was prepared by the method of Waggoner et al.[20]. *E. coli* inner membranes, purified by the procedure of Osborn et al.[6] from bacteria growing at 37 °C, were suspended in 3% sucrose, 10 mM Tris, pH 7.5 at a concentration of 10–12 mg membrane protein ml⁻¹. The procedure for incorporation of the spin-labelled fatty acid esters into the purified membranes has been described[18]. ESR spectra were obtained at a frequency of 9,145 MHz on a Varian E4 spectrophotometer equipped with an E4540 variable temperature controller. All samples were 40 μl and were contained in a quartz capillary tube. b, Similar to a, except using methyl 12-(4',4'-dimethyloxazolidinyl-N-oxyl) stearate $(I_{5,10})$ as the spin label. ●, *E. coli* B; ○, *E. coli hd* B3-1; ▲, *E. coli* B3-1.

Table 1 Inner membrane phospholipid composition of *E. coli* B, *hd* B3-1 and B3-1ʳᵉᵛ

	% Total phospholipids after 12 h ³²P label		
	Cardiolipin	Phosphatidylglycerol	Phosphatidylethanolamine
E. coli B	12 5±0.3	18 3±1 1	69 3±0.9
E. coli hd B3-1	17.3±0.1	13.4±0.3	69.3±0.3
E. coli B3-1ʳᵉᵛ	13 8±0.7	14 9±0.5	71 3±0.9

Phospholipid compositions of purified cytoplasmic membranes from *E. coli* B, *hd* B3-1 and B3-1ʳᵉᵛ. Cells were grown overnight at 37 °C in tryptone broth (1.0% Bactotryptone, 0.5% NaCl) with ³²P (1.0 μCi ml⁻¹) after which they were diluted 1:500 and grown in fresh tryptone broth with ³²P (1.0 μCi ml⁻¹) for six generations. Phospholipids were then extracted from purified cytoplasmic membranes[6] by the method of Bligh and Dyer[11]. One-dimensional, ascending chromatography on Baker Silica Gel IB2 sheets (Baker, Phillipsburg, New Jersey) was used for separation of phospholipid classes with a neutral organic solvent system of CHCl₃–CH₃OH–H₂O (65·25:4, v/v). Phospholipid spots were visualised with iodine vapour, ninhydrin (Sigma, Saint Louis), molybdate reageant[12] and autoradiography. Phospholipid spots were cut from the chromatogram and placed in 5 ml Liquifluor (New England Nuclear, Boston) for determination of radioactivity in a Beckmann LS230 scintillation counter.

liquid chromatography on a diethylene glycol succinate column[14]. The proportions of the various fatty acids in our *E. coli* B inner membrane preparations (Table 2) are similar to those reported[15]. The proportions of the various fatty acids extracted from *hd* B3-1 inner membranes, however, are distinctly different from those of B (Table 2). Compared with the membranes of B, those of *hd* B3-1 contained 28% more palmitoleic acid (16:1) plus its cyclopropyl derivative, 9, 10-methylenehexadecanoic acid and 18% less cis-vaccenic acid (18:1) plus its derivative, 11, 12-methyleneoctadecanoic acid. Palmitoleic acid is known to be the direct precursor of cis-vaccenic acid[14]. Therefore, the conversion of palmitoleic acid to vaccenic acid seems to be partially blocked in *E. coli hd* B3-1.

Fatty acids extracted from B3-1ʳᵉᵛ membranes, although containing more 9, 10-methylenehexadecanoic acid, seem to be quantitatively similar to those of B (Table 2). Although there was a 9% increase in palmitoleic acid and methylenehexadecanoic acid in B3-1ʳᵉᵛ, cis-vaccenic acid and its methyleneoctadecanoic acid derivative showed no significant decrease. Comparison of *hd* B3-1 and B3-1ʳᵉᵛ suggests that the altered fatty acid composition of the bacterial inner membrane and the block in phage capsid production are acquired or lost jointly.

Additional evidence supporting the relationship between the *hd* B3-1 host defect and inner membrane lipid alterations comes from the study of certain *E. coli* B transductants. Cotransduction of markers by P1 phages was used to map the *hd* B3-1 gene responsible for the cold sensitive block. The gene, *fat* A, responsible for the *hd* B3-1 character cotransduced with a proline marker at a very high frequency.

We purified the inner membranes from one such transductant (*E. coli* BOU3101) and from the parental strain (*E. coli* B45) and compared their fatty acid compositions. As T4⁺ capsids fail to assemble in the transductant at 27 °C, we conclude from the data in Table 2 that the *E. coli* BOU3101 transductant acquired the inner membrane fatty acid composition as well as the host-defective character of *hd* B3-1. The membranes from transductants that acquired the proline⁺ gene from B3-1ʳᵉᵛ showed normal fatty acid compositions. These studies indicate that both the inability of *hd* B3-1 to produce T4 capsids at low temperatures and the inner membrane fatty acid alterations are controlled by the single genetic locus, *fat* A.

T4⁺ phage infection is known to alter the protein and phospholipid compositions of the *E. coli* membrane[16,17]. To determine whether the differences observed among the inner membranes isolated from uninfected B, *hd* B3-1, and B3-1ʳᵉᵛ were also characteristic of membranes isolated from similar bacteria 15 min after T4 infection, cultures of B, *hd* B3-1 and B3-1ʳᵉᵛ (all of which are *su*⁻) were infected with T4*am*H11 (23⁻) particles. To prevent any differential accumulation of the major capsid protein, p23, on the bacterial inner membranes, T4*am*H11 phage were used instead of T4⁺; 15 min after infection the cells were chilled and converted to spheroplasts[6]; inner membranes were then purified using the procedure for membranes of uninfected cells.

We again extracted free fatty acids from the membrane phospholipids, after which we determined the proportions of the various fatty acids by gas–liquid chromatography. The

Fatty acid compositions of *E. coli* B, *hd* B3-1, B3-1ʳᵉᵛ, B45, and BOU3101 inner membrane phospholipids. Inner membranes were purified[6] either from uninfected bacteria (4.5 × 10⁸ ml⁻¹) growing at 37 °C or from cells which had been infected with T4*am*H11 (23⁻) particles (m.o.i. =5). Infected bacteria were centrifuged for 1 min at 12,000*g* 15 min after addition of phages. Membranes were then prepared in the usual way The phospholipids of the purified inner membranes were extracted by the method of Bligh and Dyer[11]. Free fatty acids were prepared from the phospholipids by alkaline hydrolysis[18], followed by immediate methylation with diazomethane The resultant fatty acid methyl esters were separated on a diethylene glycol succinate column in a Hewlett Packard 5700A gas chromatograph equipped with a chart integrator. Column temperature, 175 °C. N2 was used as the carrier. Quantitative mixture KD (Applied Science L., State College, Pennsylvania) was used for fatty acid standards. Proportions of the various fatty acids were determined from the areas under the peaks recorded by the chart integrator

results of this experiment (Table 2) indicate that compared with inner membranes from infected *E. coli* B, the inner membranes from infected *E. coli hd* B3-1 cells have a decreased proportion of *cis*-vaccenic plus methyleneoctadecanoic acids and an increased proportion of palmitoleic plus methylenehexadecanoic acids. Furthermore, the membranes from T4*am*H11-infected B3-1 ^{rev} show nearly the same fatty acid composition as the control. These data are very similar to the data obtained from uninfected bacteria.

Implications

The above data indicate that purified inner membranes from *E. coli hd* B3-1 bacteria have altered fatty acid and phospholipid compositions as well as an unusually high viscosity. Further, studies of transductants for the host-defective character and of spontaneous revertants suggest that both the cold-sensitive block in T4 head production and the inner membrane alterations are controlled by the same gene, designated *fat* A. As T4$^+$ heads assemble on the *E. coli* inner membrane[1], we conclude that the cold sensitivity of T4$^+$ capsid formation in *hd* B3-1 is caused by the altered lipid components of the inner membrane.

Cotransduction by P1 phage, rather than conjugation, was used to map the *fat* A locus as numerous attempts to make *hd* B3-1 male (F$^+$) failed. The parent strain, *E. coli* B, was readily made F$^+$ in control experiments. It seems that, in addition to its effect on T4 morphogenesis, the *hd* B3-1 *fat* A membrane lipid alteration blocks a step in the acquisition or expression of the F episome, both at low (30 °C) and at high (41 °C) temperatures.

The *fat* A locus, responsible for the *hd* B3-1 phenotype, seems to be near proline in the *E. coli* B chromosome. Genes coding for proteins involved in fatty acid uptake and degradation are also closely linked to proline[21]. The genetic determinants of the host-defective phenotypes of two other *E. coli* strains in which T4$^+$ capsid production is blocked[2,3] are located near melibiose, far from proline. Therefore, two bacterial genes separated by nearly one-fifth of the *E. coli* chromosome can affect T4 head formation. Both of these genes, however, seem to affect the same cellular structure because T4 mutants in the same gene—gene 31—can overcome either, and possibly both, bacterial blocks. The product of T4 gene 31 functions during the organisation of T4 head proteins on the bacterial membrane[5]. An interesting hypothesis to account for these observations is that the initiation of T4 head assembly

requires specific protein-binding sites on the *E. coli* inner membrane. Capsid production could be blocked either by altering this membrane protein (genetically linked to melibiose) or by changing membrane lipid components (linked to proline) associated with the protein, so that at low temperatures formation of the capsid protein–membrane protein complex would be sterically or allosterically inhibited. At higher temperatures the increased disorder of the membrane lipids might enable the initiation of capsid assembly. An example of this type of effect of membrane lipids on the interaction of a membrane protein with a cytoplasmic molecule is the cold sensitivity of sheep kidney ATPase activity[18]. Changes in the organisation of the cytoplasmic membrane lipids seem to be responsible for the marked reduction in the rate of ATPase activity which occurs below 20 °C.

β structures of alternating polypeptides and their possible prebiotic significance

André Brack & Leslie E. Orgel

The Salk Institute for Biological Studies, San Diego, California 92112

A survey of the commonest amino acids formed in prebiotic conditions suggests that the earliest form of genetic coding may have specified polypeptides with a strong tendency to form stable β-sheet structures. Poly(Val-Lys), like other polypeptides in which hydrophobic and hydrophilic residues alternate, tends to form β structures. We show that bilayers with a hydrophobic interior and a hydrophilic exterior may be present in aqueous solution.

MILLER and others have published a large number of papers dealing with the prebiotic synthesis of amino acids[1]. The formation of polypeptides from amino acids in prebiotic conditions has also been reported[1]. Since we know a great deal

about the conformational tendencies of the naturally occurring amino acids[2], it should now be possible to deduce the probable conformations of the polypeptides first formed on the primitive Earth.

The assignment of amino acids to trinucleotides by the genetic code is not random. Woese has emphasised that the position of an amino acid in the codon-table is strongly dependent on its hydrophobic or hydrophilic character[3]. Dickerson has suggested that the codon assignments correlate with the tendency of amino acids to occur in the interior or on the surface of globular proteins[4].

Here we bring together conformational information obtained with synthetic polypeptides, information about the abundance of prebiotic amino acids, and the suggestions of Woese and
Fig. 1 CD spectra of a freshly prepared solution of poly(Val-Lys) at *p*H 2.3 in water (— — —) and of a solution in 0.1 M NaCl after 60 h (————) at *p*H 2.3.

Dickerson in an attempt to throw light on the origin of the genetic code. In particular, we provide further support for the suggestion that peptides with alternating hydrophilic and hydrophobic residues, that form β-sheet bilayers, may have been important at an early stage in the origins of life[5].

Alternating hydrophobic–hydrophilic residues

A large number of sequential copolypeptides has been synthesised (for a review see Johnson[6]). Among those soluble in water and containing alternating hydrophobic and hydrophilic residues, we are aware of only four that have been submitted to conformational analysis. Three of these polypeptides exhibited the β structure in aqueous solution.

Alternating poly(Glu-Ala) shows a typical β-circular dichroism spectrum after standing for several weeks in neutral aqueous solution[7]. Poly(Tyr-Glu) forms soluble aggregates below *p*H 10.5. Infrared spectroscopy shows that these aggregates have the antiparallel β structure[8]. Seipke *et al.*[9] made a detailed study of the conformation properties of poly(Lys-Phe). At neutral *p*H and low salt concentration the polymer is partly in the β form. The proportion of β form is markedly increased at basic *p*H, or when sodium perchlorate or methanol is added to the solution. The corresponding random copolypeptide poly(Lys, Phe) exhibits a random coil conformation at neutral *p*H, and changes to the β form at higher *p*H, but sodium perchlorate induces a transition to the α helix, as Peggion *et al.* had already shown[10]. The remarkable difference in the behaviour of the two polymers shows that the amino acid sequence can dramatically change the tendency to form a β structure.

Two silks that contain a substantial proportion of alternating residues have been studied in the solid state. It has been shown that the crystalline β region of *Bombyx mori* silk is made up of chains of the type (Gly-X)*n* where X is alanine or occasionally serine. In the structure established by Marsh *et al.*[11] the glycyl residues are located on the same side of the sheets and the packing of successive sheets bring glycyl residues in contact, thus leading to an alternation of glycyl–glycyl and alanyl–alanyl contact layers. Such a structure is also adopted by synthetic poly(Ala-Gly)[12].

Sawflies of the family Argidae produce a silk that contains

roughly equimolecular amounts of alanine and glutamine, accounting for 70–80% of the amino acids. The X-ray diffraction patterns provide evidence that the β structure of this silk is very similar to that found in *Bombyx mori* silk[13].

Conformational analysis of poly(Val-Lys)

Poly(Val-Lys) with a molecular weight of about 5,000 was obtained by polymerisation of the *p*-nitrophenyl ester of the corresponding protected dipeptide. The optical and chemical purity of the sample was confirmed. Details of the synthesis will appear elsewhere.

At acidic *p*H in pure water the CD spectrum of poly(Val-Lys) (Fig. 1) is almost the same as that of random coiled *Bombyx mori* silk fibroin in aqueous solution[14]. We suppose, therefore, that poly(Val-Lys) is a random coil in these conditions. When a 1% or 0.01% acidic solution was brought rapidly to *p*H 8.8 a spectrum typical of the β conformation was obtained. The transition was almost reversible after 15 min at *p*H 8.8. The polymer precipitated from solution above *p*H 9.

When sodium chloride was added to a 1% solution of the polymer at *p*H 2.3 to bring the final NaCl concentration to 0.1 M (the polymer cannot be dissolved in this salt solution) a slow coil → β transition occurred and was almost complete after 60 h (Fig. 1). There was no transition in the absence of added salt, even after one week.

Addition of urea (6 M) to a 1% solution in 0.1 M NaCl at *p*H 4.0 did not prevent the appearance of the β structure, but reduced the rate of the coil → β transition. Guanidine hydrochloride (0.5–6 M) caused the precipitation of the polymer as a β structure at *p*H 4.4

The reduced viscosity of a 1% solution in 0.1 M NaCl at *p*H 2.2 was measured as a function of time. We found a significant decrease of the viscosity with time during the first 5 h (Fig. 2). No change was induced by increasing the *p*H to 7.8 after the solution had equilibrated at *p*H 2.2 for 48 h (Fig. 3). Above *p*H 7.8 the viscosity increased sharply. The appearance of a light turbidity indicated that the polymer begins to precipitate in these conditions.

The meniscus depletion technique was used to determine the apparent molecular weight distribution of the polymer in a 0.05% solution in 0.1 M NaCl at *p*H 5.5, while it was undergoing its coil → β transition. At low speed (12,590 r.p.m.), a first equilibrium was reached which produced molecular weights of about 200,000. At higher speed (59,780 r.p.m.), a molecular weight of 5,200 was measured.

Fig. 2 Time dependence of the reduced viscosity of 1% poly(Val-Lys) in 0.1 M NaCl at *p*H 2.3.
Fig. 3 *p*H dependence of the reduced viscosity of an aged 1% solution of poly(Val-Lys) in 0.1 M NaCl.

The polymer, in the disordered or the β conformation, gave a solution that frothed readily. The surface tension was measured with a Langmuir–Wilhelmy balance. Pure water (72 erg cm^{-2}) and L-α-dipalmitoyl lecithin (0 erg cm^{-2}) were taken as standards. Surface tensions were 30 erg cm^{-2} and 25 erg cm^{-2} for fresh acidic solutions and aged solutions in 0.1 M NaCl at *p*H 3.0, respectively.

Solid state

Dialysis of an aged solution in 0.1 M NaCl at *p*H 2.3 (β form) against 0.5 M sodium perchlorate precipitated the polymer. The product exhibited the characteristic infrared absorption bands of the β structure (amide I band at 1,630 cm^{-1} with a shoulder at 1,690 cm^{-1} indicating an antiparallel arrangement of the chains). The powder pattern of the X rays showed 10 lines, 4 of which were well defined at 26.2±0.5 Å, 8.62±0.6 Å, 4.65±0.03 Å and 3.82±0.02 Å. X-ray studies on the β structure of polyvaline have been reported[15], but without any details. We obtained a powder pattern with strong lines at 9.2 and 4.57 Å, which can be interpreted as the intersheet distance and the interchain distance, respectively.

Implications of conformational studies

The experimental observations described in the previous sections make it clear that the chains of poly(Val-Lys), like those of poly(Lys-Phe), adopt a β conformation in a variety of conditions. We found no evidence for the formation of an α helix, whereas the random coil was stable only in acidic solutions in the absence of added salts.

We do not have any direct experimental evidence as to the spatial organisation of the polypeptide chains into β sheets in solution. We believe, however, that indirect arguments suggest strongly that the bilayer structure shown in Fig. 4c is present rather than sheets of the types shown in Fig. 4a and b.

A striking feature of the X-ray powder photograph of the perchlorate salt of poly(Val-Lys) is the strong reflection at 26.2 Å. Analogy with the diffraction patterns obtained from other β structures[16] shows that this reflection must correspond to the repeat distance perpendicular to the plane of the sheets. The reflection at 4.65 Å corresponds to the usual interchain distance, which commonly lies between 4.62 and 4.78 Å (ref. 16). The reflections at 8.62 and 3.82 Å probably correspond to the 003 and (210+211) reflections, respectively, in an orthorhombic unit cell with *a* = 4.65, *b* = 26.2 and *c* ~6.8 Å.

If we assume this unit cell, it is possible to find a distribution of the atoms in the *ac* plane which predicts a weak 002 reflection, and an intensity ratio for the 001 and 003 reflections close to that observed. The X-ray powder pattern is, however, too poor to enable us to confirm the proposed unit cell.

The phosphate salt of polylysine forms a β-sheet structure with an intersheet distance of 17.16 Å (ref. 17). Our own measurements on the β structure of polyvaline give an intersheet distance of 9.2 Å. If we suppose that the structure illustrated in Fig. 5a would have a repeat equal to the sum of the repeats in the phosphate of polylysine and in polyvaline, we arrive at a value of 26.4 Å, in good agreement with our measured value. On the other hand, the repeat distance for the β-sheet packings illustrated in Fig. 4a and b or for the structure shown in Fig. 5b would be much smaller, probably less than 17 Å. We believe that the X-ray data strongly support a stacked bilayer structure in the solid state and, by inference, a similar bilayer structure in solution.

The behaviour of the polymer in solution is consistent with this interpretation. At *p*H 2.2, in the absence of salt, poly(Val-Lys) exists as a random coil. The addition of small amounts of salt induces a transition to a β structure. This is most simply interpreted as due to the shielding effect of the salt which enables the positively charged amino groups to come together on one side of a β sheet.

The precipitation of the polymer by larger amounts of salt can be explained in a similar way. The formation of a stacked-bilayer structure involves the bringing together of sheets of

Fig. 4 Diagrammatic representation (in chain axis projection) of various arrangement of poly(Val-Lys) chains in β sheets. Ellipses represent the backbone.
Fig. 5 Diagrammatic representation of two packings of β sheets.

positively charged residues. This is only possible if salt is present in high enough concentration to provide the necessary shielding. The precipitation that occurs in more alkaline solutions (pH 8) is made possible by the neutralisation of the charges on a proportion of the lysine residues.

The high molecular weight (200,000) of the polymer in the β sheet form shows that extensive aggregation has occurred, but throws no light on the spatial arrangement of molecules in the aggregate. Similarly, the drop in viscosity that occurs when the random coil is converted to an equilibrium β sheet in acidic solution gives no detailed structural information.

The β structure which is formed reversibly when freshly-prepared solutions are shifted from acidic to alkaline conditions must be different from the structure formed irreversibly by ageing in acidic solution. Unfortunately, we do not have any evidence as to the detailed structures. We cannot, for example, distinguish between normal β structure and cross β structures.

The surface activity of poly(Val-Lys) is consistent with our hypothesis. At an air–water interface, we should expect the polymer to form a β-sheet monolayer, with the lysine residues penetrating into the aqueous layer and the valine residues exposed to the air. It is also possible, however, that the β structure is disrupted at the interface and that the surface activity is due to the formation of micelles.

The fact that diverse alternating polypeptides form a β structure at all, also provides strong evidence favouring the bilayer structure. It is hard to see what factor other than hydrophobic interaction between residues confined to one side of a β sheet, could account for the general tendency to form β sheets. The formation of a β structure by poly(Lys-Phe), in conditions in which the corresponding random copolymer forms an α helix or a random coil, is particularly striking.

Prebiotic polypeptides

A survey of many experimental studies of the amino acids formed in prebiotic conditions shows that the two simple α-amino acids, glycine and alanine, are formed more readily than any others. In addition, serine, threonine, aspartic acid, glutamic acid and a variety of aliphatic amino acids (including

many that are non-biological) are formed in small and variable amounts. Some α-amino acid derivatives, particularly N-methyl amino acids, and some α-hydroxy and β-amino acids, are also formed. All potentially optically active compounds are obtained as racemic mixture[1].

We do not know if any substantial fractionation of the α-amino acids in the prebiotic mixture took place before condensation of polypeptides occurred. If we suppose that this was not the case, then the first prebiotic condensation products are likely to have been copolymers of glycine and DL-alanine, containing substantial amounts of other α-amino acids. The first peptides might have contained larger amounts of the higher aliphatic amino acids, if enrichment of hydrophobic amino acids was important, or of serine, threonine and the dicarboxylic acids, if hydrophilic amino acids were concentrated.

The conformation of polypeptides containing glycine and alanine have been studied. It is clear that random peptides derived from a mixture of these amino acids would not contain much α helix, if any, since glycine is a strong helix breaker. On the other hand, it seems likely that β-sheet formation would be considerable[18]. The incorporation of N-methyl-α-amino acids and hydroxy acids into the polypeptides would decrease the extent of β-sheet formation, but we are justified in assuming that, in so far as prebiotic 'polypeptides' formed structures at all, rather than random coils, they formed β-sheet structures.

This conclusion is strengthened by the observation that in those cases where a peptide can form either α helices or β sheets, the latter structure is favoured if the molecular weight of the polypeptide is low[19]. Since uninterrupted sequences of α-amino acids in prebiotic condensation products are likely to have been short, β-sheet structures would have had a further advantage over α-helices.

Alternating peptides and the genetic code

The amino acids which are specified by codons with U in the central position—Phe, Leu, Ileu, Met, Val—are all hydrophobic, while those specified by codons with A in the central position—Glu, Asn, Gln, His, Lys, Tyr—are all hydrophilic. The situation is less extreme for the two other groups, but amino acids specified by codons with central C—Ser, Pro, Thr, Ala—tend as a group to be somewhat more hydrophobic than those with a central G—Gly, Ser, Arg, Cys, Trp. Tryptophane and possibly cysteine are exceptions to this rule[3,4].

Studies of mononucleotide–polynucleotide interaction strongly suggest that, in the absence of enzymes, it would be difficult to replicate polynucleotides in which purines are adjacent. Thus polynucleotides in which purines alternated with pyrimidines are likely to have been abundant in the prebiotic soup.

On the basis of these two observations we suggested[5] that the first form of genetic coding 'translated' polynucleotides in which purines and pyrimidines tended to alternate into polypeptides in which hydrophobic and hydrophilic amino acids tended to alternate. Finally, we suggested that alternating polypeptides of this kind were important because they tended to form β sheets with one hydrophobic and one hydrophilic surface. Such sheets would stack together to form 'membrane-like' aggregates. The reader is referred to our previous paper[5] for an amplification of the arguments summarised in this section.

Experimental evidence obtained since our original publication confirms the prediction that alternating polypeptides tend to to form β sheets. Although this by no means proves that our hypothesis concerning the first step in the origin of the genetic code is correct, it suggests that it may be worth looking further for a structural basis for the code. Perhaps the code first assigned glycine to codons with a central purine and L-alanine to codons with a central pyrimidine, while L-serine was associated with both types of codon. This would have generated a crude 'silk'. It may be significant that the amino acids that tend to occur in β turns in globular proteins[2] are coded for by triplets of the form PuPuPy or PyPyPu. We have so far been

unable to provide a convincing explanation of other major features of the genetic code.

Energy spectrum of hadrons in cosmic rays at sea level

BARUCH *et al.*[1] have measured the energy spectrum of hadrons (nucleons and pions) in cosmic rays at sea level and have presented evidence for an anomalous behaviour in the energy range 2–8 TeV. For $E < 2$ TeV they find the differential vertical intensity to decrease with increasing energy as $E^{-2.6\pm0.1}$, for $2 < E < 8$ TeV the intensity is almost constant, and for $E > 8$ TeV the intensity again decreases with increasing energy (Fig. 1). The 'step' in the spectrum for $2 < E < 8$ TeV is unexpected and Baruch *et al.* propose that it is produced by the interaction of a new particle, of rest mass 40–70 GeV c^{-2}, mean lifetime $> 2 \times 10^{-7}$s and an interaction length of $1,000^{+1,000}_{-700}$ g cm^{-2}. We have made new measurements on the hadron spectrum at the higher energies in question.

The experimental arrangement used consisted of, from top to bottom; a layer of 15 cm of lead; a plastic scintillator (area 1 m²); eight layers of neon flash tubes; 15 cm of iron; a further plastic scintillator (area 1 m²) and 116 layers of neon flash tubes. Hadrons interacting in the lead and iron absorbers produce pions and on the average one-third of these are neutral. Each neutral pion decays into two γ rays and the ensuing electron photon cascade emerges from the absorber and traverses the scintillators. Detailed calculations have been made of the relationship between the average number of burst particles below the absorber and the energy of the initiating particle. The result can be represented approximately by the statement that the mean energy of the 'primary' which produces N particles is N GeV—this relationship is valid over most of the energy range in question; the difference in burst size for incident protons and pions is not large, the size being about 30% larger for pions than for nucleons in iron and 20% larger in lead. The observation of large voltage pulses from either scintillator was used as a master trigger and the pulse heights were displayed on an oscilloscope trace after being delayed by 0 3 μs and 0.9 μs. Subsequently a high voltage pulse was applied to the flash tubes and a photograph showing the geometry of the burst was obtained. Data were taken using different trigger levels and also two different time delays (20 μs and 330 μs) between the occurrence of the burst and the application of the high voltage pulse to the flash tubes. The longer time delay was used for the large burst sizes ($N > 400$ particles), so that it was possible to define the axis of the burst

more precisely—the point being that with such large bursts the total number of particles is very large, as is their lateral spread, and only by reducing the flash tube efficiency can the axis be determined accurately.

All the flash tube layers contained parallel tubes and in the front view bursts were only accepted if their axes passed through a well defined geometrical region and made an angle of $\pm$ 30° to the vertical. The maximum angle a burst could make with the vertical in the back plane was 81° and 75° for the lead and iron targets respectively. Using the method of Lovati *et al.*[2] the measured projected angular distribution of bursts was used to determine the spatial angular distribution, assuming it to be of the form $I(\theta) = I(0) \cos^n\theta$. In this way both n and the vertical intensity $I(0)$ of the burst spectrum were determined. For bursts of size above 400 particles n was found to be 8.0 ± 1.0, in agreement with the expected value.

Conversion from burst size to mean hadron energy was made assuming that all the particles are nucleons; in fact some are pions for which the conversion factor will be slightly different as mentioned already but the ratio of pions to nucleons is not expected to be a rapidly varying function of energy so that the important spectral shape should not be distorted. High energy muons also produce bursts but the effect is small. For a burst size corresponding to 5 TeV hadrons (the centre of the Baruch *et al.* step) the effect is 5% for the lead and $< 1\%$ for the iron.

The final hadron spectrum has been found by averaging the burst spectra from the lead and iron targets (the individual spectra were compatible, adding confidence to our conclusions) and the resulting energy spectrum is shown in Fig. 1 where the hadron spectrum from the measurements of Baruch *et al.*, is also plotted. The rates shown in the figure are absolute rates and no normalisation has been made to other work. Our results show no evidence for a step in the energy range 2–8 TeV and they are in fact consistent with a spectrum of the form $E^{-2.7\pm0.1}$ over the whole energy range from 10 GeV to 10 TeV. There could indeed be an irregularity in the form of the spectrum which would escape detection in this experiment because of the smoothing introduced by the method, by the fluctuations in burst size. To assess the effect of fluctuations we have calculated the probability that a primary proton produces N burst particles per unit N. Assuming the hadron spectrum to be of the form given by Baruch *et al.*, we then calculated the shape of the expected burst spectrum. The result was that the step was clearly present in the burst spectrum. We are therefore convinced that we would have detected the
Fig. 1 The differential energy spectrum of hadrons (and of nucleons alone) in cosmic rays at sea level. The low energy data ($\geq$ 100 GeV) are estimates of the total nucleon spectrum found by multiplying the measured proton intensities of Brooke and Wolfendale[3] and Diggory et al[4] by a factor 2 (assuming equal numbers of protons and neutrons). The dashed line is an estimate of the total nucleon spectrum found by increasing the measured neutron intensities summarised by Ashton[5] by a factor of 2. The solid line is the best fit to the present measurement of the energy spectrum of all hadrons. The difference between the energy spectrum of all hadrons (solid line) and the energy spectrum of all nucleons (dashed line) is due to the increasing contribution of charged pions to the total hadron flux for energies > 100 GeV. ▲, Hadrons[1]; ●, hadrons (our work); ○, nucleons[3]; △, nucleons[4].

bump if it was a real effect.

Thermal model of oceanic lithosphere

THE thermal model for oceanic lithosphere developed by McKenzie[1] assumes that oceanic plates are slabs of constant thickness. The model has been used successfully to reproduce both the heat flow and the topographic patterns observed in oceanic lithosphere[2]. There is, however, no reason to assume that the lithosphere has a constant thickness; indeed, it is likely to thicken as it moves away from the ridge and cools.

Thermal models have been derived[3,4] which predict that the thickness, L, of a section of lithosphere should be proportional to the square root of the time, t, since its formation at the ridge, and experiments using spreading layers of wax have confirmed this relationship[5]. Such a model also agrees with the available seismic data (D. Chapman and H. Pollack, personal communication).

Theoretical considerations, using the best estimates for material parameters, predict, however, that the lithosphere should thicken much faster than the available evidence suggests it actually does. This theoretical rate of thickening can be reduced if the effects of the latent heat of the asthenosphere's partial melt are taken into consideration, but to achieve thicknesses equal to those actually observed the asthenosphere must be assumed to be completely liquid[3]. We show here that realistic results can also be obtained if it is assumed that there is a heat flux into the base of the oceanic lithosphere from the underlying asthenosphere.

We have obtained an approximate solution for the temperature field and the thickness of the lithosphere by modifying McKenzie's model. If the lithosphere is viewed in two-dimensional cross section (Fig. 1) it rests on the low-velocity zone, which is taken to be a nearly isothermal zone of partially molten material at a temperature T_m. Except for thin surface layers, the lithosphere is identical to the material beneath it but colder and, therefore, more rigid. The base of the lithosphere is taken as the T_m isotherm. The material beneath the lithosphere is assumed to be capable of maintaining a uniform heat flux, Q, to the base of the lithosphere by convection. The upper surface of the lithosphere is maintained at 0 °C by sea water. At the ridge crest, hot, mantle material accretes to the plate margin. As this material moves away from the ridge it is cooled by sea water. The slab conducts heat away from the mantle beneath it, causing material to freeze on to the bottom of the lithosphere. At equilibrium, the lithosphere attains the proper thickness such that it loses heat upwards as fast as it receives heat from the mantle beneath.

As the lithosphere is very long compared with its thickness and because the temperature difference between its top and

Fig. 1 Predicted shape of the lithosphere plotted in dimensionless variables (see text).
Fig. 2 Observed variation (I) of surface heat flow with age for the northern Pacific[2] compared with theoretical predictions (—). (a, $Q = 0.8$; b, $Q = 0.56$). The error bars indicate the estimated error of the calculated mean and are much smaller than the true scatter of observed values.

bottom surfaces is large, the effects of horizontal heat conduction can be ignored, and the thermal history of a single column of lithosphere as it cools in time can be considered. Assuming that material properties are constant and that there are no radioactive heat sources, the governing heat flow equation is

$$\rho C_p \partial T/\partial t = k \partial^2 T/\partial z^2$$

where T is temperature, z is depth, k is thermal conductivity, ρ is density, and C_p is heat capacity. The boundary conditions are that $T = 0$ at $z = 0$, $T = T_m$ at $z = L(t)$, and $k\partial T/\partial z = Q$ at $z = L(t)$. An approximate solution to this equation can be obtained using a technique developed to handle boundary layers in fluid mechanics. It is assumed that the temperature at any time within a column of lithosphere can be represented by a third order polynomial in z.

$$T(z,t) = a + (bz/L) + (cz^2/L^2) + (dz^3/L^3)$$

where a, b, c, d, and L are functions of time. Considering the boundary conditions together with the fact that $\partial T/\partial t = 0$ at $z = 0$ then $\partial^2 T/\partial z^2 = 0$ at $z = 0$ means that the coefficients can be determined

$$T(z,t) = (3T_m z/2L) - (Qz/2k) - (T_m z^3/2L^3) + (Qz^3/2kL^2) \quad (1)$$

For $Q = 0$ this function is a good approximation to the error function which is the exact solution for this case. At equilibrium the temperature distribution in the lithosphere will be linear in z such that $kT_m/L = Q$, so L will equal kT_m/Q. Substituting this value of L into equation (1) the approximation of the temperature distribution becomes linear as L approaches its equilibrium value.

From equation (1) the heat flow out of the top of the lithosphere at any time is found to be

$$k\partial T/\partial z \,|_{z=0} = (3kT_m/2L) - (Q/2) \quad (2)$$

Neglecting radioactivity, this heat must come from either a deeper source or from the cooling of the slab. At any time, the heat content of a column of lithosphere is

$$\rho C_p \int_0^L T(z)dz = \rho C_p[(3T_m z^2/4L) - (Qz^2/4k) - (T_m z^4/8L^3) + (Qz^4/8kL^2)]\,|_0^L \quad (3)$$

If the slab increases its thickness by ΔL, the original thickness L would have a different, smaller heat content, given by equation (3), with $L+\Delta L$ substituted for L in the denominators of the fractions. The difference between the two values, which is the heat liberated by increasing the thickness of the lithosphere, is $\rho C_p[(3T_m/8) + (QL/4k)]\Delta L$.

In the time interval Δt the heat budget of an individual column of lithosphere is balanced if

$$[(3kT_m/2L) - (Q/2)]\Delta t = \rho C_p[(3T_m/8) + (QL/4k)]\Delta L + Q\Delta t$$

or, in the limit

$$dL/dt = (4/\rho C_p)[(kT_m/L) - Q]/[T_m + (2QL/3k)] \quad (4)$$

The latent heat of the melt solidified to the base of the slab could be included in this balance without difficulty. It is omitted here because if the fraction of partial melt in the asthenosphere is small then its latent heat has a small effect compared with those of the other terms in the equation.

If $Q = 0$, equation (4) has the solution

$$L = (8kt/\rho C_p)^{1/2} \quad (5)$$

which is of the form of previous thickening models. This is also the relationship observed in wax experiments in which there is no deep source of heat.

With Q arbitrary, equation (4) has the solution

$$(5/3)(\ln[1/(1-L')] - L') - L'^2/3 = t' \quad (6)$$

where L' and t' are dimensionless variables

$$L' = LQ/kT_m \qquad t' = t4Q^2/k\rho C_p T_m^2$$

and an arbitrary constant has been fixed so that $L = 0$ at $t = 0$. This solution is plotted in Fig. 1. For small values of
Fig. 3 Observed variation the depth of ocean basement with age[9] compared with theoretical predictions. Data are from all available oceans. ●, Depth determined by drilling; —, prediction (a, $Q = 0.8$; b, $Q = 0.56$).

L', when the contribution from Q is minor, equation (6) reduces to equation (5) as would be expected. As $t' \to \infty$, $L' \to 1$, so $L \to kT_m/Q$ as wanted.

Two numerical examples can be calculated using generally accepted values for material parameters: $T_m = 1,200\,°C$; $C_p = 0.25$ calorie $g^{-1}\,°C^{-1}$; $\rho = 3.3$ g cm^{-3}; $k = 7 \times 10^{-3}$ calorie cm^{-1} s$^{-1}\,°C^{-1}$. For estimates of Q, two values obtained from continental heat flow studies are used: $Q = 0.8$ h.f.u. (0.8×10^{-6} calorie cm^{-2} s^{-1}) represents a probable upper limit to the actual sub-lithospheric flux[6]; $Q = 0.6$ h.f.u. has been suggested as a value compatible with estimates of the heat production of the lower crust and upper mantle[2]. To represent this latter value we use $Q = 0.56$ h.f.u. because it leads to
Fig. 4 Com]arison of lithospheric thickness (derived from surface wave studies in the northern Pacific)[10] with theoretical predictions. I.. Seismic estimate; —, prediction (*a*, $Q = 0.8$; *b*, $Q = 0.56$).

convenient sc le factors. With Q equal to 0.8 h.f.u., $L = L' \times 105$ km and $t = t' \times 100$ Myr. For Q equal to 0.56 h.f.u., $L = L' \times 150$ km and $t = t' \times 200$ Myr. The theoretical heat flow curves which result from these material values give a good fit to the data (Fig. 2). Both curves are lower than the data from the older age range, but the difference is only 10–20%. The theoretical curves can probably be raised by that amount if latent heat and radioactivity effects are included in the model.

A theoretical subsidence curve can be calculated by assuming that isostatic compensation takes place at the base of the lithosphere[7]. The mass of any column of water and lithosphere at any time must then equal the mass of the same height of water plus asthenosphere at the ridge. So

$$s(t) = L(t)(\rho_L - \rho_A)/(\rho_A - \rho_w)$$

where $s(t)$ is the subsidence of the surface of the lithosphere below the height of the ridge crest, ρ_w and ρ_A are the densities of seawater and asthenosphere, respectively, and ρ_L is the mean density of the lithosphere. For the case $Q = 0$, ρ_L is constant so $s(t)$ is proportional to $L(t)$. For $Q \neq 0$, the mean density of the lithosphere can be calculated from equation (1) using the assumption that density change results entirely from thermal contraction[7]. The factor $(\rho_L - \rho_A)/(\rho_A - \rho_w)$ becomes $\rho_0 \alpha T_m[(3/8) + (L'(t)/8)]/(\rho_0 - \rho_w)$ where α is the coefficient of thermal volume expansion and ρ_0 is the density at 0 °C. To calculate subsidence curves ρ_0 is taken to be 3.3 g cm^{-3} and α is adjusted so that the subsidence equals 3 km at 100 Myr (Fig. 3). The fit to the available data is quite good. For $Q = 0.56$ h.f.u., α 'must equal 4.0×10^{-5} °C^{-1}, for $Q = 0.8$ h.f.u. it must equal 4.5×10^{-5} °C^{-1}. The measured expansion coefficient for olivine at high temperatures[8] (400–800 °C) varies from $3.1–4.4 \times 10^{-5}$ °C^{-1}, in agreement with the calculated results.

Seismic surface-wave determinations of the depth to the low-velocity zone as a function of the age of oceanic crust[10] are in reasonable agreement with the theoretical predictions (Fig. 4). The error bars in Fig. 4 do not indicate the total uncertainty, but only the allowable variation within the constraints of a preferred model of velocity structure. It is possible that the large thickness calculated to have been obtained after 150 Myr is not real.

As well as providing a physically realistic way of explaining existing heat flow, topographic, and seismic data, this thermal model offers a possible resolution of the oceanic–continental heat flow problem. The surface heat flux in the older oceanic areas is approximately the same as the surface heat flux in the older continental shield areas. Previously, it has been assumed that the older oceanic areas are in thermal equilibrium[2], an idea which was incompatible with the observed near equality of heat flux. As the oceans have much less surface radioactivity than the continents, then if they have the same flux as the

continents at depth they should have a much lower flux at the surface. Our results, however, indicate that the older oceans are not in thermal equilibrium. With a sub-lithospheric heat flux of 0.8 h.f.u., the surface flux at 100 Myr is predicted to be 45% higher than the equilibrium flux. With a sub-lithospheric flux of 0.56 h.f.u., the surface flux at 100 Myr is 85% higher than at equilibrium. Thus, the approximate similarity of surface heat flux in ocean basins and continental shields may be purely coincidental.

I thank Henry Pollack and Dave Chapman of the University of Michigan for the idea to work on this model.

Seawater near the head of the Ross Ice Shelf

THE Ross Ice Shelf (Fig. 1) is a sheet of ice that floats over 540,000 km^2 of the Ross Embayment[1]. The ice in the southern part is between 300 and 800 m thick, and floats on as much as 400 m of water[2,3]. Until now any knowledge of the water mass beneath the shelf has been inferred from studying the open water of the Ross Sea far to the north. Here, I describe a newly discovered natural access to seawater beneath the Ross Ice Shelf, 550 km south of the shelf front and 770 km from the South Pole, on the north-eastern margin of an ice rise.

The ice rise is an elongate north-westerly-trending dome about 40 km long which reaches an elevation of 100 m. The ice

of the rise is grounded[2] and the northern and eastern margins are marked by extensive crevassing that continues for many kilometres north of the rise. This crevassing is believed to reflect a flow regime of shearing and extension as the floating shelf moves past the rise on its journey north. Along the north-eastern margin of the rise the ice shelf has broken into plateau-like blocks of ice several kilometres across, separated by broad valleys floored with snowed-in, broken ice ('horst' and 'graben' structures). The southern margin of each block is a continuous

ice cliff about 15 m high (Fig. 1); the northern margin is both less regular and more snow-covered than the southern margin. At the foot of one of the cliffs a narrow rift extends down to a thin ice floor with water beneath; chemical (Table 1) and isotopic (Table 2) analyses have shown that this is seawater.

The rift can be traced for more than 2 km along the foot of the ice cliffs, and it probably extends along their entire length. For a 50-m-long section of the rift (Fig. 2) the maximum width of the floor is 2 m, and its thickness is about 0.1 m. Several soundings through holes in the ice indicated an irregular underwater topography. The greatest depth plumbed at the eastern end of the rift was 2.9 m, and at the western end was 4.9 m. The 'feel' of the line indicated, however, that the surface was rough, hard and sloping, and not bottom. Soundings from a wider part of the rift should reach much greater depths.

The only sign of life along the rift is a yellowish brown patchy staining, which is common up to about 0.5 m above the water level on the northern side. The staining proved to be the remains of algae. Filamentous wisps as much as 80 mm long are abundant in the water under ledges and beneath the ice floor of the rift. Samples of the material include living organisms containing traces of fresh pigment (H. W. Johnstone, personal communication). The samples consist largely of the disrupted cell debris of centric diatoms, with some intact frustules, and a few whole pennalean diatoms. Disruption probably resulted from the freezing of the samples after collecting, for temperatures in the field ranged from −3 to −10 °C.

I had expected to be able to observe the tide, known to have a range of between 1.0 and 1.5 m over this part of the shelf[4], and

I placed a marker in the ice at sea level to check this (Figs 2 and 3). For the first 6 h the water level did not change more than 1 mm relative to the ice, but 24 h later the ice had risen 40 mm relative to the water level. Further markers were placed and measured on several occasions, though, following a blizzard, not all could be relocated for the final measurements.

The measurements are accurate to 2 mm, and establish two points. First, no tidal cycle is detectable from markers on either side of the rift. Because the tidal range is large enough to be measured directly it is concluded that the ice on both sides of the rift is floating (see Fig. 4). Second, the data also show that the rift zone is highly mobile. All four stations on the northern side, and two on the southern side, rose more or less steadily over a five day period at rates of between 38 and 65 mm d^{-1};the other two stations rose less than 29 mm over the five day period (Fig. 3). Two strain measurement triangles across the rift between stations 3 and 4 showed that the rift widened by 0.23 and 0.27 m over the 77-h period between 1000 on December 8 and 1500 on December 11, 1974. If these high rates of movement were maintained for more than a few tens of days the ice-floored rift would be many metres across and the margins of the rift would rise metres above the valley floor. Neither feature has, in fact, been observed along the rift, and it is therefore concluded that both the horizontal and the vertical movements form part of a long term 'glaciotectonic'

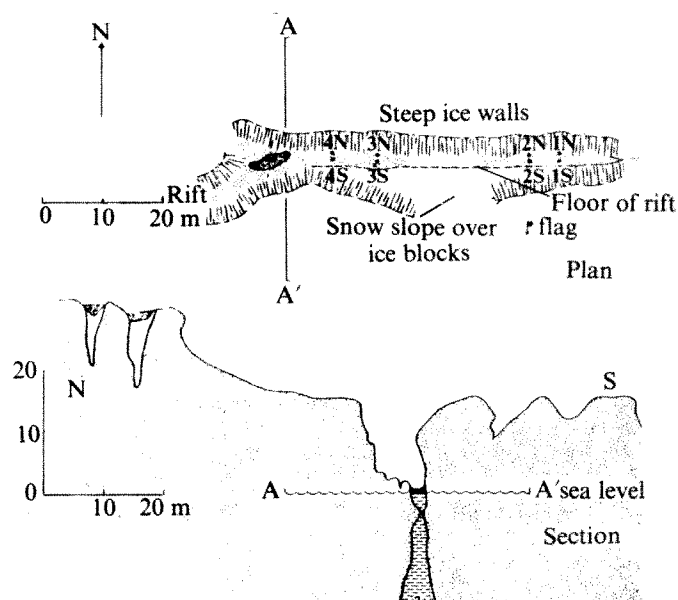
Fig. 2 Sketch plan and section of the rift containing seawater, showing locations of the eight pegs measured for Fig. 3.


Fig. 3 Vertical movement of pegs on the north and south sides of the rift floor. Peg locations shown in Fig. 2. ●, South side; ○, north side.

cycle, with a period probably in the range 10–100 d. These loca' movements are believed to relate to the regional ice flow pattern, but further and more accurate measurements are necessary to check this.

I conclude that the rift is filled with water in free circulation with the Ross Sea. The salinity is slightly higher than Antarctic surface water or circumpolar deep water, but lies within the range of Ross Sea shelf water[5] (34.75 ‰ –> 35.00 ‰). Furthermore, the presence of living algae indicates a direct connection with the waters of the open Ross Sea 550 km to the north. The
Fig. 4 Cross-section north from the edge of the ice rise to a block of the Ross Ice Shelf (A–A' in Fig. 1), showing underwater ice and bottom topography inferred from surface elevations with respect to sea level.

normal marine salinity indicates that there is little freezing or melting in the rift, or at least that the circulation is sufficient to prevent a measurable change in salinity. The mean annual temperature is −27 °C (ref. 6), but the temperature gradient, and thus the rate of freezing or melting, of ice forming the rift is not known.

The discovery of seawater near the head of the Ross Ice Shelf provides a topographic datum (sea level) that was not previously available in the region. The rift itself also provides biologists with access to an unusual new ecosystem. The fishing prospects are quite good too, for specimens of the benthic fish *Trematomus bernacchii* have recently been caught beneath permanent ice cover 100 km from the open sea in the Antarctic Peninsula[7]. Experience suggests that crevassed areas on ice shelves are worth closer examination. In the past they have been regarded as hazards to be avoided, but it is now evident that some crevasses have considerable scientific value as natural access ways to the sea beneath.

Cryptic suture in the eastern Grenville Province

IN order to explain palaeomagnetic data from the Precambrian Shield of North America (Laurentia), Irving *et al.*[1] have suggested that Grenvillia was separated from Interior Laurentia 1,150 Myr ago and then rejoined it about 1,000 Myr ago to form the present day Canadian Shield. This hypothesis requires that a suture exists within the Grenville Province south of a region of Grenville rocks which are considered to be metamorphosed equivalents of rocks within the adjacent, older structural provinces, and north of sampling sites used to determine Grenvillia poles (Fig. 1); the Grenville Front has been discounted as the site of the suture[1]. A weakness of this hypothesis is that there is no known geological evidence for a suture in the appropriate location. It has been suggested[1], however, that the crust now exposed as the Grenville Province originally occupied deep crustal levels (10–20 km) and that any traces of former intervening oceans may have been destroyed. We present here an interpretation of gravity data in the region which is in accord with the presence of a cryptic suture within, or proximal to, the eastern part of the suture zone as delineated by the palaeomagnetic investigations.

A Bouguer anomaly map of the eastern Grenville and neighbouring regions (Fig. 1) shows a striking, linear negative anomaly, the Grenville Front Low[2], extending from Lake Mistassini to the Labrador coast, a distance of about 1,200 km. For the whole of this distance the anomaly straddles the Grenville Front and its axis lies consistently within the Grenville Province. In profile (Fig. 2) the anomaly is asymmetrical with gradients on the northern flank consistently averaging about 0.35 mgal km⁻¹, and those on the southern flank maintaining an average of about 1 mgal km⁻¹. The linearity of the southern flank is locally disturbed by anomalies associated with large gabbroic intrusions. The background level of anomalies north of the Grenville Front Low is noticeably lower by about 15 mgal (ref. 2) than that over the Grenville Province.

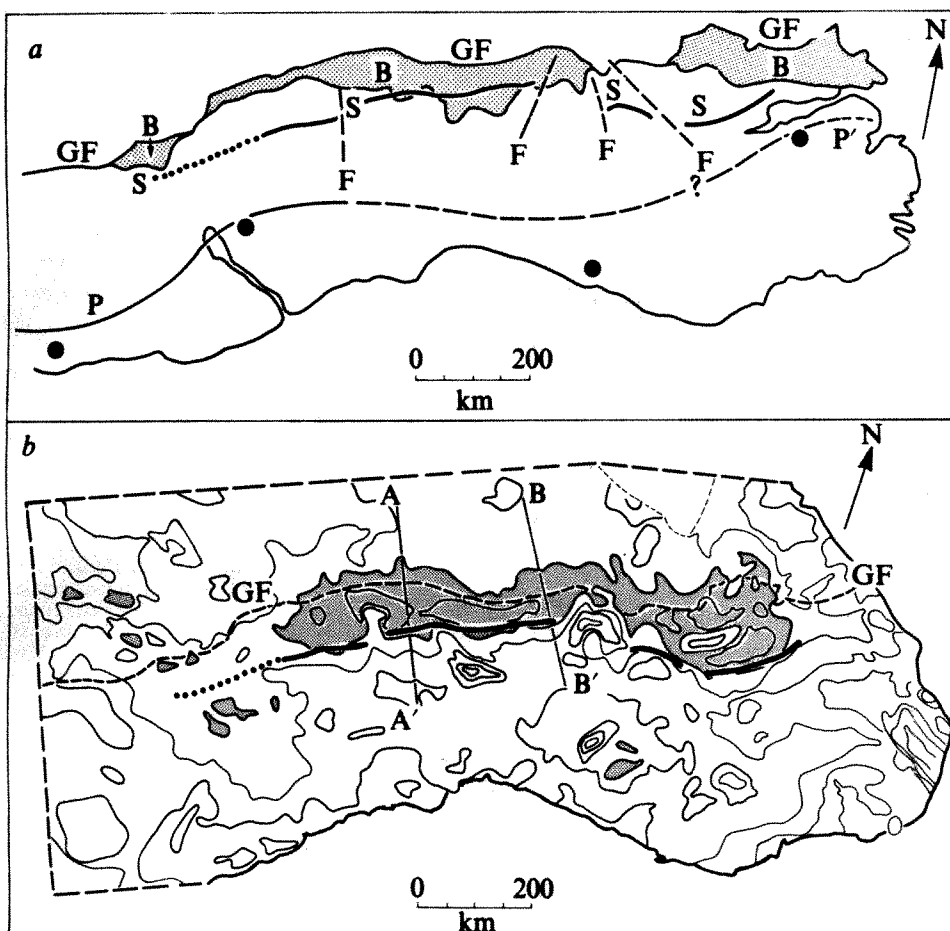
Various hypotheses—massive granites[3], a metasedimentary trough[4], and a crustal root combined with low velocity–low density seismic layers[5]—have been advanced to explain the anomaly, but strong evidence in favour of one or other of these hypotheses is largely lacking[2]. The anomaly is clearly the expression of large scale, crustal structure and not a manifestation of discrete lithological variations. Tanner[6] has suggested a model comprising a denser than 'normal' Grenville upper crust in contact with Superior crust of 'normal' density; the remaining portions


Fig. 1 *a*, Outline map of eastern Grenville Province: B (shaded areas), terrain B of Irving *et al.*[1]; GF, Grenville Front; P–P', northern limit of palaeomagnetic poles obtained for Grenvillia; dashed lines (F), interpreted faults; heavy solid lines (S), trace of suture interpreted from gravity anomalies; dotted line (S), trace of suture interpreted from magnetic anomalies; ●, sampling sites for palaeomagnetic sudies[1]. *b*, Bouguer anomaly map of eastern Grenville Province; contour interval, 20 mgal: shaded areas, anomalies with values of less than —80 mgal; position of suture outlined with same line pattern as in *a*; GF, Grenville Front; A–A', B–B', lines of gravity interpretations illustrated in Fig. 2.

of both crusts are of 'normal' density. On this model the compensating base of the thicker Grenville crust would be the principal cause of the low and of the gentle northern flank of the anomaly, and the denser upper crust, dipping about 45° south-eastwards from near the Grenville Front to a uniform depth of 20 km, would explain the steep southern flank and the higher background level of anomalies over the Grenville Province. The thicknesses of the Superior and Grenville crusts (35 and 40 km, respectively[6]) have been confirmed seismically[5].

Seismic work[5] has also indicated a two-layer crust for both structural provinces, with the Conrad discontinuity occurring at depths of 14 and 21 km, respectively, under the Superior and Grenville provinces; a thicker crust (45 km) with the Conrad discontinuity at a depth of 24 km was indicated under the axis of the Grenville Front Low. Using the seismic information Thomas[2] proposed a model in which the gentle northern flank of the anomaly results from the downward flexuring of the older structural provinces towards the axis of the anomaly. The effect of such downwarping is to induce lateral density changes between the upper and lower crusts and between the lower crust and the mantle, thus producing mass deficiencies. Supporting evidence for such flexuring is provided by the preservation of the string of Aphebian and Helikian sedimentary–volcanic basins along the northern side of the Grenville Front. The seismic root[5] may also contribute to the gravity low. The steep flank is formed by a major break separating a denser Grenville crust from Superior crust. This postulated break occurs up to 100 km south of the Grenville Front, thereby placing the front itself entirely within Superior-type crust. We suggest that this break is the line of the cryptic suture.

Gravity interpretations for a single layer crust along the lines A–A' and B–B' of Fig. 1 are shown in Fig. 2. The

models are extremely simple and in each case comprise Superior-type crust (34 km thick) in contact with Grenville crust (39 km thick) which is 0.06 g cm^{-3} denser; the density of the mantle is 0.4 g cm^{-3} greater than that of the Superior crust. Under the axis of the anomaly the Superior-type crust attains a thickness of 38 km, but this value falls short of the 45 km predicted from the seismic analysis[5]. It is impossible to reconcile gravity and seismic thicknesses without changing the density of the lower crust under the axis of the gravity anomaly. The contact between the two crustal blocks in both models slopes southwards under the Grenville Province, from points near the lower portion of the southern flank of the anomaly; these points are located 37 km (A–A') and 55 km (B–B') south of the Grenville Front. On the basis of these interpretations it has been possible to sketch the surface trace of the suture (Fig. 1) which is extended south-westwards along a line separating areas of strongly contrasting magnetic patterns[7].

Evidence of a major, continuous structural feature has not yet been recognised on the surface along the predicted trace. We believe, however, that this feature represents a cryptic suture of the type presented in the continental collision–basement reactivation model of Dewey and Burke[8] (such as the Indus Suture). The widespread distribution of anorthosites and granulite facies metamorphism within the Grenville Province is compatible with this model for the crustal levels exposed at present. At these levels it is likely that ultramylonites and pseudotachylites, which are believed to occur in the deeper levels of sutures[8], will ultimately be discovered in the region of the proposed suture. Dewey and Burke[8] believe that the analogue of the Indus Suture for the Grenville situation lies south-east of the exposed Grenville Province. Our model suggests, however, that suturing has occurred along the northern edge of the Grenville Province which concurs with the hypothesis
Fig. 2 Profiles of observed Bouguer anomalies (heavy solid lines) and calculated anomalies (light dashed lines), near-surface geological sections (GS), and interpreted crustal models (ICM) along lines A–A' and B–B' of Fig. 1; density contrasts $(g\,cm^{-3})$ are indicated for the interpreted crustal models. Design of organic metals and superconductors

I WISH to draw attention to the potential of odd alternant hydrocarbons (OAHs) in the design of organic metals and superconductors which gives reason to suppose that they may prove equal or even superior to present systems. There is now strong evidence for the existence of the metallic state in certain organic charge transfer salts, and a suggestion of low temperature superconducting fluctuations in the case of tetrathiofulvalene–tetracyanoquinodimethane (TTF–TCNQ); present interest is now focused on the stabilisation of these states at greater (critical) temperatures[1]. In contrast to the molecular crystals usually formed by conjugated organic molecules (which are held together by van der Waals' forces and characterised by a relatively weak intermolecular interaction), these salts crystallise as segregated one-dimensional stacks of cation and/or anion radicals in which the charge transfer process and thus the electronic mobility within a stack is greatly enhanced by the abnormally high overlap of the π-electron wave functions of nearest neighbours in the stack and by the ability of the constituent molecules to stabilise an ionic fluctuation.

Odd alternant hydrocarbons are described in refs 2 and 3; it will be sufficient to note that within the Huckel molecular orbital (HMO) theory, neutral OAHs possess one unpaired electron in a formally non-bonding molecular orbital, and as alternant hydrocarbons have zero charge density at all atoms. It also follows that an OAH can give rise to a stable, closed shell cation and anion (in which there is effective dispersal of charge density) and that the bond orders (and by inference bond lengths) remain invariant among this triad of oxidation states. Furthermore, the discussion will depend on the extrapolation of the properties of the isolated molecules into the crystalline state. This assumption is likely to provide a reasonable description of the solid state properties, as these one-dimensional

charge transfer compounds give rise to a single narrow conduction band (the bandwidth of which is proportional to the intermolecular electron-transfer integral (t)), and may be studied in the tight-binding approximation[1,4]. The conduction band is formed from a linear combination of the singly occupied molecular orbitals (conveniently termed conduction molecular orbitals (CMOs) on each molecule in the one-dimensional lattice. The systems are usually treated in terms of the Hubbard[5] Hamiltonian, and within this model the Hartree approximation indicates that the metal–insulator transition[6,7] will occur at $U_{eff}/4t = 1$, where U_{eff} is the energy of an ionic fluctuation $(..M...M...\rightarrow..M^+...M^-..)$ and t is the intermolecular transfer integral which arises from overlap between the CMOs on adjacent sites M (where $M = $ TTF$^+$, TCNQ$^-$ or OAH).

For comparison I choose the ionic charge transfer salt (TTF–TCNQ) (refs 1, 8 and 9), the CMOs of which are shown in Fig. 1 together with those of OAHs phenalenyl (PLY) (refs 3 and 10 and my unpublished work) *sym*-tribenzophenalenyl[11,12] and *sym*-nonabenzophenalenyl. The various criteria which are thought to be important in the design of organic metals and superconductors have been thoroughly discussed by others[1,13-15]; they are: (1) The existence of unpaired electrons. Neutral OAHs are free radicals and as such possess one unpaired electron in a non-degenerate MO (just as TTF$^+$ and TCNQ$^-$).

(2) A uniform crystal structure. Unlike TTF$^+$ and TCNQ$^-$, no counter-ion is required for OAHs which may form totally homogeneous crystals.

(3) Relatively weak electron–electron repulsion (minimisation of U_{eff}). SCF MO calculations (my unpublished results) show that PLY has an ionic fluctuation (or disproportionation) energy of the same order of magnitude as TTF$^+$ and TCNQ$^-$. This stems from the favourable dispersal of charge and the absence of di-ions in this process (that is, 2 OAH $\rightarrow$ OAH$^+$ + OAH$^-$; compare with 2 TCNQ$^-$ $\rightarrow$ TCNQ + TCNQ^{2-}) in this latter respect OAHs are more like normal (Group IA and IB) metals. This is particularly dramatic when it is remembered that PLY is a hydrocarbon, and a further reduction in the ionic fluctuation energy would be expected in systems which are appropriately substituted at the active positions, and in the larger OAHs where there is an even greater delocalisation of charge density.

(4) Maximisation of the intermolecular transfer integral (t). This may be accomplished in two basic ways: First, by maximisation of the degree of overlap between the CMOs of adjacent molecules in the stack; second, by reducing the intermolecular spacing. As shown below, OAHs may be expected to prove superior to ionic charge transfer salts on both counts.

The TCNQ$^-$ ions in charge transfer salts are known to occur in a variety of columnar stacking arrangements[16-20], but in none of these are the TCNQ$^-$ ions directly over each other, so as to give optimal overlap of the CMOs. In the highly conducting salts, such as (TTF–TCNQ) (ref. 20), the ions stack to give overlap patterns of the CMOs which are essentially translated by one node in the wave-functions, and probably correspond to the second best phase relationship between adjacent molecules. The non-optimal stacking arrangement in charge transfer salts may be attributed to a combination of two factors: the need to maximise the coulomb attraction with counter-ions[21] (see (2) above), and the unfavourable intracolumnar electrostatic interaction between the high charge densities which are present in these ions. This repulsion is maximised in a completely superimposed stacking arrangement (even in the offset configuration the interaction is high, see below). This contrasts with the case of OAHs which are neutral radicals, and where the local charge densities are extremely small (zero in the HMO approximation). It is therefore to be expected that OAHs will adopt a totally eclipsed stacking arrangement with optimum overlap of the CMOs, particularly if the unpaired electrons in charge transfer compounds make a significant contribution to the cohesive binding of the crystal[21] (as in
Fig. 1 The CMOs of TTF$^+$ (*a*), TCNQ$^-$ (*b*), PLY (*c*), *sym*-tribenzophenalenyl (*d*), and *sym*-nonabenzophenalenyl (*e*). The CMO is the highest (singly) occupied MO in the molecule and forms the basis for the conduction band in one-dimensional face-to-face charge transfer compounds. The dimensions and wave functions of (*a*)–(*c*) were calculated by SCF MO theory, whereas (*d*) and (*e*) are shown with HMO wave functions and standard geometries[2]. Open and stippled circles represent the positive and negative coefficient, respectively, of the $2p\pi$ atomic orbital; ., denotes a node in the wave function.

normal metals).

Turning now to the second point, the reduction of the intermolecular spacing in charge transfer compounds, it is appropriate to begin by considering the Madelung constant (α) of a one-dimensional lattice of positive or negative point charges (which are assumed to represent TTF$^+$ or TCNQ$^-$). The result is the same in both cases, and the Madelung constant is given by $\alpha = 2(1 + \frac{1}{2} + \frac{1}{3} - \frac{1}{4} + ...)$. This series is divergent, and as the magnitude of the repulsion between adjacent sites is quite large (a value of 3.0 eV has been estimated[22] for TCNQ$^-$ ions), it is apparent that the intermolecular approach between adjacent molecules in salts such as TTF$^+$ and TCNQ$^-$ is limited by this unfavourable electrostatic contribution to the cohesive binding energy of the crystal along the one-dimensional axis. Of course OAHs, being neutral molecules, have a Madelung constant $\alpha = 0$. With the removal of the coulombic repulsion along the one-dimensional axis, decreased intermolecular spacing would be expected to follow. Furthermore, the intermolecular spacing between adjacent TCNQ$^-$ molecules has been shown to exert a profound effect on the electronic structure of these solids, and it is significant that the salt with the highest conductivity so far [1,8,9] has the closest approach between adjacent TCNQ$^-$ ions[20]. This is not surprising as t is of exponential form, and at the characteristic separation shows great sensitivity to distance. For example, a decrease in the intermolecular separation of 0.2 Å from the "normal" value of 3.2 Å (TCNQ$^-$) leads to an increase in t of more than 30% (my unpublished work).

(5) The question of superconductivity in organic metals is now in a state of flux (see refs 1, 9, 13–15, 23–29). A full discussion of the relevance of OAHs to this general area will be deferred to a later paper; the likely differences in the phonon spectra of OAHs and conventional systems such as TTF and TCNQ suggest that OAHs hold promise in the design of organic superconductors. In the parent OAHs the coupling between the intramolecular vibrational levels and the conduction electrons is minimal (zero in the HMO approximation), as the CMOs are formally non-bonding and the occupancy of these orbitals therefore makes no contribution to the bond order. This contrasts with systems such as TTF and TCNQ, where in the case of TCNQ electron addition progressively

changes the molecular character from quinonoid to benzenoid with accompanying nuclear reorganisation. This effect (which in the crystal may be viewed as the intramolecular phonon contribution to the polaron binding energy) has been implicated in both the high conductivity[1,25] (as a mechanism for electron-pair formation), and in the non-metallic transition observed for (TTF–TCNQ). In the latter case it has been suggested[30-33] that the librational distortion provides the driving force for a Peierls transition[34]; clearly this behaviour would be inhibited in OAHs where, in the case of PLY, I calculate the distortion energy to be decreased by at least an order of magnitude. Furthermore, if the intramolecular contribution to the transverse optical branch of the phonon spectrum does make a contribution to the high conductivity of salts such (TTF–TCNQ)[1,25], an analogous effect may be introduced into OAHs in an easily controllable manner by exocyclic substitution at the active positions. Finally it is appropriate to point out that ionic fluctuations in charge transfer compounds will always be strongly coupled to the longitudinal acoustic branch of the phonon spectrum and in the case of OAHs will lead to a shortening of the intermolecular spacing (with concomitant increase in the transfer integral) due to the formation of an adjacent cation–anion pair, which should be particularly favourable to the collective mode involved in Frohlich-type superconductivity[23,24,35] and may even stimulate cooperative polaron formation between chains.

Of the OAHs, PLY is probably best known[3], and there is an extensive chemistry for cation, neutral radical (there is some tendency towards dimerisation in solution[3,10]), and anion; nevertheless, one of the chief attractions of OAHs is the diversity of structures and substitution patterns which may be chosen from, in order to satisfy the design specifications of organic metals and superconductors.

Recent climatic warming around New Zealand

MANY papers have described the climatic fortunes of areas in the Northern Hemisphere over the past few hundred years; the progressive warming during 1890–1940, and the present deterioration. Some people have suggested that the globe could be descending into an ice age (see ref. 1), but such assumptions are derived mainly from data for the Northern Hemisphere. Moreover, data for the Southern Hemisphere used[2,3] so far have chiefly been obtained from locations between the Equator and 40 °S. Information from higher latitudes, where any variations are amplified, is sparse. Here we present the results of an examination of a small area in the mid-latitudes of the Southern Hemisphere which has been warming over the past thirty years.

New Zealand is a long narrow country which straddles the lattitudes 34°–47°S, with a SW–NE oriented axial range, the Southern Alps, rising to 3,764 m in the South Island. The southern westerly wind belt which crosses southern New Zealand gives higher precipitation on the windward west coast, and less on the leeward east, whereas the north of the country protrudes into the subtropical high pressure belt.

Extensive records of temperature, rainfall and air pressure for ten locations (Fig. 1) were analysed: six urban, two rural, and two small islands[4,5]. All stations had minimal site changes except Auckland where temperature correction factors were applied. The data were investigated using 5-yr (short term variation) and 20-yr (longer term trends) running means. The rural stations were used to check that changes seen in urban areas were not attributable to the

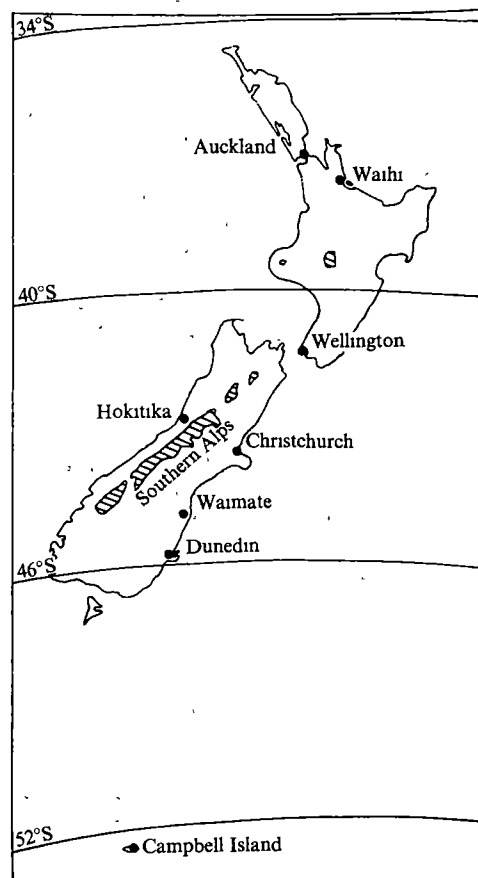
Fig. 1 Location diagram of all sites in the New Zealand region quoted in this report. Hatched area indicates land above 2,000 m.


Fig. 2 ——, Twenty-year running means of mean annual temperature showing trends typical of New Zealand locations; . . ., five-year running means. Temperature scale shown diagrammatically at left. Numbers indicate average annual mean temperature of the entire station record. Breaks in graphs indicate incomplete records.

heat island effect found in cities. Auckland barometric pressure acted as a position indicator for the subtropical anticyclonic belt. The Auckland–Dunedin pressure differences was used as an index of the strength of the westerlies over New Zealand.

Figure 2 shows typical temperature fluctuations and variations in the New Zealand area. Fluctuations over the whole region are in phase, though of different amplitudes. The urban heat island effect does not interfere with the

now the area is enjoying its warmest spell since temperature measurements began. The warmest single year yet recorded over all New Zealand was 1971.

Rainfall analysis over New Zealand shows no significant temporal variation. Air pressure analysis (Fig. 3) reveals higher pressure over the country around the early 1890s when weak westerlies occurred The subtropical ridge has migrated north gradually since 1894 accompanied by a great strengthening of the southern westerlies over New
Fig. 3 *a*, Running means of mean annual air pressure at Auckland and Dunedin; *b*, running means of the Auckland–Dunedin air pressure gradient. Notation as in Fig. 2.

trends observed; Waimate, a rural centre 180 km from Christchurch, has variations almost identical to those of urban Christchurch; Waihi and Auckland respond similarly.

The climatic vicissitudes show no great fluctuations in the initial record up to 1880 (Fig. 2). Climatic deterioration occurred in the two decades 1880–1900, the temperatures being cool about 1885, and mild around 1893, but with a declining trend over the whole of New Zealand. The period 1900–1935 was the coldest over the country in recorded history with the years about 1904, 1913, 1921 and 1931 being especially harsh. Climatic amelioration has been experienced throughout the whole region during 1935–1970, temperatures climbing by 1 °C over these years. The mid-1950s were very much warmer than average and

Zealand by 1898, and strong westerlies persisted for the next 10 yr. The migration of the subtropical ridge, with strengthening of the westerlies could well explain the climatic deterioration experienced. Auckland barometric pressure has risen slowly since records began again in 1918 indicating a slow and continual southward shift of the subtropical anticyclonic belt over the past 50 yr. The westerlies over New Zealand weakened around 1935, the time when the present amelioration began. Apart from a small strengthening of the westerlies around 1946 when a small downward fluctuation in the rising temperature trend occurred, the westerlies have not been strong. The southerly migration of the high pressure zone and weaker westerlies over New Zealand seems to explain the recent warming.

Our results reveal that climatic changes in the New Zealand area do not parallel published curves for the globe[2,3], so we must re-examine the validity of climatic trends for the Southern Hemisphere computed with little regard to data from points south of the 40th parallel. New Zealand was cooling in the period 1880–1900, and had its coldest period during 1900–1935 when the Northern Hemisphere was experiencing some of the warmest years on record[4]. Conversely, in the past three decades the New Zealand area has warmed up while northern continents have been cooling rapidly. The five year running means of Scott Base, Antarctica, show a rise from −21 °C in 1960 to −15.9 °C in 1969 (ref. 5). Of eight main Australian urban centres examined from statistical publications for individual Australian states[6-8], seven show at least a 0.5 °C rise since 1945. Orcadas Island at latitude 60° 45' S near South America, similarly has warmed[1] by 0.5 °C since 1940. So it seems that the warming in the New Zealand region is common to a wider range in the Southern Hemisphere.

Solid state batteries containing silver sulphonium iodide electrolyte

THE high ionic conductivity α phase of AgI can be stabilised at room temperature by the addition of various inorganic or organic salts (such as Ag_4RbI_5, ref. 1) to the AgI. These systems have attracted considerable interest as electrolytes in solid state batteries[2,3].

We have investigated the properties of electrolytes based on silver iodide with various sulphonium iodides, and we have shown that the solids so prepared are good ionic conductors. Conductivities of pressed pellets were measured as a function of the molar ratio of the components and the composition corresponding to the maximum conductivity was used in subsequent formulations. Examples of the systems studied are $AgI-(CH)_3SI$, $AgI-(CH_2)_4SCH_3I$, $AgI-O(C_2H_4)_2SCH_3I$, $AgI-(CH_2)_5SCH_3I$ (ref. 4) for which the maximum conductivities fall in the range 3×10^{-3} $(\Omega\, cm)^{-1}$ to 4×10^{-2} $(\Omega\, cm)^{-1}$. We are now investigating these and related electrolytes in solid state batteries; we have shown that battery systems can be prepared which have good voltage–time characteristics, good mass efficiency and in which the electrolyte is compatible with the electrode material (thus indicating potentially good shelf life). Such a battery has the characteristics of a commercially viable system.

$Ag_7(CH_2)_4SCH_3I_8$ electrolyte has been used in a typical battery. The anode is composed of Ag powder, electrolyte and graphite or carbon black. It was found that mass efficiency was increased by using silver powder of low particle size (Johnson Matthey Cypher 88 silver powder, 90% by weight having particle size less than 5 μm).

The cathode, which in these examples is functioning as a source of iodine, is prepared by reacting a sulphonium iodide with iodine to form a sulphonium polyiodide which is then mixed with electrolyte and graphite. In practice, only $(CH_2)_4$-SCH_3I_3 (melting point 89 °C) and $(CH_2)_4SCH_3I_5$ (melting point 54 °C) of the cheap sulphonium polyiodides are useful because the melting points of the others are too low to be of practical use.

The anode, electrolyte and cathode powders are pressed together into a compacted pellet which forms the battery in the subsequent tests. For reasons of compatibility, the system chosen for the initial tests had the same sulphonium iodide in both the electrolyte and in the cathode.

With this system, using $(CH_2)_4SCH_3I$ as the sulphonium iodide, the electrolyte was unstable in the presence of polyiodides higher than the tri-iodide. The evidence for this was:

(1) The resistances of pressed pellets of mixtures of $Ag_7(CH_2)_4$ SCH_3I_8 + iodine, $Ag_7(CH_2)_4SCH_3I_8$ + $(CH_2)_4SCH_3I_5$ and $Ag_7(CH_2)_4SCH_3I_8$ + $(CH_2)_4SCH_3I_3$ were taken at various intervals at 37 °C. The change (Fig. 1) in resistance indicated the following reactions:

$$Ag_7(CH_2)_4SCH_3I_8 + I_2 \xrightarrow{\text{fast}} 7AgI + (CH_2)_4SCH_3I_3 \quad (1)$$
$$\text{(resistance rose sharply)}$$

$$Ag_7(CH_2)_4SCH_3I_8 + (CH_2)_4SCH_3I_5 \xrightarrow{\text{slow}}$$
$$7AgI + 2(CH_2)_4SCH_3I_3 \quad (2)$$
$$\text{(resistance rose slowly)}$$

$$Ag_7(CH_2)_4SCH_3I_8 + (CH_2)_4SCH_3I_3 \longrightarrow \text{no reaction} \quad (3)$$
$$\text{(no change in resistance)}$$
Fig. 1 Time variation of resistance, at 37 °C, illustrating results on which equations (1), (2) and (3) are based.

(2) Batteries at 37 °C using $(CH_2)_4SCH_3I_3$ in the cathode showed good voltage time characteristics whereas $(CH_2)_4SCH_3I_5$ in the cathode showed poor voltage time characteristics (Fig. 2).
Fig. 2 Time variation of cell voltage, at 37 °C, for cathodes containing: *a*, $(CH_2)_4SCH_3I_3$; *b*, $(CH_2)_4SCH_3I_5$.

(3) When the batteries were cut open at the end of the test the electrolyte with $(CH_2)_4SCH_3I_3$ in the cathode still remained a pale yellow colour whereas the electrolyte with $(CH_2)_4SCH_3I_5$ in the cathode had reacted according to the second equation and was much darker in colour.

We thank Mallory Batteries (UK) Ltd for support. Further details will be reported elsewhere.

Heavy metal binding sites in river water

THE transport of heavy metals (HMs) and their effects on biological systems in natural waters are greatly influenced by their interactions with soluble and insoluble water components[1,2].

We have found that ion-specific electrodes can serve as a convenient, precise and sensitive means of measuring the binding ability of solutions for a number of HM ions. We have studied the binding strengths and binding sites of river water for Hg^{2+}, Pb^{2+}, Cd^{2+}, and Cu^{2+} ions, using specific electrodes (see also ref. 3). We used standard membrane filters to retain particles (0.45 μm pore size) as have been used in past studies[4,5]. We also found that the use of standard ultrafilters to retain macro-molecules (in these studies, of molecular weights 45,000, 16,000 and 1,400) may give a much finer definition of the size of binding sites than those obtained previously by filtration studies. These techniques may prove to be very valuable in

studying the dynamics of heavy metal transport and utilisation in natural waters. They could probably be automated for *in situ* determinations of chelation capacity of such waters.

The Hg^{2+} binding capacity (expressed as α, the fraction of the added ion which is bound) of a sample of water from the Ottawa River before and after filtration through different sized ultrafilters is shown in Fig. 1. The ion was strongly bound until 15 p.p.m. had been added; then the bound fraction decreased rapidly, indicating that saturation of the binding capacity of the water had been achieved. Passage of the water through filters, even those retaining molecules with a molecular weight of 1,400 had little or no effect on binding capacity.

The binding capacity of other heavy metal cations showed a different response to filtration. With Pb^{2+} ions, for example, saturation of the metal-binding capacity of water was spread over a much wider range of added HM ions (Fig. 2). Thus, an equilibrium could exist with substantial amounts of free Pb^{2+} ions. Passage of the water through a 0.45 μm filter did not reduce Pb^{2+} binding capacity, but passage through smaller filters significantly reduced it. Some of the Pb^{2+} binding components were less than 0.45 μm in diameter but had molecular weights greater than 45,000. Others had molecular weights between 45,000 and 16,000, and still others had molecular weights of less than 1,400.

The binding capacity of river water for all the ions, and the equilibrium binding constants of these ions with river water are presented in Tables 1–3, which also show the changes in binding capacity for different HM ions caused by the passage through different sized filters. Cu^{2+} ions behaved like Pb^{2+} ions, except that substantial amounts of Cu^{2+} binding activity were removed after passage through a 0.45-μm filter; that is, as shown earlier for other water samples[4], a good deal of Cu^{2+} binding activity is particulate. The low Cd^{2+} binding ability was unchanged by filtration through any but the smallest filters.

Fig. 1 Binding of Hg^{2+} by river water. α, The bound fraction, is calculated as $(T_M - [M^{2+}])/T_M$ where T_M is the total HM^{2+} added and $[M^{2+}]$ is the concentration of free HM^{2+} determined by the specific ion electrode. Increments of $Hg(NO_3)_2$ were added to 50-ml samples of Ottawa River water, unfiltered or passed through membrane filters or ultrafilters: *a*, 45,000 molecular weight filter; *b*, unfiltered and 0 45-μm filter; *c*, 16,000 and 1,400 molecular weight filter.

The chemical nature of the HM binding sites in river water is unknown, but we have shown that the binding is not dependent on the presence of HCO_3^- or CO_3^{2-} ions in Ottawa River water. When the water was acidified, gassed with N_2 to drive off CO_2 and neutralised, the binding ability for all HM ions remained the same. In contrast, water from other bodies of water lost a good deal of binding activity after this treatment, implying that HCO_3^- or CO_3^{2-} ions play an important part in such binding. These ions have been implicated in the binding of Cu^{2+} and Cd^{2+} by water from rivers in England[4,5]. We considered the possibility that other inorganic anions might be involved in HM binding. The level of phosphate in this water (about 1 part per 10^9) was too low to be significant in HM binding. The limit of detection of sulphate was about 5 p.p.m.; if present, such levels could be significant. When samples of ultrafiltered (molecular weight, 1,400) Ottawa River water were evaporated to dryness, ashed (at 900 °C for 16 h) and reconstituted with deionised water, all the HM binding activity was lost. Separate experiments showed that such treatment did not reduce the HM-binding ability of pure Na_2SO_4 solution. We know of no other inorganic anions likely to be present in significant amounts. The ultrafiltered water is free from suspended particles or macromolecules, and so binding must be a result of the formation of chemical complexes rather than of physical adsorption on surfaces. We think it very probable that the complexing components are organic molecules, destroyed or volatilised during ashing.

Table 2 Total loss (%) in metal-binding capacity after ultrafiltration

	Filter types			
M^{2+}	0.45 μm	45,000 m.w.	16,000 m.w.	1,400 m.w.
Hg^{2+}	0	0	11.7	11.7
Pb^{2+}	0	31.9	47.9	56.4
Cu^{2+}	34.4	82.6	82.6	82.6
Cd^{2+}	0	0	0	46

Table 3 Metal-binding capacity (p.p.m.) of ultrafiltered (molecular weight 1,400) river water before and after removal of inorganic and organic carbon compounds

M^{2+}	Untreated	Inorganic carbon removed	Total carbon removed
Hg^{2+}	11.0	11.04	0.6 p.p.m.
Pb^{2+}	4.0	4.0	No binding
Cu^{2+}	1.6	1.7	0.075 p.p.m.
Cd^{2+}	0.6	0.55	No binding

Fig. 2 Binding of Pb^{2+} by river water. Calculations as in Fig. 1. $Pb(NO_3)_2$ was added to river water samples. *a*, Unfiltered and 0.45 μm filter; *b*, 16,000 m.w. filter; *c*, 45,000 m.w. filter; *d*, 1,400 m.w. filter.

The possibility that fulvic acid, probably the most important soluble 'humic substance' in natural waters[6-8], played a major part in HM binding was investigated by comparing the binding pattern of a sample of fulvic acid isolated from Podzol B_h soil[8] with the binding pattern of Ottawa River water towards different HM ions. Quite a different pattern was obtained: a 10 p.p.m. solution of fulvic acid had about the same binding ability towards Hg^{2+} ions as did river water, but a much weaker ability to bind the other heavy metal ions than did filtered or unfiltered river water samples. A comparison of the equilibrium constants of Ottawa River water and fulvic acid with the different HM ions (Tables 1-3) shows that fulvic acid cannot account for the HM binding capacity of this water. Studies on the HM binding pattern of fulvic and humic acids isolated from natural waters could help in deciding the role of these complex groups of substances in metal binding and transport by water systems.

A more detailed description of this work and information on the HM binding of other bodies of water has been submitted

for publication elsewhere. The work was supported by the Ottawa River Project, a joint study by the National Research Council of Canada Laboratories and the University of Ottawa.

Controlled growth of crystalline silicate fibres

DURING studies of the crystallisation kinetics of aluminosilicate glasses of approximately metasilicate composition, surface nucleated crystals have been observed to grow in a fibrous habit[1]. This has been attributed to the presence of β-CaSiO$_3$, the low-temperature polymorph of calcium metasilicate, the mineral equivalent of which, wollastonite, occurs naturally in a similar form.

To produce β-CaSiO$_3$ fibres in a more controlled fashion it is necessary to increase crystal growth rates in these glasses so that a zone heat treatment can be applied. An investigation by hot stage microscopy of the crystallisation kinetics of various compositions in the CaSiO$_3$ phase region has revealed that certain ternary glasses possess satisfactory growth-rate/temperature characteristics for this purpose. A glass of composition CaO–SiO$_2$–ZnO (30:50:20 weight %) was chosen as the most suitable material for initial experiments as it can be drawn easily into vitreous rods of about 1 mm diameter.

Attempts to induce longitudinal crystallisation in these rods by moving them slowly past an annular heating element proved ineffective as not only did crystals nucleate from the surface but the heated zone also slumped considerably, thus forming a brittle and distorted product. But if the rod is passed through an electrically heated platinum coil supporting a molten zone, any such crystals are removed, and β-CaSiO$_3$ crystallises from the supercooled melt on the far side in a truly aligned and fibrous habit. Since the glass does not pass through a low temperature before crystallising, neither surface nor internal nucleation can occur spontaneously.

The essential features of this experimental arrangement are shown in Fig. 1, together with an estimated longitudinal temperature profile and the corresponding growth rate profiles. Crystallisation is initiated by introducing a platinum probe into the melt at the start of the process, and thereafter the crystal front is self-stabilising at a position and temperaure where its growth rate is equal to the speed of travel of the rod. The temperature of crystallisation in a particular rod thus depends solely on its speed of travel, whereas any variation in heating power to the molten zone (which must be above the liquidus of the glass) merely changes the shape of the temperature profile and therefore the position of the crystal front. Since the glass composition is such that the α/β-CaSiO$_3$ inversion temperature is situated on the growth rate curve above the temperature peak, speeds below about 20 µm s^{-1} will cause the high-temperature polymorph α-CaSiO$_3$ to crystallise, whereas speeds greater than the growth rate maximum of about 50 µm s^{-1} will produce a non-crystalline glass rod.

Examination of thin sections of rod by optical microscopy reveals that β-CaSiO$_3$ crystallises as an array of parallel fibres some 5 µm in diameter right through the rod, so that only a few percent of residual glass remains. Laue X-ray patterns confirm a very high degree of orientation, with the crystallographic b-axis (which corresponds to the chain direction of the SiO$_4$ tetrahedra) aligned longitudinally. There is, in addition, some orientation in the plane perpendicular to the fibre axis, apparent in scanning electron micrographs of fracture surfaces (Fig. 2). In contrast, α-CaSiO$_3$ grown from the same glass composition but at lower speeds exhibits very little fibrous character or fracture behaviour, and the Laue pattern shows no recognisable orientation of its Si$_3$O$_9$ ring structure.

Rods of α-CaSiO$_3$ which are 1 mm in diameter have a rupture strength of 320 MN m^{-2} and an elastic modulus of 91 GN m^{-2}. These values are virtually identical to those of the base glass; but β-CaSiO$_3$ rods show significantly higher values of 540 MN m^{-2} and 124 GN m^{-2}, respectively. By comparison, rods prepared by conventional methods, which contain fairly random orientations of surface nucleated and internally nucleated crystals are too delicate to allow three-point bend tests to be carried out.
Fig. 1 Schematic diagram of apparatus for crystallisation from the melt (not to scale). The longitudinal temperature distribution, difficult to measure directly, is inferred to be approximately exponential, and corresponding growth rate curves are drawn from hot-stage micrography data. HC, Heating coil; MZ, molten zone.
Fig. 2 Scanning electron micrograph of β-CaSiO₃ rod fractured in three-point loading (longitudinal view). Scale bar: 20 µm.

This novel technique of directional devitrification from a molten zone may be extended both to produce aligned crystal growth in rods with larger cross sections and to draw continuous filaments directly from molten glass compositions which will crystallise at higher rates. Furthermore, it could be applied to any silicate or other system which crystallises in a sheet or chain structure.

New primitive therian from the early Cretaceous of Mongolia

THERIAN mammals with tribosphenic molars were probably in existence at the beginning of the Cretaceous[1]. This conclusion is based on a single heavily worn lower molar from the Lower Wealden (Neocomian) of England, named *Aegialodon dawsoni*. The molars of the Jurassic therians, (Pantotheria and Symmetrodonta) were capable only of puncturing and shearing. Tribosphenic molars have an additional cusp on the upper molars (protocone) which fits into a basin (talonid) on the matching lower molar. Unfortunately, the single lower molar of *Aegialodon* is extensively worn and slightly damaged. Consequently, it is difficult to discuss with confidence the structure of the earliest known tribosphenic molars, or the inferred structure of the matching upper molars, or the occlusal relationships. In this paper a brief description is given of an early Cretaceous mammalian lower molar from the Aptian of Asia. It is almost identical to that of *Aegialodon*. Because it is exceptionally well preserved and practically unworn, it provides critical information on the structure and function of the very early tribosphenic molars.

The Khovboor beds in Guchin Us somon (county) in the province (aymak) of Arvaykher contain a fauna of early

Cretaceous mammals. Collections from this site (Laboratory of Stratigraphy and Palaeontology, Geological Institute, Academy of Sciences in Ulan Bator) consist of numerous isolated teeth and fragmentary mandibles of triconodonts, multituberculates and therian mammals, as well as the isolated lower molar described here. About seven tons of sediments from the same locality have been washed and screened[2], and the large collection of mammals obtained is housed in the Palaeontological Institute of the USSR Academy of Sciences in Moscow (currently being investigated by Dr B. A. Trofimov). Four new mammalian genera have already been named but not described[3]: *Gobioconodon borissiaki* Trofimov, *Gobiodon infinitus* Trofimov, *Prokennalestes kozlovi* Trofimov and *Prozalambdalestes simpsoni* Trofimov. The classification line is: Theria of metatherian–eutherian grade; Family Aegialodontidae; *Kielantherium* gen. nov. Dashzeveg; *Kielantherium gobiensis* sp. nov. Dashzeveg (*Kielantherium* is a monotypic genus, the generic diagnosis is the same as for the type species), (Figs 1 and 2).

Holotype: Right lower molar, possibly M₂—GI (Ulan Bator) No. PST 10–14.

Horizon and type locality: Lower Cretaceous (possibly Aptian), Khovboor, Guchin Us somon, Arvaykher aymak, Mongolian People's Republic.

Derivation of name: *Kielantherium*—named in honour of Professor Zofia Kielan-Jaworoska; *therion* Gr., an animal; *gobiensis*, from the Gobi Desert.

Material: The type is a lower molar and is the only representative of this new genus and species in the collection. In the collection in Moscow a mandible with two lower molars, PIN No. 3101–32 seems to be conspecific with the type. The Moscow specimen was not named or cited in the list of species from Khovboor[3].

Diagnosis: Lower molar with a relatively narrow talonid, a small hypoconid and hypoconulid and a poorly differentiated ridge supporting two or three crenulations along its medial border, but a distinct ectoconid is not present. The protoconid was considerably higher than paraconid and the latter only slightly higher than the metaconid. Paraconid and metaconid were clearly separated at their bases on the medial face of the tooth.

Kielantherium is assigned to the Aegialodontidae on the basis of a strong similarity to the lower molar of *Aegialodon* in that: the trigonid is small and narrow; shearing surfaces 5 and 3 are small[4]; both anterobuccal and anterolingual cusps are present; relative height of the principal trigonid cusps are the same in both genera; there is a clear separa-

Fig. 1 *Kielantherium gobiensis* gen. et sp. nov. Outline drawings of lower M₂(?). *a*, Crown; *b*, exterior; *c*, interior; *d*, anterior; *e*, posterior views.
Fig. 2 *Kielantherium gobiensis* gen. et sp. nov. Stereophotographs. *a*, Posterior; *b*, crown; *c*, anterior of lower $M_2(?)$. $\times 36$.

tion between the bases of the paraconid and metaconid on the medial face of the tooth and; facet 1 can be divided into two subfacets by a line running parallel to the crista obliqua. *Aegialodon* and *Kielantherium* are remarkably similar to *Kermackia texana*[5] which is based on a single lower molar. The question which obviously arises is whether the type of *Kielantherium* is a premolar rather than a molar. The well developed trigonid cusps, the acute angle between the protocristid and paracristid and the referred specimen with two teeth *in situ* in the lower jaw in the collection from the Khovboor beds housed in Moscow, seem to rule out this possibility.

Kielantherium and *Kermackia* seem to be slightly younger in age than *Aegialodon* and are found in association with more advanced therians; *Prokennalestes* in the case of the former and *Pappotherium* and *Holoclemensia*[5] in the case of the latter. *Kermackia* and *Kielantherium* therefore seem to be survivors of mammals which had only recently developed a protocone in late Jurassic or early Cretaceous. This suggests that mammals with this feature may have had a wide distribution during the early part of the Cretaceous

(*Kermackia* in North America, *Aegialodon* in Europe, and *Kielantherium* in Asia).

Kielantherium differs from the late Cretaceous Deltheridiidae of Mongolia, *Deltatheridium* and Deltatheroides[6-8], in having a much more primitive structure, with a relatively smaller talonid, smaller talonid basin, in possessing an antero-lingual cusp which is absent in the Deltatheridiidae and in smaller dimensions.

I thank Professor A. W. Crompton for reading the manuscript and for helping in its preparation, Dr B. A. Trofimov for permission to study the collection of Khovboor mammals in his charge, and Professor Zofia Kielan-Jaworowska for the loan of the manuscript of her paper.

Cerebral dominance and reading habits

FREQUENTLY when an Israeli provides travel information in Hebrew, he points in one direction while simultaneously naming its opposite, for example he points to the left while saying: "You must turn right". When this contradictory behaviour is brought to his attention, he excuses himself and either points in the direction he had verbally indicated or corrects his error by changing the verbal expression to correspond with the physical. Observation of such verbal–spatial dissociation prompted the following experiments to explore systematically the possibility that Israelis make more errors in response to questions relating to left–right orientation than do non-Israelis.

Experiment 1 was a screening test. Four hundred right-handed college and high-school students (age range 16–27) participated. Two hundred were native-born Israelis; two hundred were new immigrants to Israel who had arrived within the past three years from Europe and North or South America. Each subject was asked, in random order and in his native language, to respond to a single command: "Look to the left" or "Look to the right." Eye movement responses were recorded by the examiner. Examiners were not informed of the purpose of the test.

Of the 200 new immigrants, 194 (97%) responded immediately and correctly; 6 (3%) responded with hesitation and with an initial movement of the eyes in the wrong direction (4 to the right, 2 to the left), but with subsequent self-correction. By contrast, only 128 (64%) of the 200 Israelis responded immediately and correctly, whereas 72 (36%) responded with hesitation and error (39 to the left; 33 to the right). The difference between native-born Israelis and new immigrants was highly significant ($z > 14.0$, $P < 0.001$; test for z value of significance of difference between proportions). Two types of error were noted among Israelis: 50 subjects (25% of the total Israeli group) responded with hesitation and with initial movement of the eyes in the wrong direction, followed by self-correction; 22 subjects (11%) looked in the wrong direction and did not self-correct. They did correct their direction of gaze, however, when the examiner repeated the command.

This screening test was repeated, in Arabic, with a group of 40 right-handed Arab students (age range 17–32). Twenty-three of the 40 subjects (57.5%) responded immediately and correctly; 17 (42.5%) responded with hesitation and with an initial movement of the eyes in the wrong direction (10 to the left, 7 to the right). Fourteen corrected

their errors without advice from the examiner; 3 did not correct their direction of gaze until the examiner repeated the question.

Experiment 2, a more demanding test of right–left orientation, was presented to 60 right-handed college students. Thirty were native-born Israelis (15 men, 15 women, age range 18–27, mean 21). Thirty were new immigrants to Israel who had arrived within the past three years from various European, North American and South American countries (15 men, 15 women, age range 18–26, mean 22). The test, developed for this experiment, required that the subject respond to an oral command by pointing to parts of the body, either on himself or on the examiner, as the examiner and subject sat facing each other.

Four types of questions were asked. In the 'self-uncrossed' condition, the subject had to point to a part of his own body without crossing the midline (for example, "With your right hand point to your right knee"). In the 'self-crossed' condition, the subject had to point to a part of his own body, across the midline (for example, "With your left hand, point to your right ear"). In the 'examiner-uncrossed' condition, the subject had to point to a part of the examiner's body, without crossing the midline of his own body (for example, "With your right hand, point to my left shoulder"). In the 'examiner-crossed' condition, the subject had to point to a part of the examiner's body by crossing the midline of his own body (for example, "With your right hand, point to my right eye"). Forty commands were given; ten for each condition. Half of the commands involved left hand and half right hand; commands were counterbalanced in each of the four conditions. The forty commands were presented in a predetermined, unpredictable order, and in the native language of each subject by examiners whose mother tongue corresponded with that of the subject. Examiners were not told of the purpose of the study until all testing was completed.

There was a striking difference in performance between native-born Israelis and new immigrants. Of a total number of 1,200 trials per group (30 subjects × 40 commands), Israelis made a total of 336 errors, whereas new immigrants made a total of 61 errors ($t=13.46$, $P<0.0001$; Student's t test).

Each of the sixty subjects made at least one error. No errors were made in the 'self uncrossed' condition. Most errors were made when subjects had to point to parts of the examiner's body and errors were more frequent in the crossed condition (see Table 1). Significantly more errors were made by the right hand than by the left hand, and by men than by women. These observations were similar for both Israeli and non-Israeli groups. Hesitation before response was more frequent in Israelis (23) than in non-Israelis (11).

These results show that native-born Israelis and Arabs

have significantly more difficulty with right–left orientation in response to oral verbal commands than do Europeans and Americans matched for age and educational level. These striking differences may be due to the influence of early-learned reading habits on cerebral function. I propose that reading habits of Europeans and Americans facilitate interhemispheric integration for initiating combined, verbal–spatial activity, whereas reading habits of Israelis and Arabs interfere with this integration.

Israelis and Arabs read from right to left; and Europeans and Americans read from left to right. These different patterns of reading are associated with different patterns of hemispheric activity. When Europeans and Americans start to read a word or line, both hemispheres are activated : the right hemisphere is activated for conjugate deviation of the eyes to the left; the left hemisphere is activated for verbal comprehension. When Israelis and Arabs start to read a word or line, the left hemisphere is activated both for conjugate deviation of the eyes to the right and for verbal comprehension.

Kinsbourne has proposed an attentional model of cerebral organisation which links orientation behaviour (as manifested by direction of gaze) to hemispheric laterality of thought process[1]. Thus, when silent verbal problem solving is being carried out, the eyes turn to the right, presumably because of activation of the left (language dominant) hemisphere. When silent visuospatial problem solving is being carried out, the eyes turn to the left, presumably because of activation of the right (spatial dominant) hemisphere. He further suggested that the physiological principle of reciprocal innervation[2] may apply not only at the spinal cord level but also at the level of the cerebral hemispheres. Accordingly, as one hemisphere is activated in the process of carrying out its functions, the other is inhibited with respect to its own major functions.

Applying these concepts to what was stated above concerning reading habits, we may conclude that initiation of reading for Europeans and Americans involves bilateral cerebral hemispheric activation, and concurrent bilateral hemispheric inhibition. For Israelis and Arabs the onset of reading involves activation of the left hemisphere, with concurrent inhibition of the right hemisphere. When repeated during a period of many years, the act of initiating the reading process gradually fosters the development in Europeans and Americans of bilateral interhemispheric integration for the initiation of tasks which require the simultaneous action of both hemispheres. This is not true, however, for Israelis and Arabs.

Thus, in the current experiments, in which an oral verbal command involving left hemispheric activation required a spatial response involving right hemispheric activation, the initial response of the European and American was more likely to be correct because the two cerebral hemispheres of these individuals had been educated to respond in an integrated manner at the beginning of such combined activity, whereas the initial response of the Israelis and Arabs was more likely to be slower or incorrect, because their brains require more time to allow interhemispheric integration to overcome the effects of the influence of reading habits.

I thank Drs H. Gordon and L. K. Obler for advice. Dr Phyllis Albert clarified the concepts and translated the paper into English.

MARTIN L. ALBERT*

Electrophoretic differences between sympatric ecotypes

ELECTROPHORESIS has been used extensively for characterising genetic variability within and between natural populations[1,2] but has not been applied to sympatric ecotypes. In the mosquito *Aedes aegypti* a dark feral form predominates throughout sub-Saharan Africa, but elsewhere in the tropics and moist subtropics a paler domestic form is found. The two ecotypes occur together in Africa in areas with a dry season during which natives store water in pots inside huts[3,4]. The indoor ecotype breeds continually in water stored in human dwellings, and the outdoor ecotype lives in treeholes and other sites around the dwellings and

The starch-gel electrophoresis methods of Ayala[5] were used except as noted in the tables.

Gene frequencies for six loci are listed in Tables 1-3. The indoor and outdoor ecotypes differed considerably at three loci. In alkaline phosphatase, the indoor ecotype was fixed whereas outdoor strains had considerable genetic variation. For Coomassie blue (a protein stain), however, the reverse was true—the outdoor ecotype was completely or nearly fixed whereas the indoor ecotype was quite variable genetically. In the outdoor ecotype leucine aminopeptidase bands 0.54 and 0.59 were similar in amount of staining, whereas in the indoor ecotype band 0.59 stains heavily and band 0.54 is usually absent or obliterated by band 0.59. Band 0.59 is nearly always present, and its obliteration of 0.54 made counting frequencies of 0.54 impossible.

Table 1 Gene frequencies for esterase, alkaline phosphatase, Coomassie blue and malic enzyme

	Esterase			Alkaline phosphatase			Coomassie blue			Malic enzyme

A. albopictus	0.78	0.22	91	1.00	0	76	1.00	0	99	0	1.00	14

The techniques of Ayala[5] were modified as follows. Esterase, no incubation in borate, 1.5 ml β-naphthyl acetate solution (1:1 water–acetone solvent) added; alkaline phosphatase, stain with no PVP, no NaCl; Coomassie blue, 60 mg Coomassie blue, 90 ml methanol, 18.3 ml glacial acetate, 91.7 ml water, after several hours washed with the same solution to clear background; malic enzyme, 0.056 M Tris-HCl buffer, PMS added only after 1 h incubation. Alleles are assigned positions relative to the distance travelled by the borate band, except for malic enzyme, for which the most frequent allele is assigned position 1.00. There are two esterase alleles at one locus[7]. For alkaline phosphatase, Coomassie blue and malic enzyme, band frequencies do not deviate from Hardy–Weinberg equilibrium assuming two Mendelian alleles at one locus.
*Sampled within one to two generations from field capture. Other samples were from laboratory colonies up to several years old.
†Gene frequency is for pupae only; older larvae have frequencies of 0.39, 0.61 (n = 28); half-grown larvae 0.95, 0.05 (n = 20).

breeds seasonally. Our data provide the first demonstration of electrophoretic differences between sympatric ecotypes.

The indoor and outdoor ecotypes used all came from an area (several square kilometres) around Rabai, near Mombasa, Kenya—the indoor samples from inside dwellings and the outdoor samples from feral habitats. The Kwa Dzivo sample came from eggs from tin cans nailed to trees in a village. A sample of *A. aegypti* from south-west Puerto Rico (Corozo, Maguayo, Sabana) in the Caribbean, *A. albopictus* from Singapore, and *A. mascarensis* from Mauritius in the Indian Ocean, were studied for comparison.

Crucial to the idea of sympatric polymorphism is the conspecificity of the two ecotypes. Both forms seem to be fully interfertile, with the colour pattern differences subject to continuous variation[4]. In our laboratory interbreeding occurred freely between the two ecotypes (the Mwamsabu indoor and the Bejumwa outdoor strains). Hybridisation experiments were carried out in the laboratory in cages with 20%, 50%, and 80% mixtures of the two ecotypes and 50% of each sex. Promiscuous coupling in *A. aegypti* precludes the use of coupling as a criterion of insemination. We therefore reared the offspring of each female and

Table 2 Gene frequencies of phosphoglucomutase alleles

	Locus A	Locus B						
Allele position	0.56	0.75	1.00	1.29	1.53	1.76	2.00	n
Indoor								
Rabai	0	0.05	0.60	0.35	0	0	0	54
Moyo	0	0.04	0.92	0.03	0	0	0	44
Mgandini*	0	0	0.82	0.13	0.06	0	0	95
Outdoor								
Rabai	0	0	1.00	0	0	0	0	46
Kombeni	0	0.01	0.99	0	0	0	0	44
Kombeni*	0	0.06	0.87	0.07	0	0	0	83
Kwa Dzivo*	0	0.04	0.86	0.10	0.01	0	0	91
Puerto Rico*	0	0	1.00	0	0	0	0	123
A. mascarensis	1.00	0	1.00	0	0	0	0	18
A. albopictus	0	0	0	0.04	0.19	0.58	0.19	13

The four alleles in *A. aegypti* were found by hybridising inbred lines to be at one locus[6], but band 0.56 of *A. mascarensis* is at a separate locus, and the alleles of *A. albopictus* may be at either or none of the previous loci. The most frequent allele (A1[5]) is designated position 1.00. Techniques are those of Ayala[5].
*Sampled within one to two generations from field capture. Other samples were from laboratory colonies up to several years old.

Table 3 Gene frequencies for leucine aminopeptidase

Sample	Locus A	Locus B		n
	0.59	0.76	0.81	
A. aegypti	1.00	0	0	1,675
A. mascarensis	1.00	0.98	0.02	61
A. albopictus	0	0	1.00	84

The techniques of Ayala[5] were modified as follows: incubation in 0.25 M borate; NaOH solution is 0.32 M not 0.2 M. Bands 0.76 and 0.81 are assumed to be two Mendelian alleles at one locus. Bands are assigned positions relative to the distance travelled by borate band. Fifteen bands were observed. In larvae band 0.70 stains heavily and predominates and band 0.66 seldom appears, whereas in pupae both bands, especially 0.66, usually appear and stain equally. Band 0.54 appears only in pupae in *A. albopictus*; it sometimes occurs in larvae of *A. mascarensis* and *A. aegypti*. Pupae of the latter two species sometimes have an additional band (0.36) next to band 0.40.

graded the abdominal scale pattern[4] to determine the ecotype of the male that inseminated each female. These experiments have so far not demonstrated any significant deviation from randomness in mating within and between ecotypes. Previous authors have always considered them to be one species[4,8]. We have demonstrated partial reproductive isolation between them; therefore, what we are calling two 'ecotypes' may actually be incipient species, partially isolated by habitat selection.

Persistence of the indoor ecotype in village huts seems to be the result of strong behavioural habitat selection for dwellings[9]. Such habitat selection may enable persistence of fairly discrete gene pools as shown by our data.

We will present elsewhere a mathematical model of the evolution of the indoor ecotype from the outdoor ecotype. We hypothesise that the indoor ecotype arose in sub-Saharan African areas with a dry season, when humans began to store water in pots in dwellings. During the dry season these pots are the only suitable habitat. We believe that habitat selection for the dwellings, and natural selection for different life history attributes and for preference for feeding on man arose during repeated dry seasons. The indoor ecotype has slower larval development, larger eggs, larger adults, and greater resistance to desiccation as adults. The indoor ecotype is preferentially attracted to human odour, the outdoor ecotype to guinea pig odour. Oxygen tension of water must be lower for eggs of the outdoor ecotype to hatch than for eggs of the indoor ecotype. Detailed evidence concerning the ecological differences between ecotypes will be published elsewhere.

Nitrogen fixation by *Rhizobium* cultured on a defined medium

IT has been widely believed that the legume root-nodule bacteria (*Rhizobium* spp.; rhizobia) fix N_2 only within the tissues of the host plant[1]. There have however been recent reports that a strain of cowpea rhizobia, 32H1, developed nitrogenase activity when grown in association with legume or non-legume plant cells[2,3]. The induction of nitrogenase was apparently due to a diffusible factor(s) secreted by the plant cells, since nitrogenase activity was detected when strain 32H1 was grown adjacent to, but not in contact with, tobacco cells[3]. Several plant metabolites, including sugars known to favour rhizobial growth[4,5] and citric acid cycle intermediates[6,7], were examined for their effect on this latter system and as possible direct inducers of nitrogenase activity in cultured rhizobia. This led to the formulation of a defined medium on which strain 32H1 fixed N_2 in the absence of plant cells.

This medium (CS7) contained (in mM) KH_2PO_4 (2.2), $CaCl_2.2H_2O$ (0.7), KCl (0.9), $MgSO_4.7H_2O$ (0.14), glutamine (2), myo-inositol (5.6), Na-succinate (25), L-arabinose (25) and (in μM) $MnSO_4.4H_2O$ (58), H_3BO_3 (82), $ZnSO_4.7H_2O$ (3.5), KI (6), $CuSO_4.5H_2O$ (0.8), $Na_2MoO_4.2H_2O$ (0.4), $CoCl_2.6H_2O$ (0.4), $FeSO_4.7H_2O$ (54), Na_2-EDTA (54), thiamine-HCl (15), nicotinic acid (41), pyridoxine-HCl (2.4), and 1% w/v agar (Difco Noble) at pH 5.9. In all experiments the bacteria were initially cultured on yeast-mannitol agar (YMA), suspended in sterile water (10^8–10^9 cells ml^{-1}) and spread as 1 cm^2 areas on CS7 medium. On other plates, similar areas of bacteria were grown 5 mm from uninoculated cell cultures of *Nicotiana tabacum* cv. Wisconsin 38. Cultures were incubated at 29 °C. Segments of agar bearing 1 cm^2 of dense bacterial growth were excised daily and assayed for nitrogenase activity by the acetylene reduction technique[8].

Nitrogenase activity was detected on day 4 and increased linearly during the following 4 d (Fig. 1). The rates of C_2H_2 reduction were similar for bacteria cultured in the presence or absence of plant cells. When arabinose (Fig. 1), succinate, or glutamine was omitted from the CS7 medium, nitrogenase activity was low or undetectable. Fumarate was, however, found to be a suitable replacement for succinate and galactose could replace arabinose in the basic medium. The bacteria also showed nitrogenase activity when $(NH_4)_2SO_4$ (1 mM) replaced glutamine in the medium, but the level of activity was less. The reduction in the glutamine concentration from that used in previous studies of plant cell–rhizobia associations[3,7,10] followed experiments which showed that 2–10 mM was the optimum concentration range for nitrogenase activity in the tobacco-strain 32H1 association.

The optimal P_{O_2} for C_2H_2 reduction was found to be 0.15–0.20 atm (2.5 and 1.9 nmol C_2H_4 per segment per h

Fig. 1 Time course of acetylene reduction by strain 32H1 cultured on CS7 medium. Agar segments (1 cm^2) containing bacteria (about 2 mg bacterial protein[9] per segment at 8 d) were sealed in vials with serum stoppers, evacuated, and filled with a gas mixture containing 20% O_2: 10% C_2H_2: 70% argon, incubated at 30 °C for 2–3 h and assayed for C_2H_2 reduction by gas chromatography. Activity on CS7 with ● and without ○ arabinose; activity on CS7 plus tobacco cells (see text) with ▲ and without △ arabinose.

Table 1 Strains* of different *Rhizobium* species assayed for C_2H_2 reduction when cultured on CS7 medium

Rhizobium spp.	Nitrogenase positive†	Nitrogenase negative
Rhizobium sp. (Cowpea group)	CB756, CC751, CC1066, 41F2, 61B9, 127N1, 127N2	CC402, CC430, NU197, 32Z3, 29C2, 8B4, 41A1
R. japonicum	61A76, CB1809, CC705, CC715, CC717, CC713, CC716, CC723	129, CC714, CC718, CC720, CC721 WU274, WU425, CC603, CC624
R. lupini	—	CC8, SU47, SU388, SU574
R. meliloti	—	
R. trifolii	—	TA1, WU95, CC2238c, WA67, 2009
R. leguminosarum	—	TA101, NA505

*The strains, all of which nodulate "Siratro" (including *R. japonicum*) or their homologous hosts, were provided by Dr J. C. Burton, Nitragin Co., Milwaukee, USA, Dr D. A. Phillips, Indiana State University, Terre Haute, USA, Dr J. Dobereiner, IPEACS, Km 47, Campo Grande, Brazil, and J. Brockwell, Division of Plant Industry, CSIRO, Canberra, and we are grateful for their cooperation. Details of strain isolation and source will be provided on request to the authors.
†All positive strains produced >0.5 nmol C_2H_4 per culture per h, with the exception of CC705 (0.2 nmol C_2H_4 per h).

respectively). In assays without O_2 added to the gas mixture (10% C_2H_2, 90% argon), or with $P_{O_2} = 0.4$ atm, the activity was 0.1 nmol C_2H_4 per segment per h.

Strain 32H1 was cultured on CS7 medium for 7 d and exposed to an atmosphere of 20% O_2 and 80% N_2, containing 80 atoms % ^{15}N, for 24 h. The bacteria were washed from the agar and ^{15}N enrichment of the total N of the samples determined[8]. The highly significant values of 0.948 and 0.643 atom % excess for two samples, compared with zero values for control bacteria incubated in air, indicated that the cultures fixed N_2.

In previous experiments, 32H1 was shown to be a pure culture of rhizobia[2,3]. We have subsequently examined the following clones of strain 32H1 (1) 15 single colonies isolated from YMA cultures[3], (2) 12 single colonies isolated from nodules formed following inoculation of cowpea plants with strain 32H1[3] (3 isolates from 4 nodules) and (3) 12 single colonies isolated from 32H1 segments on CS7, replicates of which were active in reducing C_2H_2 (Fig. 1). All of these isolates reduced C_2H_2 when cultured on CS7, and also nodulated the tropical legume "Siratro" (*Macroptilium atropurpureum*) grown from surface-sterilised seed on sterile agar slopes in cotton-plugged tubes. No natural C_2H_4 production by strain 32H1 cultured on CS7 was detected, nor did this strain reduce C_2H_2 when grown on YMA medium, or on media[3] used previously. Ten single colonies of 32H1 growing on CS7 failed to grow when transferred to nutrient agar (Difco). We therefore concluded that the cultures which fixed N_2 were authentic, pure cultures of cowpea rhizobia.

In addition to strain 32H1, 42 strains from 5 *Rhizobium* species and the cowpea group (*Rhizobium* spp.) were tested for nitrogenase activity on CS7 (Table 1). Of the 6 active strains from the cowpea group, strain CB756, and all 12 single colony isolates from nodules on CB756-inoculated cowpea plants, showed a level of activity comparable to that found with strain 32H1. Three of the strains (61A76, 29C2, 32Z3) tested here were reported previously to form an N_2-fixing association with soybean cells[11-13]; of these, only *R. japonicum* 61A76 showed nitrogenase activity on CS7.

These results show that some rhizobia strains can exhibit nitrogenase activity when cultured on a defined medium in the absence of plant cells. This provides direct proof that these rhizobia possess the genetic information for the biosynthesis of the nitrogenase enzyme, thus confirming earlier suggestions of an indirect nature based on genetic[14] and biochemical[15,16] evidence and results of tissue culture experiments[2,3]. Significant levels of nitrogenase activity seem to depend on the provision of preferred carbon (for example arabinose, galactose) and nitrogen (for example glutamine, $(NH_4)_2SO_4$) sources for bacterial growth and a citric acid cycle intermediate (for example succinate, fumarate). The glutamine-synthesising enzymes are important in the regulation of nitrogenase synthesis and ammonia assimilation in *Klebsiella*[17,18], and although these enzymes are found in nodule bacteroids[19,20], our current results do not permit conclusions regarding a regulatory function for these enzymes in rhizobia. So far, attempts to demonstrate workable levels of nitrogenase activity by strain 32H1 in CS7 liquid culture have been unsuccessful. We suggest

that N_2 fixation by rhizobia may depend on the development of favourable conditions within the mass of bacterial growth.

We thank Mr G. L. Turner for the ^{15}N analyses and J. Adamson, M. Ashby, Y. Hort, and L. McCurley for their technical assistance. Dr J. J. Child is currently on leave from the NRC Prairie Regional Laboratory, Saskatoon, Canada.

Nitrogenase activity in rhizobia in absence of plant host

RHIZOBIA can infect legume roots and fix dinitrogen in the root nodules. Repeated attempts have failed to demonstrate fixation by rhizobia on defined medium or in plant extracts. *Rhizobium japonicum* grown anaerobically with nitrate produces a haemoprotein pattern similar to that of N_2-fixing bacteroids[1] and synthesises the Mo–Fe protein of nitrogenase[2], but it has seemed that infection of legume cells was a prerequisite for the expression of nitrogenase. It has been shown recently[3,4], however, that cowpea *Rhizobium* 32H1 could fix dinitrogen when grown close to, but not in contact with, callus cultures of legumes or non-legumes. This supported other evidence[5,6] that it was the rhizobia which contained the genetic information for nitrogenase, and showed that its expression was promoted by diffusable factors from plant cells.

To characterise these factors we tested callus cultures of

several plant species, and found carrot and rice most effective. Extracts of carrot cells, or carrot root, when added to LNB5 medium[7] permitted the expression of nitrogenase (C_2H_2) activity by cowpea *Rhizobium* 32H1 grown in the absence of plant cells. We also screened carbohydrates for their use in promoting the callus–*Rhizobium* association[7], and found xylose, arabinose and galactose particularly stimulating. Subsequently it was found that when plant callus was omitted, one or the other of these sugars plus sucrose sufficed to induce nitrogenase activity. This communication describes nitrogenase activity in rhizobia growing alone on defined medium.

Rhizobial strains were maintained on a medium containing K_2HPO_4 0.5 g; $MgSO_4.7H_2O$ 0.2 g; $NaCl$ 0.1 g; yeast extract 0.5 g; $CaCO_3$ 0.5 g; mannitol 10 g; per litre of water. The rhizobia produced effective nodules on their appropriate hosts. Neither growth nor acetylene reduction were observed when the bacteria were subcultured on nitrogen-free media[3].

The LNB5 medium[7] contained KNO_3 1,000 mg; $(NH_4)_2SO_4$ 50 mg; $MgSO_4.7H_2O$ 250 mg; $NaH_2PO_4.H_2O$ 150 mg; $CaCl_2.2H_2O$ 150 mg; Fe (as Sequestrene 330) 28 mg; $MnSO_4$ 10 mg; H_3BO_3 3 mg; $ZnSO_4.7H_2O$ 2 mg; $Na_2MoO_4.2H_2O$ 0.25 mg; $CuSO_4$ 0.025 mg; $CoCl_2.6H_2O$ 0.025 mg; KI 0.78 mg; myo-inositol 100 mg; thiamine. HCl 10 mg; nicotinic acid 1 mg; pyridoxine. HCl 1 mg; sucrose 30 g; agar 12 g l^{-1}. The pH was adjusted to 5.5.

Cowpea *Rhizobium* 32H1 reduced acetylene when grown on a defined modified LNB5 medium containing galactose, arabinose or xylose together with sucrose (Table 1). For reasons not clear to us, nitrogenase activity is absent if only one carbon source is available.

A source of fixed nitrogen is necessary for dinitrogen fixation by *Rhizobium* under our *in vitro* conditions. In the case of *R. japonicum* 61A76, there is no dinitrogen fixation when fixed nitrogen is not supplied (Table 2). Fixation occurs in the presence of relatively high levels of ammonia, and is not significantly changed in the presence of L-methionine sulphone, which can interfere with NH_3 repression of nitrogenase. In these respects, *R. japonicum* differs from some other N_2-fixing organisms such as *Azotobacter vinelandii* and *Klebsiella pneumoniae*[9]. Ammonia can be replaced as N source by 0.002 M glutamine, glutamic acid and aspartic acid. Alanine and leucine are less effective and only slight dinitrogen fixation is obtained with valine or citrulline.

R. leguminosarum TA101 fixes nitrogen on a defined nutrient containing xylose (Table 3). There is scant growth and no fixation in the absence of nitrate. Ammonia apparently neither inhibits nitrogenase nor permits its expression in the absence of nitrate.

Dinitrogen fixation in the presence of fixed nitrogen may seem remarkable, for it is often assumed that nitrogenase is always repressed by fixed nitrogen. Some strains of *Azotobacter vinelandii* will fix dinitrogen in the presence of nitrate, however,

Table 2 Effect of ammonia and methionine sulphone on nitrogenase activity of *R. japonicum* 61A76

$(NH_4)_2SO_4$ concentration	Nitrogenase specific activity nmol C_2H_4 per h per mg protein
0.001 M	1.85
0.001 M+MSO	1.89
0.01 M	1.39
0.01 M+MSO	1.16
0.1 M	0
0.1 M+MSO	0
0+MSO	0
0	0

R. japonicum 61A76 was added to the surface of 10 ml solid medium slant in a 30-ml test tube. The nutrient was LNB5 except that the carbon source was arabinose (10 g l^{-1}) and sucrose (10 g l^{-1}) and nitrate was omitted. Methionine sulphone (MSO) was added at 3 mg ml^{-1}. After 9 d, nitrogenase activity and protein content were measured. Each figure is the average of three samples.

and may use both sources simultaneously[10], and in chemostat cultures of *A. chroococcum*, stable cultures are obtainable in which nitrogenase is only partially repressed by ammonia[11]. There is no reason to believe that the controls on nitrogenase in rhizobia are exactly the same as those in *Azotobacter* or *Clostridium*, and the symbiotic bacteria may require higher levels of fixed nitrogen to repress the enzyme. It has already been established elsewhere that *R. japonicum* can synthesise the Mo–Fe protein in the presence of ammonia and nitrate[2].

We only observe acetylene reduction in strains which produce a copious slime. It is probable that this serves to protect the nitrogenase from oxygen[12]. The bacteria near the surface of the colony may lower the oxygen tension whereas those below produce nitrogenase. In this case, the specific activities underestimate the activity of the nitrogen-fixing rhizobia.

Table 3 Nitrogenase activity in *R. leguminosarum* TA101

Nitrogen source (mg l^{-1}) KNO_3	$(NH_4)_2SO_4$	nmol C_2H_4 per h per mg protein
1,000	50	0.91
—	50	0
1,000	—	0.97
—	—	0

R. leguminosarum TA101 was added to the surface of 10 ml solid medium slanted in a 30-ml test tube. The nutrient was LNB5 except that the carbon source was xylose (10 g l^{-1}) and sucrose (20 g l^{-1}). Nitrogenase activity and protein were determined after 14 d.

The significance of our results rests on the assumption that our rhizobial cultures are uncontaminated by nitrogen-fixing bacteria. Absence of *Klebsiella* was demonstrated by lack of growth, acid or gas formation in anaerobic semi-solid peptone media containing mannitol, sucrose, glucose or xylose[8]. Lack of growth on standard nitrogen-free media[3] and fixation at pH 5.5 also make it unlikely that our cultures are contaminated by *Azotobacter*. Fixation is not observed if test cultures are maintained under dinitrogen, and this argues against the presence of *Clostridium* or *Bacillus*. We have not detected acetylene reduction in any experiment in which sucrose, glucose, fructose or mannitol was provided as sole carbon source. Fixation was promoted by xylose or arabinose, however. Because pentoses are preferred carbon sources by rhizobia, it is certain that the acetylene reduction activity we observe is due to the non-symbiotic nitrogenase activity by rhizobia.

Acetylene reduction by *Rhizobium* in pure culture

ASSOCIATIONS between legume callus cultures and *Rhizobium* have been shown to fix nitrogen[1-6]; we have found that at least one strain of *Rhizobium* will do so when cultured alone on certain media.

The strains of *Rhizobium* used were: 32H1, a cowpea strain (Dr J. Burton, Nitragin Co., Milwaukee, Wisconsin); NGR46, another cowpea strain (Dr M. J. Trinick, CSIRO Wembley, Western Australia); and MU1, an isolate from nodules of *Trema cannabina*, (Mr D. R. Coventry, University of Western Australia). MU1 is a strain able to nodulate siratro (*Macroptilium atropurpureum*) and cowpea (*Vigna unguiculata* ssp. *unguiculata*). *Rhizobium* cultures were maintained on a yeast extract–mannitol–potato extract medium[7].

Confirmation that the initial culture of 32H1 was a *Rhizobium* was obtained by testing it for ability to nodulate cowpea. One series of four pots, each containing five plants, was inoculated with 32H1, another series with NGR46, while a third was left uninoculated as a control. Ten days after the seed inoculation, the appropriate pots were each treated with 100 ml of the test *Rhizobium* suspended in sterile water to give about 10^9 bacteria ml^{-1}. The controls remained unnodulated, while NGR46 nodulated all plants, as did 32H1. A strain of 32H1 was recovered from the nodules and used in further experiments (it is referred to as the first reisolate).

Cultures from eight individual colonies of the first reisolate were then used to each inoculate pots containing five cowpea plants. Suitable uninoculated controls were again included, and did not form nodules. Twenty-two clones of 32H1 were recovered, at least one from each pot, and these clones are referred to as the second reisolates.

A rabbit antiserum prepared against the first reisolate of 32H1 (ref. 8) showed that the initial strain, the first reisolate and the second reisolates were serologically indistinguishable.

The *Rhizobium* plant symbioses set up[2,3] used soybean (*Glycine max*) and snake bean (*Vigna unguiculata* ssp. *sesquipedalis*) suspension cell cultures and rhizobial strains 32H1, NGR46 and MU1. *Rhizobium* cultures for inoculation of control bottles were derived from cultures grown on maintenance medium (broth or solid) and were adjusted to contain 1.0×10^7–9.0×10^7 bacteria ml^{-1} in sterile water. The flat surface of 15 ml of callus medium in a 30 ml McCartney bottle was inoculated with 0.1 ml of rhizobial suspension. The callus culture medium was SCN (ref. 2) with or without 10 mM glutamine and 40 mM succinate[3]. The succinate was added as succinic acid, which lowered the pH of the callus medium to 2.5–3.0; the pH was then returned to 6.0 with KOH before adding the agar. Cultures were grown in diffuse light at 25 °C.

After 14 d, the aluminium caps on the cultures were removed and replaced with a black rubber seal, and an aluminium cap with a hole. Endogenous ethylene was read 24 h later on a Pye-Unicam gas chromatograph fitted with a 1.4 m column of Porapak T and operated at 100 °C. The cultures were then flushed with sterile air in a laminar flow cabinet before the caps were replaced and 0.75 ml of acetylene injected. After 24 h, ethylene was again measured, and acetylene-dependent

ethylene production calculated by subtracting the endogenous production.

Plant calluses with or without rhizobia showed an endogenous ethylene production of 0.08 nmol or less per culture bottle. Rhizobia on callus media had an endogenous ethylene production usually undetectable and never greater than 0.01 nmol.

Soybean callus cultures inoculated with strain 32H1 reduced acetylene at rates comparable to those reported by Phillips[2,3], but inoculated callus cultures of snake bean did not do so (Table 1). Strain 32H1 also performs poorly with calluses

Table 1   Acetylene-dependent ethylene production by various rhizobial strains, callus cultures, and associations between them

Rhizobium strain	Plant callus	Mean ethylene production per culture (nmol)	Standard error
None	None	0.08	± 0.02
MU1	None	0.08	± 0.02
NGR46	None	0.10	± 0.02
32H1	None	37.89	± 6.93
None	Snake bean	1.24	± 0.53
None	Soybean	0.03	± 0.02
NGR46	Snake bean	0.09	± 0.06
32H1	Snake bean	1.41	± 0.62
32H1	Soybean	68.39	±24.98

All cultures on SCN medium supplemented with 10 mM glutamine and 40 mM succinate.

of *Vigna unguiculata*[5], and varies in performance with different soybean cultivars[2]. Internal variability was often high, as reported by others[2,4].

Neither the plant calluses alone nor bacterial strains NGR46 and MU1 showed acetylene reduction. Cultures of 32H1, however, reduced acetylene actively on the SCN medium supplemented with glutamine and succinate.

The first reisolate also reduced acetylene on SCN medium supplemented with glutamine and succinate; neither it nor the initial culture did so on SCN alone, or on SCN supplemented only with glutamine. Twenty-two of the second reisolate clones of 32H1 reduced acetylene on SCN supplemented with glutamine and succinate, but not on SCN alone (Table 2). Since 32H1 associations with callus cultures incorporate $^{15}N_2$ (ref. 5), we assume that acetylene-dependent ethylene production can be attributed to nitrogenase activity.

Contamination by nitrogen-fixing bacteria is an unlikely explanation for our results. It seems improbable that the initial culture and the isolate from the first nodule passage should both have contained a nitrogen-fixing contaminant, and even less probable that eight individual colonies from an apparently pure culture could undergo a second nodule passage and again be reisolated with a nitrogen-fixing contaminant in each of the twenty-two second reisolates. We conclude, therefore, that 32H1 is a *Rhizobium* strain capable of acetylene reduction in these conditions.

Table   2 Acetylene-dependent ethylene production by *Rhizobium* strain 32H1 after second nodule passage

First isolate colony no.	Mean ethylene production (nmol) on		Standard error
	SCN	SCN+glutamine+succinate	
1	0	20.53	± 5.33
2	0	25.97	±17.87
3	0	20.34	± 4.80
4	0	18.44	± 7.93
5	0	55.10	±15.02
6	0	54.68	±13.47
7	0	20.95	± 7.64
8	0	34.71	± 6.68
Mean (77 observations)	0	34.04	± 4.67

The medium used was SCN, or SCN supplemented with 10 mM glutamine and 40 mM succinate.

Table 3 Acetylene-dependent ethylene production by the first reisolate of *Rhizobium* strain 32H1 on SCN medium with various supplements

Additions	Mean ethylene production (nmol)	Standard error
None	0.00	± 0.00
10 mM glutamine	3.17	± 1.42
40 mM succinic acid	0.00	± 0.00
10 mM glutamine+40 mM succinic acid	31.69	± 6.64
10 mM glutamic acid	21.64	± 5.45
10 mM glutamic acid+40 mM succinic acid	40.59	±10.58
40 mM Na succinate	0.00	± 0.00
10 mM glutamine+40 mM Na succinate	11.16	± 2.39
10 mM asparagine	0.79	± 0.04
10 mM asparagine+40 mM succinic acid	25.79	± 6.74

All amino acids are the L-isomer.

We examined the effects of various media supplements on acetylene reduction by 32H1 (Table 3). Glutamine and asparagine were equivalent in the presence of succinic acid, but glutamine in the presence of sodium succinate was significantly inferior. The acidity of succinic acid was apparently important, but only where an amide nitrogen compound was used. Since neither succinic acid nor sodium succinate alone was effective, an available nitrogen source was apparently necessary. The significant increase in acetylene reduction when succinic acid was added with glutamate (which is acid stable) suggests that an available carbon source was also needed. Since slow-growing rhizobia do not usually grow on disaccharides[9], the sucrose in the callus medium would be ineffective.

Given that glutamine and asparagine are not available for growth of 32H1, and that relatively slight hydrolysis of them to available glutamate, aspartate or ammonia occurs when they are treated with succinic acid, it seems probable that the responses can be explained by growth requiring available sources of carbon and nitrogen.

Acetylene reduction occurs with 32H1 in association with many types of callus, including non-legumes[2,3,5,6], and when callus and rhizobia are not in physical contact[5], suggesting that the calluses provide substances for growth or nitrogenase production. Snake bean callus seemed to prevent nitrogenase production, since the medium contained the necessary supplements for 32H1 alone (Table 1). This conclusion must remain tentative, since rhizobial numbers in the callus and agar surface systems are not comparable.

The finding that strain 32H1 reduces acetylene on laboratory media directly establishes that genes for nitrogenase are present in *Rhizobium*, as suggested by other workers[10,11] and renders invalid the theory[12] that part of the nitrogenase in legume nodules might be specified by plant DNA.

We thank Mrs J. Ryan for technical assistance and Dr D. L. Chatel of the Western Australian Department of Agriculture for serologically typing the various cultures and the Rural Credits Development Fund and the Australian Research Grants Committee for financial support.

High frequencies of haploid production in wheat (*Triticum aestivum*) by chromosome elimination

The production of haploid plants from hybrids, followed by chromosome doubling, provides the plant breeder with a means of accelerating the development of desirable true breeding lines. This could be advantageous in breeding programmes particularly among some of the cereals where many generations, taking many years, may be required before an acceptable pure line variety can be obtained.

A major limitation to haploid breeding is the lack of techniques for obtaining haploids in sufficiently large numbers. In cultivated barley (*Hordeum vulgare* $2n=14$) the discovery[1] of a high frequency of "vulgare" haploids in hybridisations with *Hordeum bulbosum* ($2n=14$) by means of chromosome elimination, combined with recent improvements in cultural techniques[2-4], promises to overcome the limitation in this cereal.

So far the possibility that chromosome elimination giving rise to haploids may be exploited in other crop plants has not been investigated. To determine if elimination can occur in hexaploid wheat, *Triticum aestivum* ($2n=6x=42$), crosses were made between the wheat variety Chinese Spring and both diploid and tetraploid *H. bulbosum* as pollen parents. Seed set was obtained in both crosses (Table 1) although

Table 1 Seed set induced from intergeneric crosses between *T. aestivum* var. Chinese Spring and *H. bulbosum*

Male parent	No. florets pollinated	No. of seeds set	Seeds set (%)
2x *H. bulbosum*	622	85	13.7
4x *H. bulbosum*	435	188	43.2

the frequency was much higher using tetraploid *H. bulbosum*. The initial development of the seeds was vigorous but after 14–18 d the seeds showed signs of abortion, the endosperm having degenerated, making embryo culture necessary. The embryos were dissected out in a sterile cabinet, transferred to orchid agar (27–29 g l⁻¹) and placed in the dark at 20 °C until they germinated.

Of the 70 plants obtained (Table 2), 57 were examined cytologically in root tips stained by the Feulgen procedure and, whether produced from crosses with diploid or tetraploid *H. bulbosum*, all were found to have 21 chromosomes indistinguishable karyotypically from the haploid complement of wheat (Fig. 1). Nor did any of the plants as seedlings, or the ten plants which have reached maturity so far, exhibit any of the morphological features of *H. bulbosum*.

The frequency with which haploids were obtained when

Table 2 Plants obtained from intergeneric crosses between *T. aestivum* var. Chinese Spring and *H. bulbosum* using embryo culture

Male parent	No. of embryos cultured	No. of plants produced	Embryos giving plants (%)
2x *H bulbosum*	39	11	28.2
4x *H. bulbosum*	110	59	53.6
Fig. 1 Somatic chromosomes of a haploid wheat plant (2n = 21) obtained by crossing *Triticum aestivum* var. Chinese Spring with diploid *Hordeum bulbosum*. The satellited chromosomes 1B and 6B of wheat are clearly visible. ×750

using tetraploid *H. bulbosum* (13.6% of florets pollinated) is similar to the frequencies being achieved in haploid barley production. The mechanism of production of these haploids also appears to be the same as that for haploid barley from crosses of *H. vulgare* with *H. bulbosum* in which elimination of the *H. bulbosum* chromosomes takes place following fertilisation. In developing seeds fixed 1–6 d after pollination with tetraploid *H. bulbosum*, chromosome counts of 35 at zygotic metaphase indicated that fertilisation was normal. At a later stage, however, the presence of micronuclei in both embryo and endosperm tissues as well as lagging chromosomes and bridges in endosperm divisions (Fig. 2) showed the subsequent elimination of chromosomes.

Fig. 2 Chromosome elimination in a dividing endosperm cell of a developing grain obtained by crossing *Triticum aestivum* var. Chinese Spring with tetraploid *Hordeum bulbosum*. ×700
Investigations are now being carried out to determine whether *H. bulbosum* can be crossed readily with other wheat varieties. These initial results, however, demonstrate the potential of producing haploid wheats by means of chromosome elimination following hybridisation with *H. bulbosum*.

Visual spatial summation in two classes of geniculate cells

VISUAL perception can be viewed as a transformation and a distortion of the spatial patterns which exist in the outside world. The transformation of external objects into neural images is accomplished by the summation of excitatory and inhibitory influences over the visual field of each neurone. Distortion occurs when the neural response is not simply proportional to the sum of excitation and inhibition because of nonlinear mechanisms in spatial summation. If the responses of all visual cells were distorted by such nonlinear summation, fine visual discriminations like those necessary for reading *Nature* would be impossible. Nonlinear mechanisms do however, seem to be important in one class of visual neurone, perhaps for signalling change or motion in the external world. We have attempted to understand the importance of the different kinds of spatial summation by studying single cells in the cat visual system.

There are several classes of ganglion cells in the cat retina. Two main groups of these cells send axons to the dorsal lateral geniculate nucleus (LGN). These were originally classified and non-committally named X and Y cells by Enroth-Cugell and Robson[1]. They found that the main distinction between X and Y ganglion cells is the degree of linearity of spatial summation. A stationary spatial grating, amplitude-modulated in time can be located over the receptive field of an X cell so as to produce no modulation of the impulse rate of the cell. This position of the grating is called the null position. For even a slight relocation of the pattern away from the null position, modulation of the pattern produces modulation of the impulse rate. For Y ganglion cells no null position exists. Signals generated by a change in illumination over one region of the field of a Y cell can never be completely cancelled by signals due to an equal but opposite change in illumination in another region and therefore the Y cells must have some nonlinearity preceding, or at the level of, spatial summation. We have extended this work on the linearity of spatial summation to cat LGN cells. Geniculate cells can also be classified as X or Y on the basis of the linearity or nonlinearity of spatial summation. So X and Y cells are segregated at least as far as the input to the visual cortex. Other workers have used different criteria for grouping retinal ganglion and lateral geniculate cells[2-4]. These criteria include: axonal conduction velocity, preferential target speed, pattern of response to a drifting grating and response dynamics. We have not investigated the first two of these, but have measured the last two. Elevation of the mean impulse rate in response to a drifting grating is invariably present in Y cells, and we think this characteristic is caused by the same nonlinearity in spatial summation which prevents the cell from having a null position. There is, however, no direct relationship between spatial summation and response dynamics. There are some "transient" X cells and "sustained" Y cells. Because the spatial summation properties of X and Y cells are so distinct, there must be func-
Fig. 1 Null positions in geniculate cells. The right hand column contains two responses (PST histograms of 30 sweeps) of an X geniculate cell to an alternating phase spatial sine grating, spatial frequency 1.8 cycles per degree, temporal frequency 0.54 Hz. The upper response was elicited by the grating at a position of maximum sensitivity. The lower response was elicited when the grating had been moved a quarter cycle (90°) away, to the null position. Contrast for both runs was 2.5%, and the time course of the temporal modulation of the contrast is indicated at the top of the column. Cell 12/1, on-centre, contralateral, LGN afferent recorded at cortex. The left hand column shows data from a Y geniculate cell in response to a 0.45 cycle per degree grating modulated on–off at 0.5 Hz. Contrast for both runs was 10%. Higher spatial frequencies were much less effective in exciting the cell, and response to on–off or alternating phase gratings were very similar when stimuli were equated for contrast. This cell had no null and at certain positions gave a burst of spikes when the grating went on and also when it was withdrawn. Cell 32/3, on-centre contralateral, recorded at LGN.

Fig. 2 Contrast sensitivity against position (spatial phase). *a*, An X geniculate cell; *b*, a Y geniculate cell. Sensitivity to elicit an average peak response of 20 impulses s^{-1} is plotted against position of the grating on the abcissa. Zero phase was set by the experimenter to give approximately maximum sensitivity. The ordinate, contrast sensitivity, is the reciprocal of the contrast required to give criterion response. The sign of the sensitivity was determined from the temporal phase of the response. Response at pattern on was considered positive; response at pattern off negative. A sine curve is fitted to the sensitivity function of the X cell. X cell 30/1 on-centre contra-lateral. Y cell 33/11 off-centre contralateral. Both recorded at LGN. The temporal frequency in both cases was 0.5 Hz; the spatial frequencies were 0.9 cycles per degree for the X cell and 0.45 cycles per degree for the Y cell.
tional consequences of their parallel input to the visual cortex[5].

We used 18 X-like cells and 6 Y-like cells in 9 cats anaesthetised with urethane and paralysed with gallamine triethiodide. Action potentials were recorded from LGN cells and from LGN afferents to the striate cortex with tungsten-in-glass microelectrodes. LGN cells were distinguished from optic tract terminals by impulse wave form and polarity. Nerve impulses were averaged into post-stimulus time (PST) histograms with a computer. The cat looked at an oscilloscope screen through a contact lens with a 3-mm diameter artificial pupil. Refraction was determined with an ophthalmoscope and corrective lenses used when required.

Spatiotemporal patterns were created by means of a television-type raster display, with electronic modulation of the intensity on the oscilloscope screen. The patterns used for the experiments reported here were: (1) an on–off spatial sine grating introduced at a fixed contrast and then blanked, repetitively; (2) an alterating phase spatial sine grating, that is a grating which reversed contrast, or in other words shifted phase by a half cycle (180°), repetitively. For both kinds of patterns, mean luminance across the screen was always constant; only the spatial distribution of luminance varied with time. Pattern contrast was controlled by the experimenter. The mean luminance on the screen was 1 cd m^{-2}.

Some LGN cells had null positions when presented with on–off or alternating phase patterns. These cells are analogous to X retinal ganglion cells. An example is shown in Fig. 1. Shown on the right are the averaged responses of an X-type cell to an alternating phase grating when the grating was at the null position and when the grating was placed a quarter cycle (90° in spatial phase) away from the null. We also found Y-type cells in the cat LGN which had no null position for a grating regardless of spatial frequency and which at some positions produced bursts of impulses at pattern on and pattern off, or at both phases of pattern alternation, as shown for example in the left hand column of Fig. 1 (ref. 1).

We developed a quantitative measure of the strength of the null position of an LGN cell. This was the contrast sensitivity for a grating as a function of position. The reciprocal of the modulation depth required to elicit a criterion peak response, the contrast sensitivity, was plotted against position of the grating. (We called sensitivity for an on response positive and for an off response negative.) Such graphs for an X cell and a

Y cell are shown in Fig. 2. In this case, contrast sensitivity for the X cell at the null was more than a factor of thirty down from the peak sensitivity. For X cells, sensitivity was approximately a sinusoidal function of position of the grating. With linear spatial summation, a visual cell acts like a linear spatial filter for spatial patterns. Among other things, this means that the response to a sine grating must be a sinusoidal function of position, or spatial phase, of the grating in the visual field. The sensitivity profile of the cell need not be symmetrical to yield this result.

There was less variation of contrast sensitivity with position for Y cells, particularly at high spatial frequencies. Also, since at many positions a Y cell responds at both pattern on and pattern off, there are positive and negative contrast sensitivities at these points. Thus, two features of the graph of contrast sensitivity against position served to help classify a cell as either an X or Y cell: sinusoidal sensitivity curve with two nulls or a flatter sensitivity curve and the presence of single or double sensitivity values.

We found LGN cells which had null positions but very transient responses to standing contrast. Cell 30/1 in Fig. 2 was such a cell. Other X cells had a sustained component in their response, for example cell 12/1 in Fig. 1. Y cells with a sustained response also exist. Such results imply that the X/Y classification[1] and the "sustained/transient" classification of Cleland et al.[2,3] (see also Hoffman et al.[4]) may not be identical, at least for LGN cells. The classification of visual cells into two groups, X and Y, based on their spatial interactions is as clear and unambiguous, in the LGN as in the retina. Our work shows that the X/Y retinal dichotomy, characterised by the degree of linearity of spatial summation, is preserved all the way to the visual cortex.

Sporulation-inducing factor in slime mould *Physarum polycephalum*

THE highly synchronous sporulation of *Physarum polycephalum* is an attractive model of cell differentiation. Virtually all of the nuclei in a starved plasmodium proceed in step through the sporulation process in response to a well defined stimulus, light[1-4]. The regulatory mechanisms of this differentiation are unknown but several studies have been presented on the conditions necessary for sporulation. These have been reviewed by Sauer[5], who concludes that two elements are necessary for sporulation, substrate and light. These must be applied sequentially. The substrate requirement is for starvation in the dark for at least 4 d in the presence of niacin and niacinamide[4]. The light requirement is for at least 4 h illumination by a 40 W fluorescent light. Sauer also cites unpublished results which suggest that the effect of illumination is a local one which cannot be transferred to an unilluminated, starved plasmo-

Table 1 Induction of sporulation by microinjection

Injected substance	Sporulation frequency No. of plasmodia sporulating / No. tested	(%)
None	0/4	0
Distilled water	0/10	0
Unilluminated plasmodial contents	0/14	0
Illuminated plasmodial contents	11/18	61
UM10 filtrate	3/5	60
UM10-retained	7/10	70
NaCl (0.06 M)	33/113	29
KCl (0.06 M)	4/33	12
Na_2SO_4 (0.03 M)	2/19	11
$(NH_4)_2SO_4$ (0.03 M)	2/16	13

Results are the means of several experiments. Macroplasmodia were established in 9-cm Petri dishes containing sporulation medium (1) in 2% agar. After starvation on this medium for 6 d in the dark at 21 °C, these macroplasmodia were microinjected with 10 μl of the indicated substances and immediately placed back in the dark at 21 °C. Illuminated macroplasmodia were prepared in the same manner except that, at the end of the starvation period, they were placed 6 cm from a 40 W fluorescent light bulb for 6 h. A fan kept the temperature of the dishes below 24 °C. Clarified extracts were prepared by homogenising ten macroplasmodia in 1.5 ml deionised water and centrifuging for 10 min at 26,000g in a Beckman J21 centrifuge. Extracts were then ultrafiltered with Amicon UM10 membranes.

dium or even from the illuminated half to the unilluminated half of the same plasmodium.

In this report we present results which show that the sporulation-inducing effects of illumination can indeed be transferred to an unilluminated, starved plasmodium by microinjection. Furthermore, the requirement for light can be circumvented altogether by the injection of a small amount of salt solution into a starved plasmodium.

The top part of Table 1 shows that a small quantity of plasmodial contents from an illuminated, starved plasmodium will induce sporulation in a starved, unilluminated plasmodium. The sporulation thus induced is usually complete 20 h after injection, but it sometimes takes up to 48 h. Thus, this process is slower than sporulation induced by light, which takes 13-15 h, but it is homogeneous, involving the entire plasmodium synchronously and is morphologically indistinguishable from that observed in an illuminated slime mould. This effect is not produced by injecting an equivalent amount of water, pricking with a micropipette, placing the plasmodium on the dissecting microscope stage in the light for 5 min (the duration of the injection process) or by injecting an equivalent amount of plasmodial contents from an unilluminated, starved plasmodium.

The approximate size of the inducing factor has been determined by ultrafiltration with Amicon membranes. The middle part of Table 1 shows that a factor passes through a UM10 filter and therefore has a molecular weight of less than 10,000. The active substance in the UM10-retained fraction could be the same as that which passes through the filter, as filtration was not taken to completion. It is also possible that there is another, larger component present in the retained fraction.

The bottom part of Table 1 shows that a variety of salts, injected into a starved, unilluminated plasmodium also induced sporulation. The concentration of the cation was held constant in each case. The effect of NaCl seems most pronounced, although the differences may not be significant.

We are unable at this time to determine whether illumination and salt operate through the same or distinct mechanisms of sporulation control. It is evident, however, that there is some differentiation-inducing factor in illuminated slime mould which can be transferred to an unilluminated slime mould. Elucidation of the nature of the triggering

substance(s) may thus help to explain the mechanism of control of differentiation in this organism.

Inhibition of fungal growth by wheat germ agglutinin

GROWTH of fungal hyphae is the result of a complex and poorly understood process of cell wall synthesis and extension, that is restricted to the hyphal apex[1-3]. In fungi with chitin–glucan hyphal walls, such as the Deuteromycetes *Trichoderma viride* and *Fusarium solani*[1], hyphal extension and septa formation involve the synthesis of chitin in hyphal tips and septa[4]. We therefore studied the effect on such fungi of wheat germ agglutinin (WGA), a lectin which interacts specifically with chitin oligomers[5,6].

Although interactions of plant lectins with a variety of animal cells and with different microorganisms are well documented (for reviews see refs 7 and 8), no information on their effect on fungi is available. We have found that WGA inhibits growth and spore germination of *T. viride*. These findings suggest a role for the lectin in nature, and provide further insight into the mechanism of fungal cell wall growth.

The binding of WGA to *T. viride* Pers. ex Fries isolate No. M 2042, was studied using fluorescein isothiocyanate-conjugated WGA (FITC-WGA). The lectin binds exclu-

sively to hyphal tips and septa, whereas most of the hyphae are not labelled (Fig. 1). The chitin in the septa and tips seems to be accessible to WGA whereas in the mature regions of the hyphae, the overlayering of chitin by glucans may prevent WGA binding. Effective labelling could be observed even after only a 10 s exposure of *T. viride* to a solution of 15 μg per 0.1 ml FITC-WGA. No labelling was observed when the colonies were preincubated with non-fluorescent WGA or when treated with FITC-WGA preincubated (30 min at 37 °C) with chitotriose (2 mM), a specific inhibitor of the lectin[5].

[3]H-acetate has been used as a morphogenetic marker of intact *T. viride* colonies[4]. Short pulse labelling of colonies in the course of differentiation clearly labels the growing zones of the hyphae. Although acetate is not incorporated specifically into chitin, it is noteworthy that in young hyphae of *T. viride* chitinase removed all label from the cell wall after short ^{3}H-acetate incorporation, thus demonstrating that most of the cell wall synthesis during short pulses is confined to production of chitin. As we had observed that WGA binds to hyphal tips, we studied the effect of the lectin on hyphal growth as indicated by ^{3}H-acetate incorporation. Figure 2 demonstrates that as little as 125 μg WGA per 0.1 ml growth solution markedly inhibits ^{3}H-acetate incorporation into hyphal tips, which is an indication of arrest of growth[4]. The incorporation of ^{3}H-acetate was not affected in experiments in which WGA, preincubated with chitotriose (2 mM), was added to the colonies.

Fig. 1 Microscopic appearance of *T. viride* hyphae treated with WGA labelled with fluorescein isothiocyanate. WGA was purified by affinity chromatography[9] and conjugated with fluorescein isothiocyanate[10]. *T. viride* was cultured on 25 × 75 mm glass slides with frosted ends[4]. After 30–40 h growth in dark, FITC-WGA (50 μg in 0.1 ml phosphate buffered saline, pH 7.4) was spread over half of the colony and allowed to interact for 10 min at room temperature. Slides were then washed with saline and observed with a standard RA Zeiss fluorescence microscope. Exciter filter BG-12 was used in the path of the excitation light and barrier filter No. 53 in the path of the emitted light. *a*, Binding to hyphal tips; *b*, binding to septa. Bars represent 10 μm.
Fig. 2 Microautoradiographs of *T. viride* hyphae. Colonies of *T. viride* grown on slides[4] were overlayered with WGA (30–500 μg in 0.1 ml minimal medium consisting of 10 g glucose, 0.5 DL-alanine, 1 g KH$_2$PO$_4$ and 0.5 g MgSO$_4$ in 1 l water). After incubation of 10 min at 25 °C, ^{3}H-sodium acetate (18 Ci mmol^{-1}; 4 μCi in 0.1 ml minimal medium) was added on top of the WGA solution, and incorporation of label was allowed to proceed for 10 min. The slides were washed, fixed and processed for autoradiography as described[4]. *a*, Hyphae from a colonial front after incubation for 10 min with ^{3}H-sodium acetate, normal optics. Note heavy labelling of hyphal tips and septum. *b*, Hyphae from a colony which was preincubated with 250 μg WGA and then labelled and photographed as in *a*. Note decrease in labelling at hyphal tip. Bars represent 20 μm.

To obtain a more quantitative evaluation of the inhibition of ^{3}H-acetate incorporation by WGA, we studied the effect with *T. viride* cultured by shaking in suspension. WGA markedly inhibited ^{3}H-acetate incorporation into a suspension of young hyphae (60% inhibition at 0.8 mg ml^{-1} WGA), whereas the incorporation of ^{3}H-leucine was practically unaffected (Fig. 3*a*). In these experiments chitotriose (2 mM) also inhibited the effect of WGA.

To observe this possible inhibition of hyphal growth macroscopically, Petri dishes (9 cm diameter), containing potato dextrose agar were inoculated with *T. viride* and
Fig. 3 *a*, Inhibition by WGA of ³H-sodium acetate incorporation into young hyphae. A suspension of young hyphae was obtained by allowing *T. viride* spores to germinate by shaking for 18 h in minimal medium at 25 °C. Aliquots (2 ml) of this suspension (0.27 mg dry weight ml⁻¹) were added to WGA solution (50–2,000 µg in 0.5 ml minimal medium) in 10 ml Ehrlenmeyer flasks. After 15 min of shaking at 25 °C, ⁴H-sodium acetate (Δ18, Ci mmol⁻¹, 4 µCi in 0.1 ml minimal medium) was added to each flask and the flasks were shaken for a further 5 min. The pulse labelling was terminated by addition of 3 ml cold solution CCl₃COOH (10% w/v) and the flasks kept in the cold for 15 min. Suspension was filtered over GF/C glass filters (Whatman) and washed with 20 ml 1 N acetic acid. Filters were dried for 2 h at 100 °C and the radioactivity remaining counted in toluene scintillation liquid with an efficiency of 52%, using a Packard Tri-Carb scintillation spectrometer. In parallel experiments, the incorporation of ³H-leucine (19 Ci mmol⁻¹, 4 µCi in 0.1 ml) was followed in the same conditions. Percentage inhibition was calculated from the ratio of the radioactivity incorporated in the presence of WGA to that incorporated in its absence. ▲, Obtained when WGA was preincubated (30 min at 37 °C) with chitotriose (2 mM). *b*, Inhibition by WGA of *T. viride* spore germination. WGA (10–300 µg in 15 µl minimal medium) was mixed with *T. viride* spores (15 µl suspension of 0.27 mg dry weight per ml in minimal medium) and the spores were allowed to germinate for 18 h at 25 °C. Aliquots (25 µl) were spread on a microscope slide and germination was observed under the microcope. Percentage germination was calculated after counting 1,000 spores germinated in the presence and absence of WGA. ■, Germination in presence of WGA and 2 mM chitotriose.

kept in the dark at 25 °C. When the colonies reached a diameter of 4 cm (after 2 d), they were exposed to laboratory light; three wells were drilled in the agar, 1 cm from the front of the colony (3 cm from the centre of the plate) and filled with WGA (30–500 µg in 50 µl minimal medium) and the colonies were allowed to grow (4 d) until they covered the dish. Exposure to light induced conidiation[11] and green rings of conidia marked the pattern of the colonies' extension. As little as 60 µg WGA in a well inhibited hyphal extension (Fig. 4*a* and *b*). The area of the clear zone around the wells, where growth was inhibited, was concentration-dependent. The specificity of the effect is indicated by the normal growth of the fungus when WGA was placed in wells in the presence of the WGA-inhibitors, chitotriose (2 mM) or teichoic acid of *Staphylococcus aureus* H (0.6 mM), (Fig. 4*c*). The latter is a very potent inhibitor of WGA (ref. 12).

It has been shown that the cell wall of hyphal tubes emerging out of germinating spores of the fungal group V (ref. 1), to which *T. viride* belongs, contain chitin[3]. Indeed, a marked inhibition of spore germination was observed when WGA was mixed with spores of *T. viride* (Fig. 3*b*). The effect of WGA in inhibiting the germination of the spores of these fungi seems to be the result of its binding to the chitin at the tip of the emerging hyphal tube rather than to the spore coat, as no binding of FITC-WGA to the spores could be observed. Furthermore, the spores were not agglutinated by WGA.

The evidence presented above indicates that binding of WGA to hyphal tips inhibits chitin synthesis, hyphal growth and spore germination. Although the mechanism of apical growth is poorly understood, it has been suggested that the addition of newly synthesised chitin for extension of the hyphal cell wall and the onset of germination in spores, require the cleavage of pre-existing chitin in the hyphal tip by selective lysis[3]. Binding of the multivalent WGA (refs 13 and 14), to the chitin at the hyphal tip may result in cross-linking of the latter and thus inhibit the extension process. The perturbation of the delicate balance between wall synthesis and wall lysis which presumably controls apical wall growth[3] may cause the arrest of chitin synthesis. The effect of WGA seems to be of a fungistatic nature as it does not cause inhibition of leucine incorporation during short pulses (Fig. 3*a*).
Fig. 4 Inhibition of conidiation and arrest of *T. viride* hyphal extension by wheat germ agglutinin. *T. viride* was grown on potato dextrose agar in Petri dishes. When the colonies reached a diameter of 4 cm, WGA was placed in wells drilled in the agar 1 cm from the front of the colony and the colonies were allowed to grow further. The wells on top, right, and left contained: *a*, 500 µg, 250 µg and 125 µg WGA, in 50 µl minimal medium, respectively; *b*, 125 µg, 60 µg and 30 µg WGA respectively; *c*, top well contained 250 µg WGA, right-hand well contained the same amount of lectin together with 1 mg purified teichoic acid of *S. aureus* H, left-hand well contained 250 µg WGA and 2 mg chitotriose; *d*, all the wells contained minimal medium (50 µl).

A possible role of plant lectins in attaching nitrogen-fixing bacteria to plant roots has been proposed[15,16]. In view of the experiments described in this paper, as well as our finding that FITC-WGA binds to the hyphal tips of *Fusarium solani* (Mart.) Sacc. and inhibits ³H-acetate incorporation into their cell wall, it is tempting to suggest a role for this lectin in nature. It is possible that WGA protects wheat against chitin-containing phytopathogens during seed imbibition, germination and early seedling growth. The role of lectins in protecting plant seeds in which their concentration is usually high, may be a general one. Accordingly, lectins with sugar specificities which differ from that of WGA may inhibit the growth of other soil microorganisms, the surface of which are covered by polysaccharides such as glucans, galactans, mannans, or various heteropolysaccharides[1].

Inhibition of mobility of cell-surface receptors by factors which mediate specific cell–cell interactions

PREVIOUS studies on embryonic chick neural retina cells[1] have demonstrated that cells in intact tissues or single cells prepared by mechanical dispersion have relatively little ability to redistribute their surface receptors into caps. In contrast, cells prepared by trypsinisation and dissociation of intact tissues were found to exhibit lateral redistribution of surface receptors even in the absence of a multivalent ligand. After 4 h culture, however, cells dissociated by trypsinisation have lost the capability for both spontaneus and lectin-induced rearrangements of surface components. Mobility of cell-surface receptors thus seems to be related to, or determined by, trypsin-labile components at the cell surface. One kind of component which seems to be trypsin labile is also important in intercellular recognition and adhesion[2,3]. We now report that the binding of tissue-type specific cell-surface ligands which seem to mediate recognition and adhesion causes inhibition of directed rearrangement of plant lectin receptors in the plane of the membrane.

Procedures for collection of aggregation-promoting supernatant solutions (APMs), retina aggregation promoting material (RAPM) and cerebral lobe aggregation promoting material (CLAPM) were as described previously[4]. The assay for redistribution of fluorescent-labelled lectin receptors on the surface of 10-d embryonic chick neural retina cells freshly dissociated from tissues by trypsinisation was carried out as described previously[1]. The same procedure was used for 10-d cerebral lobe cells. Fluorescein-isothiocyanate conjugated concanavalin A (FITC–con A), wheat germ agglutinin (FITC–WGA) and soybean agglutinin (FITC–SBA) were purchased from Miles. Cells labelled with fluorescent lectin were examined under a Zeiss Universal microscope using an epifluorescence system and ×40 oil-immersion objective. Protein determinations on dialysed aliquots of RAPM and CLAPM were carried out by the method of Lowry *et al.*[5].

As shown in Fig. 1, RAPM inhibits cap formation of FITC–con A receptors on trypsin–dissociated 10-d chick neural retina cells. The effect depends on concentration with a plateau value at approximately 80% inhibition at RAPM concentrations greater than 25 μg ml protein. Added CLAPM or foetal calf serum (Gibco) have a
Fig. 1 Effect of APMs and foetal calf serum on cap formation of con A receptors in 10-d chick neural retina cells. Cells (20 × 10^6) prepared by trypsinisation were incubated with 60 μg FITC–con A in 1 ml Eagle's basal medium for 20 min at 0°C, followed by incubation for 60 min at 22°C with or without additives, pelleted at 200g for 5 min, and fixed in 2% glutaraldehyde (pH 7.4) for 30 min at 0°C. ●, RAPM; ○, CLAPM; ▲, foetal calf serum.

maximal effect of approximately 25% inhibition of capping over the same protein concentration range. None of these preparations had any effect on patch formation.

The inhibitory effect of RAPM on surface receptor mobility is not limited to the con A receptors. Figure 2 illustrates that receptors for both FITC–WGA and FITC–SBA are also rendered increasingly immobile after treatment with various concentrations of RAPM, although the maximal inhibition of capping by RAPM only reaches a level of approximately 50% for these receptors. As is the case for the con A receptors, CLAPM causes much less inhibition of capping of WGA and SBA receptors, with maximal inhibition of 15–20%.

To examine the tissue-type specificity of the effect of APMs on lectin receptor mobility, 10-d chick cerebral lobe cells were used in otherwise identical experiments. In this case, CLAPM inhibits cap formation of con A receptors in a concentration-dependent manner to a level of approximately 80%. The maximal inhibition obtained with

Fig. 2 Inhibition by APMs of cap formation of wheat germ agglutinin (●, ○, solid lines) and soybean agglutinin (▲, △, dashed lines) receptors in 10-d chick neural retina cells. Experimental conditions as described in Fig. 1. ●, ▲, RAPM; ○, △, CLAPM.
RAPM on cerebral lobe cells is 25% (Fig. 3). These results suggest that RAPM and CLAPM are able to specifically immobilise receptors on the cell type from which they originate.

Control of the mobility of one surface component by another has also been reported in lymphocytes[6,7]. In this system, incubation of cells with concentrations of con A greater than 5 μg ml^{-1} causes inhibition of cap formation of surface immunoglobulin molecules. Drugs which are thought to disrupt microtubules, however, were able to reverse the inhibition by con A. To examine whether inhibition of the mobility of lectin receptors by RAPM is an analogous situation, cytochalasin B (Aldrich, 20 μg ml^{-1} in dimethyl sulphoxide) or colchicine (40 μg ml^{-1}, Sigma) were added to retina cells being assayed for receptor redistribution with FITC–con A. No reversal of the inhibition by RAPM was observed. Moreover, we have previously observed[1] that treatment with these drugs does not overcome to the inhibition of con A receptor mobility in the presence of excess con A.
Fig. 3 Inhibition by APMs of cap formation of con A receptors in 10-d chick cerebral lobe cells. Experimental conditions as described in Fig. 1. ●, RAPM; ○, CLAPM.

It has previously been demonstrated in this laboratory that binding of RAPM to retina cells depends on a terminal N-acetyl-galactosamine residue, whereas binding of CLAPM to cerebral lobe cells depends on a terminal mannosamine residue[8]. To establish a positive correlation between binding activity and inhibition of surface component redistribution activity, RAPM was treated with purified N-acetyl-hexosaminidase (Miles) and CLAPM with purified α-mannosidase (Miles). Enzyme-treated RAPM preparations have a decreased ability to inhibit con A receptor mobility on neural retina cells that almost exactly corresponds to the loss of binding activity (Table 1). Similarly, CLAPM treated with α-mannosidase shows a parallel decrease in ability both to bind to cells and to inhibit con A receptor mobility of cerebral lobe cells (Table 1). Thus, by the criteria of both specificity of action and behaviour after enzyme treatment, it seems that the portion of the APM preparation which has binding activity is very similar to, or identical with, the portion which inhibits surface receptor mobility.

Taken together, these results suggest that supernatant preparations from cultures of 10-d chick neural retinae or cerebral lobes enhance reaggregation of dissociated single cells in a tissue-type specific fashion[3,9], specifically bind to such cells[4], and are also able to specifically induce an alteration in some membrane-related parameter, the effect of

Table 1 Comparison of loss of binding activity with loss of inhibition of lectin receptor redistribution activity after glycosidase treatment

APM	Preparation	Loss of binding activity (%)	Loss of inhibition of lectin receptor redistribution activity (%)
RAPM	1	20	14
	2	40	35
	3	60	70
CLAPM	1	10	26
	2	50	45
	3	70	63

RAPM was incubated in 0.05 M sodium acetate buffer (pH 4.0) at 37 °C for 30 min with 0.10, 0.25, and 0.45 U ml^{-1} purified N-acetyl-hexosaminidase (Miles) for preparations 1, 2, and 3, respectively. Enzyme-treated RAPM was boiled for 10 min and dialysed overnight against Tyrode's solution. CLAPM was treated with purified α mannosidase at concentrations of 0.01, 0.03, and 0.04 U ml^{-1} for preparations 1, 2, and 3, respectively, using the conditions above with the exception that the incubation was for 60 min. Boiled enzyme controls were done in each experiment. Binding to cells was carried out as described previously[4]. Experimental conditions for the assay of inhibition of lectin receptor mobility were as described in the legend to Fig. 1. RAPM was assayed on 10-d chick neural retina cells, CLAPM on 10-d chick cerebral lobe cells.

which is to inhibit directed rearrangements of surface receptors into caps. As receptors for three different lectins which have been shown to redistribute independently in the plane of the membrane[1] are all affected in basically the same manner by APMs, we infer that the inhibition is a general one, affecting most or all of the cell-surface components.

Control of cell-surface topography by ligands specific for tissue type may be of fundamental importance to the processes of cell recognition, adhesion and histotypic rearrangement. Whether or not neighbouring cells form stable contacts may depend, at least partially, on the distribution of surface components important for recognition and adhesion. The action of such ligands at the surface of each cell may be to maintain the surface of appropriate neighbouring cells in a configuration most suitable for stable contacts. A similar hypothesis has been advanced by Bennett et al.[10] which suggests that epigenetic control of cell-surface architecture is an important element in determination and morphogenesis. The combined use of general surface markers, such as lectin probes, with tissue-type-specific surface markers, such as APMs, should enable exploration of this hypothesis in normal morphogenetic contexts.

Stimulation by cyclic GMP of lymphocytes mediated by soluble factor released from adherent cells

THE activation of lymphocytes by mitogens is a complex phenomenon which can be subdivided into reactions occurring on the surface of the cells[1] followed by a chain of intracellular reactions caused by biochemical alterations in the membrane[2]. With respect to the mediation of the mitogenic signal from the membrane to the nucleus it has been claimed that 3',5'- cyclic GMP either directly fulfils a role as a 'second messenger'[3], or that a 3',5'-cyclic GMP-dependent step is involved in the chain of intracellular reactions culminating in cell mitosis[3,4]. These assumptions are based on the facts that after the addition of lectins to peripheral white blood cells depleted of granulocytes and monocytes, an increased intracellular concentration of 3', 5'-cyclic GMP was detected[3] and that 3',5'-cyclic GMP added exogenously activated DNA synthesis in spleen and thymus cells *in vitro*[4-6]. The prerequisites for the validity of the above mentioned hypothesis, however, are that the 3',5'-cyclic GMP levels are indeed increased in all cells entering the mitotic phase and that 3',5'-cyclic GMP added exogenously acts directly on the lymphocytes, without the participation of other cells.

Here we present results which show that stimulation of DNA synthesis in lymphocytes by exogenously added 3',5'-cyclic GMP requires the presence of adherent cells, and that peritoneal cells of mice, rich in macrophages, release a non-dialysable factor which stimulates DNA synthesis in lymphocytes if cultured in presence of 3',5'-cyclic GMP or with various mitogens.

The results of a typical experiment are summarised in Table 1. Spleen cells of BALB/c mice depleted of glass-adherent cells gave a smaller response to 3',5'-cyclic GMP than a normal spleen cell population as measured by thymidine incorporation. Addition of peritoneal cells to the non-adherent cell population restored or even enhanced the response of the cells. Removal of adherent cells, however, does not diminish markedly the response of the cells to either 2',3'-cyclic GMP, lipopolysaccharide (LPS), or phytohaemagglutinin (PHA). The response of thymocytes to 3',5'-cyclic GMP was enhanced in the presence of peritoneal cells. These results indicate that the stimulatory activity of 3',5'-cyclic GMP on DNA synthesis in spleen cells and in thymocytes is at least partially mediated by a process dependent on an adherent cell population.

To test the possibility that lymphocyte activating factor(s) released from peritoneal cells[7] may be involved in these effects,

we cultured peritoneal cells of BALB/c mice with various cyclic nucleotides. Thymocytes or spleen cells were then cultured in a medium containing various amounts of supernatants derived from peritoneal cells incubated with the various cyclic nucleotides. The results of a typical experiment are shown in Table 2. As measured by thymidine incorporation only supernatants derived from 3',5'-cyclic GMP-treated peritoneal cells stimulated DNA synthesis in thymocytes or spleen cell cultures. Peritoneal cell supernatants from non-treated cultures failed to stimulate spleen cells and only marginally stimulated (stimulation index less than 1.8) thymocyte cultures. The response to the active supernatants was dose dependent, and optimum stimulation was obtained when the cells were incubated in the presence of supernatants at a final concentration of 10% (data not shown). 2',3'-cyclic GMP at a concentration of 10^{-3} M, which has been reported to induce DNA synthesis in lymphoid cells including thymocytes[8], or 3',5'-cyclic AMP, a compound which antagonises the mitogenic activity of 3',5'-cyclic GMP at the concentration used[4], both failed to produce an active supernatant.

Dialysed supernatants of 3',5'-cyclic GMP-treated cultures as tested on thymocyte cultures had markedly more activity (Table 2), indicating the presence of a low molecular weight inhibitory principle, probably identical with that found in serum-stimulated peritoneal exudate cell culture fluids[9]. Similar stimulatory activities could be obtained by incubation of peritoneal cells with LPS or PHA (data not shown) indicating that the stimulatory principle released by 3',5'-cyclic GMP may be similar to, or identical with, that described[7,9] as lymphocyte activation factor.

Most of the biological activities of 3',5'-cyclic GMP have been reported to require Ca^{2+} (ref. 10). The release of the stimulatory principle from peritoneal cells by 3',5'-cyclic GMP, however, seems to be independent of Ca^{2+} (Table 2). Ethyleneglycol-*bis*-(2-amino-ethylether)-N,N'-tetraacetic acid (EGTA), a chelator for Ca^{2+} added at a concentration (0.6 mM) which completely inhibits the response of lymphocytes to mitogens[11,12], including the effect of 3',5'-cyclic GMP[4], failed to abolish the release of the active principle from peritoneal cells by 3',5'-cyclic GMP. Addition of 3',5'-cyclic AMP at concentrations which inhibit completely the stimulatory activity of 3',5'-cyclic AMP, PHA or LPS[4] on spleen cells also failed to abolish the release of lymphocyte activating factor by 3',5'-cyclic GMP from peritoneal cells.

In conclusion, the action of 3',5'-cyclic GMP on lymphocytes is not exclusively a direct one and the stimulation of lymphocytes by 3',5'-cyclic GMP is at least in part mediated by

Table 1 The stimulatory activity of peritoneal cells on response of non-adherent spleen cells and of thymocytes to 3',5'-cyclic GMP

Responder cells	None	3',5'-cyclic GMP (5 × 10⁻³ M)	2',3'-cyclic GMP (10⁻³ M)	PHA (10 μg ml⁻¹)	LPS (50 μg ml⁻¹)
			c.p.m. per culture		
Spleen	119	1,191	3,187	4,262	974
Non-adherent spleen	79	238	2,379	5,487	818
Non-adherent spleen + 2% PC	355	721	2,631	13,952	1,285
Non-adherent spleen + 5% PC	357	1,234	2,978	16,038	1,250
Non-adherent spleen + 10% PC	377	1,839	3,137	16,066	1,197
Thymocytes	48	157	388	224	84
Thymocytes + 10% PC	52	546	447	· 493	178

Spleen or thymus cell suspensions of BALB/c mice in a total volume of 0.15 ml (2 × 10⁶ cells ml⁻¹) were cultured in Microtitre plates M24AR, system Cooke (C. A. Greiner, Nürtingen, Germany) in an atmosphere of 5% CO_2 in air at 37 °C for 48 h in RPMI1640 medium supplemented with 5% fresh heat-inactivated human serum, 2 mM L-glutamine, 100 U penicillin and 100 μg streptomycin ml⁻¹ (culture medium). ³H-thymidine (0.1 μCi; 2 Ci mM⁻¹; Radiochemical Centre, Amersham) was added to the cultures for the last 4 h of incubation period. Cells were collected on glass fibre filters using a Skatron multiple cell culture collecter. Incorporation of ³H-thymidine into the nuclear DNA was then determined as described previously[4]. Non-adherent spleen cells, containing less than 1% macrophages, were obtained using a glass bead column as described previously[13]. Peritoneal cells (PC) of BALB/c mice were obtained by injecting 5 ml culture medium intraperitoneally and aspirating the fluid from the peritoneal cavity 5 min later. The cell population obtained consisted of ~75% monocytes, 10% polymorphs, and 15% lymphocytes. Cyclic nucleotides were obtained from Boehringer, Mannheim; LPS (lipopolysaccharide of *E. coli* 055:B5) and PHA from Difco, Detroit. Results represent arithmetic means of c.p.m. detected in triplicate cultures, s.e. less than 10%. As determined by separate experiments the highest number of PC (3 × 10⁴ cells) added to the cultures gave a negligible response to mitogens (less than 30 c.p.m.)

Table 2 3',5'-cyclic GMP-dependent release of lymphocyte-activating factor from peritoneal cells of mice

Source of supernatant	Stimulation index	
	Thymocytes	Spleen cells
PC + 3',5'-cyclic GMP	12.0 (23.2)	3.0
PC + 2',3'-cyclic GMP	0.9	1.1
PC + 3',5'-cyclic AMP	0.7	1.0
PC + 3',5'-cyclic GMP + 3',5'-cyclic AMP	11.0	2.8
PC + 3',5'-cyclic GMP + EGTA	13.0	2.8

Peritoneal cells (PC) of BALB/c mice were incubated in a culture medium (see Table 1) with either 3',5'-cyclic GMP (5 × 10⁻³ M), 2',3'-cyclic GMP (1 × 10⁻³ M), 3',5'-cyclic AMP (1 × 10⁻³ M), or a combination of 3',5'-cyclic GMP (5 × 10⁻³ M) and 3',5'-cyclic AMP (1 × 10⁻³ M), or a combination of 3',5'-cyclic GMP (5 × 10⁻³ M) and EGTA (0.6 mM) (see Table 1). Culture fluids were collected after 24 h and sterilised by filtration (Millipore filters). Thymocytes or spleen cells (2 × 10⁶ ml⁻¹) of BALB/c mice were then cultured as described in Table 1 in the presence of 10% various supernatants (final concentration). Incorporation of ³H-thymidine into the nuclear DNA was determined in 48 h cultures. Results are expressed as stimulation indices (c.p.m. in cultures in presence of 10% supernatant of PC cultures/c.p.m. in cells cultured without addition of supernatant). Each value represents mean of triplicate cultures, s.d. less than 10%. Value in brackets shows response of thymocytes to same supernatant after extensive dialysis against culture medium (without serum) for 24 h.

adherent cells. 3',5'-cyclic GMP induces the release of a soluble non-dialysable factor from peritoneal cells with lymphocyte (predominantly thymocyte)-activating properties. The factor seems to be similar or identical with the lymphocyte activating factor already described[7,9], indicating the possibility that the production of the factor is mediated by a 3',5'-cyclic GMP-dependent process.

Interaction antigens detected by cytotoxic T cells with the major histocompatibility complex as modifier

THE most exciting aspect of immunology at the moment is the way in which the major histocompatibility complex regulates certain functions of the immune system. Understanding the basis of this will revolutionise our thinking about T cell responsiveness and perhaps explain the puzzling degree of genetic polymorphism of the major histocompatibility complex. Most rewarding also will be the clinical applications, since susceptibility to many diseases is linked to HL-A (refs 1 and 2). Genes which control the response of thymus-derived (T) lymphocytes to certain antigens map in the major histocompatibility complex[1]; 1–10% of T lymphocytes respond in

an allogeneic mixed lymphocyte culture, or graft-*versus*-host reaction, against non-self major histocompatibility antigens[3-5]; cytotoxic T cells derived from mixed lymphocyte cultures seem to be directed against the classical serologically defined antigens coded in this region[6,7]. The work described here derives from another recently reported link between murine T cell function and the major histocompatibility complex. It has now been demonstrated that T-cell mediated lysis of virus infected target cells is restricted by H-2 (refs 8–10). Lysis of TNP modified
Fig. 1 Assay of lysis of six targets by BALB/c(H-2ᵈ) anti-B10.D2(H-2ᵈ) cytotoxic T cells. Normal BALB/c mice were immunised by intraperitoneal injection of 44 × 10⁶ spleen and lymph node cells from B10.D2 mice in Hanks' balanced salt solution. The spleen was removed 18 d later and 4 × 10⁶ viable cells ml⁻¹ were restimulated *in vitro* with 4 × 10⁶ cells ml⁻¹ irradiated (1,000 rad from a ⁶⁰Co source) B10.D2 spleen cells. Responder and stimulator cells were from female mice. After 4 d the cultures were collected and washed once before the assay. Targets were spleen cells which had been cultured for 3 d in the presence of 10 µg ml⁻¹ LPS to induce blast transformation of the B cells[7,13]. Targets were collected, washed, labelled with ⁵¹Cr-sodium chromate, washed twice, and viable blasts counted. Threefold dilutions of the responder cells were titred against a constant number (5 × 10⁴) of ⁵¹Cr-labelled LPS blasts for 4 h in 35-mm Petri dishes on a rocking platform. At the end of the assay, the contents of the dishes were transferred to tubes, centrifuged, and half the supernatant removed for counting. The results are plotted as the ratio of responders originally cultured to 5 × 10⁴ ⁵¹Cr-targets (logarithmic scale) against the percentage specific ⁵¹Cr-released (arithmetic scale) calculated as:

$$\frac{\text{Experimental release} - \text{spontaneous release}}{100 - \text{spontaneous release}} \times 100$$

Targets were: B10.D2(H-2ᵈ) (○); DBA/2(H-2ᵈ) (□); B10.BR (H-2ᵏ) (△); C57BL/6(H-2ᵇ) (■); B6.C/H-2ᵈ (synonym HW19) (●); and BALB/c(H-2ᵈ) (▲). Spontaneous release (release by 5 × 10⁴ targets cultured alone) varied from 18.2 to 25.9%.

targets is similarly restricted in another system[11]. I have now shown that cytotoxic T cells derived from mice immunised with cells from an allogeneic strain which carries the same H-2 region will lyse only targets which share the same H-2 as the immunising strain.

Schematically the results can be summarised as follows: cytotoxic T cells of strain A(H-2¹) immunised against cells of strain B(H-2¹) will lyse B(H-2¹) targets but not B(H-2²) targets; they do, however, crossreact strongly and kill cells of strains C(H-2¹) or D(H-2¹) but not C(H-2³) or D(H-2⁴). Such cytotoxic target antigens apparently include hybrid specific antigens (that is, antigens present on an F_1 but not on either homozygous parent). Schematically, A(H-2¹) anti-B(H-2¹) will not lyse A(H-2¹) nor B(H-2²) but will lyse F_1(A(H-2¹)×B(H-2²)) targets. I favour the hypothesis that all the allogeneic surface structures which are targets for cytotoxic cells in this system are interaction antigens created by an H-2 coded modification of the products of non-H-2 coded genes—probably minor histocompatibility genes.

The immunisations were done by priming the mice with an intraperitoneal injection of living allogeneic H-2 similar stimulating cells and 18–40 d later removing the spleen and boosting *in vitro* with irradiated stimulating cells. All the cytotoxic effector activity generated has been shown to be sensitive to treatment with anti-Thy-1.2 serum and complement immediately before the assay. Figure 1 shows the lytic activity of BALB/c (H-2ᵈ) anti-B10.D2 (H-2ᵈ) cells against targets from six strains of mice. Cells syngeneic with the responders were not lysed (Fig. 1*b*). B10.D2 was lysed very efficiently, but B10.BR (H-2ᵏ) which is genetically the same as B10.D2, except for the H-2 region, was not lysed (Fig. 1*a*). Targets from another unrelated strain, DBA/2, which carries H-2ᵈ were killed quite efficiently (Fig. 1*a*). A trivial explanation of this cross reaction was that, since B10.D2 derived its H-2ᵈ region from DBA/2, the BALB/c cells were immunised against a surface alloantigen closely linked genetically to, or within, the DBA/2 and B10.D2 H-2 region. This explanation is ruled out in Fig. 1*b*, which shows the results with another congenic pair of targets. C57BL/6 (H-2ᵇ) was lysed only very weakly by this population of BALB/c anti-B10.D2 cytotoxic cells, whereas B6.C/H-2ᵈ which is congenic with C57BL/6 and derived H-2ᵈ from BALB/c[12], was lysed very efficiently, about as well as B10.D2 targets.

Figure 2 shows the activity of BALB/c and B10.D2 cytotoxic cells obtained after immunisation with P815, a DBA/2 (H-2ᵈ) mastocytoma, when assayed at the same time against targets from six strains of mice. Neither population caused lysis of syngeneic targets. Both lysed cells of the immunising (DBA/2) strain very efficiently (Fig. 2*a* and *b*). BALB/c anti-P815 cross-reacted strongly on B10.D2, as would be predicted from Fig. 1,

but did not lyse B10.BR(H-2ᵏ) (Fig. 2*a*); B10.D2 anti-P815 on the other hand crossreacted strongly on BALB/c targets (Fig. 2*b*). The BALB/c cytotoxic population did not lyse syngeneic targets, and only caused slight lysis of C57BL/6 (H-2ᵇ), but F_1 (C57BL/6 × BALB/c) targets were lysed very well (Fig. 2*a*). Thus the cytotoxic T cells detected antigens found only on F_1 cells but not either parent, implying the existence of hybrid specific antigens.

In the experiment shown in Fig. 2*a*, BALB/c anti-DBA/2 cytotoxic cells lysed B10.D2 (H-2ᵈ) targets efficiently but not B10.BR(H-2ᵏ) targets, even though the two strains are congenic and differ only at H-2. It seemed possible that B10.BR did express antigens which the cytotoxic cells recognised on B10.D2, but the lytic function was somehow impaired by the different H-2 antigens. The question was thus whether the lysis of ⁵¹Cr-labelled B10.D2 targets caused by BALB/c anti-DBA/2 cytotoxic cells could be inhibited by the addition of unlabelled B10.BR cells. In this "cold target competition" experiment, damage of B10.BR cells was not measured, only their capacity to be bound by receptors on the cytotoxic cell[7,14]. As a control, unlabelled targets of BALB/c (syngeneic with the cytotoxic cells) or B10.D2 (syngeneic with the labelled target) were used as inhibitors. Table 1 shows that an 8 or 33-fold excess of B10.BR cells over ⁵¹Cr-B10.D2 cells did not inhibit release of label any more than did the same excess of BALB/c cells. Unlabelled B10.D2 naturally inhibited lysis. This is strong evidence that the cytotoxic cells did not see the same non-H-2 coded antigens on B10.BR as they did on B10.D2.

Two hypotheses will now be considered to explain this finding that, even after an allogeneic immunisation when responder and stimulator share the same H-2, there is a requirement in lysis for the target also to share the same H-2. The first is that there is dual recognition by the cytotoxic effector cell of H-2 coded and non-H-2 coded structures on the target cell surface. This could mean that the cytotoxic cell receptor for non-H-2 is clonally restricted but all cells bear receptors for H-2, that is, a requirement for self-H-2 recognition. There are four lines of evidence against this. First, Zinkernagel and Doherty showed that F_1 cells immune to LCM-infected F_1 cells, after boosting in parent 1 virus-infected hosts, killed infected cells of parent 1 but not of parent 2 (ref. 15). Second, I have performed a similar experiment in which F_1 (BALB/c × BALB.B) (H-2ᵈ/ᵇ) immune to B10.D2 (H-2ᵈ) did lyse B10.D2, but did not lyse B10 (H-2ᵇ). Third, the cold target competition experiment reported here (Table 1) shows that B10.BR cells fail to inhibit the binding of BALB/c anti-DBA/2 cytotoxic T cells to B10.D2 targets. Fourth, cytotoxic cells with specificity for foreign H-2 exist, with no apparent requirement in lysis for recognition of other surface structures. Alternatively, both the cytotoxic cell re-

Table 1 Inhibition by unlabelled cells of the lysis of ⁵¹Cr-B10.D2 targets mediated by BALB/c anti-DBA/2 cytotoxic cells

Unlabelled LPS blasts used for inhibition*	Genotype: H-2	background	Experimental–spontaneous release†	Factor of inhibition of lysis‡
None	—	—	37.7	—
BALB/c (×8)	d	BALB/c	32.4	1.0
BALB/c (×33)	d	.BALB/c	29.3	1.0
B10.BR (×8)	k	B10	32.3	1.0

BALB/c mice were immunised by intraperitoneal injection of 10⁷ P815 and by a secondary boost *in vitro* with 5,000 rad irradiated P815. These cytotoxic BALB/c anti-DBA/2 cells were titred against 5 × 10⁴ ⁵¹Cr-labelled B10.D2 LPS blasts for 4 h at ratios of from 43:1 to 0.18:1. At a ratio of 12:1, an 8-fold (4 × 10⁵), or 33-fold (1.65 × 10⁶) excess of unlabelled LPS blasts from BALB/c, B10.BR or B10.D2 were added to the assay to inhibit ⁵¹Cr release

*Numbers in parentheses refer to the numerical excess of unlabelled LPS blasts over ⁵¹Cr-B10.D2 blasts present in the assay.
†Spontaneous release was 34.8%.
‡A factor of 1.0 refers to no inhibition relative to the same excess of BALB/c LPS blasts. An 8-fold excess of BALB/c blasts in fact gave a 1.8-fold inhibition, and a 33-fold excess a 2.4-fold inhibition compared with when no unlabelled inhibitor cells were present. The factor of inhibition was calculated from the titration curve as described previously[7].
Fig. 2 Lysis of six targets by cytotoxic T cells from: *a*, BALB/c (H-2^d) and *b*, B10 D2(H-2^d) mice immunised against DBA/2 (H-2^d) cells. Responder mice were injected intraperitoneally with 10^7 viable DBA/2 mastocytoma cells, P815, which were grown in tissue culture. 20 days later the spleen was removed and cultured at 4×10^6 cells ml^{-1} with 2×10^5 cells ml^{-1} irradiated (5,000 rad from a ^{60}Co source) P815. After 4 d the cells were washed and threefold dilutions titred against ^{51}Cr-labelled LPS blast targets as in Fig. 1 Targets were: DBA/2(H-2^d) (△); B10.D2(H-2^d) (■); C57BL/6(H-2^b) (□); B10.BR(H-2^k) (▽); BALB/c(H-2^d) (●); and F$_1$(C57BL/6 × BALB/c) (○). Spontaneous release varied from 24.2 to 31.4%.

ceptor for non-H-2 and for H-2 may be clonally restricted. Evidence against this includes the third and fourth arguments above.

Hypothesis 1 is rejected at this stage of experimentation in favour of the second. This states that the H-2 region codes for a product which interacts with the products of genes coded elsewhere, and the result of this is the creation of new complex determinants (interaction antigens) which are recognised by allogeneic cytotoxic T cells. Although viral infection may alter H-2 antigens[16], the targets in my work are normal cells and a wealth of previous literature[6,17] and one preliminary experiment performed in this laboratory do not suggest a difference in the H-2 antigens on BALB/c against those on DBA/2 or B10.D2 which are recognised by anti-H-2^d cytotoxic cells. I therefore favour the explanation that H-2 codes for a modifier of all the other surface components which are targets in this system. In a hybrid, such as F$_1$ (C57BL/6 (H-2^b) × BALB/c (H-2^d)), the maternal (C57BL/6) and paternal (BALB/c) non-H-2 coded components are modified by both the maternal (H-2^b) and paternal (H-2^d) H-2 complex. This results in the creation of hybrid specific alloantigens, that is, the H-2^d (paternal) modification of the C57BL/6 (maternal) non-H-2 coded components and the H-2^b (maternal) modification of the BALB/c (paternal) non-H-2 coded components (Fig. 2a). The strong cross reaction shown here between unrelated strains with the same H-2 haplotype can be explained if the non-H-2 components are coded by minor

histocompatibility genes. Strains differ by a large number of minor histocompatibility loci but the number of alleles at each locus is small[18]. The basis for the cross reaction between DBA/2 and BALB/c detected by B10.D2 (Fig. 2b) is explicable if the two strains share the same allele at some minor histocompatibility loci where B10.D2 carries a different allele.

In terms of the molecular nature of the H-2 coded modification, the most attractive idea at the moment is that the major histocompatibility complex codes for a glycosyl transferase system which uses as substrate the products of genes which code for surface components (P. Trefts and B. E. Rothenberg, unpublished). This predicts that in allogeneic T-cell mediated killing the target antigens are carbohydrate in nature.

I thank Melvin Cohn, Rod Langman, Park Trefts and Barry Rothenberg for discussion. This work was supported by the US National Institute of Allergy and Infectious Diseases.

Interchange of adenyl and guanyl cyclases as an explanation for transformation of β- to α-adrenergic responses in the rat atrium

STUDIES have indicated that the response of the heart[1-5], and possibly other tissues[6], to exogenous catecholamines changes from β-type to α-type in conditions of decreased metabolic activity, including lowering the temperature. Attempts to correlate this with changes in cyclic AMP metabolism which are thought to reflect β-adrenoceptor activity were unsuccessful[7,8]. We have therefore studied the effects of lowering the temperature on the intracellular levels of both cyclic AMP and cyclic GMP in the spontaneously beating rat atrium. Cyclic GMP concentrations seem to mediate α-adrenergic responses in a variety of systems[9-12], and we therefore investigated whether its levels increased in conditions of increased α-adrenoceptor activity. Our results indicate that the same receptors that stimulate cyclic AMP synthesis at 37 °C, trigger the synthesis of cyclic GMP at a colder temperature (24 °C).

Figure 1 shows that the changes in cyclic nucleotide concentration induced by the low optimal concentrations of three catecholamines preceded their chrono- and inotropic effects. Increases in cyclic GMP levels were more prominent at 24 °C than at 37 °C, whereas changes in cyclic AMP were not impressive and confirm the previously observed lack of correlation between cyclic AMP levels and β-adrenoceptor activity at low agonist concentrations[13].

When peak changes in rate × force were used as an index of atrial performance, lowering the temperature to 24 °C resulted in transformation of β to α-adrenoceptors (Fig. 2).
Fig. 1 Time course of effect of three catecholamines on rat atrial performance and cyclic nucleotide contents at 24 and 37 °C. a, Isoproterenol; b, adrenaline; c, noradrenaline Right and left atria were removed together from 150–200 g male Sprague–Dawley rats and suspended in a tissue bath containing 25 ml Chenoweth's solution[14] aerated with 5% CO_2 in O_2. Bath temperature was maintained at 24 or 37 °C throughout. Right atrial appendage was fixed in the bath, left atrial appendage was attached by a fine silk thread to a Grass FT03 force transducer, and contractile activity was recorded with a Grass model 7 polygraph. Diastolic tension was maintained at 2 g. Atria were allowed to equilibrate for 30 min Spontaneous heart rate and contractile force were obtained from the record and were 98–125 beats min^{-1} and 0 82 to 0.97 g at 24 °C and 286–304 beats min^{-1} and 0.28 to 0 37 g at 37 °C, respectively, immediately before the additions of the agonists (10^{-7} M) which were added to the bath at zero time. To determine cyclic nucleotide levels, atria were quickly frozen at the predetermined times using modified Wollenberger clamps previously cooled in liquid nitrogen Atria were kept frozen at −70 °C until analysed for cyclic nucleotide contents not more than 2 weeks later The two cyclic nucleotides were separated from each other on Dowex–formate columns[15]. Cyclic AMP was determined by the protein binding method of Gilman[16] and cyclic GMP was determined by radioimmunoassay[17]. Internal standards of tritiated cyclic nucleotides were used to calculate recoveries, which were 87–95% for cyclic AMP and 55–78% for cyclic GMP. Phosphodiesterase treatment destroyed all assayable cyclic nucleotides. Data for both atrial performance and cyclic nucleotide contents are the average of six experiments ±s.e.m. ─ ─ ─, Percentage change in rate, ─ ─ ─, percentage change in force, ─────, cyclic AMP contents; · · · · ., cyclic GMP contents. *Statistical significance from corresponding zero time control.

This is shown by the disappearance of the order of potency, isoproterenol > adrenaline or nonadrenaline, characteristic of the β-receptor; and the greater susceptibility of the catecholamine effects to blockade by the α-adrenoceptor blocker phentolamine, which is ineffective at 37 °C; at this temperature propranolol or sotalol (not shown) were the more effective blockers. Similar results were obtained when rate alone instead of rate × force was used as an index of atrial function, except that the effects of noradrenaline in the cold were less susceptible to blockade by phentolamine. These data agree well with those reported for frog and rat hearts[1-4].

At 37 °C cyclic AMP levels seemed to reflect β-adrenoceptor activity, as isoproterenol was more effective than adrenaline and noradrenaline in raising this cyclic nucleotide level, particularly at the higher agonist concentration (Table 1). In addition the changes in cyclic AMP induced by isoproterenol and adrenaline were blocked by the β-adrenergic blocker propranolol, thus emphasising the β-adrenoceptor nature of the cyclic AMP synthesising system. When the temperature was lowered to 24 °C, decreased effectiveness of isoproterenol and increased

activity of both adrenaline and noradrenaline in promoting cyclic AMP synthesis were observed. Furthermore, increases in cyclic AMP levels by isoproterenol and adrenaline were susceptible to blockade by the α-adrenoceptor blocker phentolamine.

At 37 °C cyclic GMP synthesis seemed to reflect the activity of the α-adrenoceptor as the order of potency of the catecholamines used was noradrenaline > adrenaline > isoproterenol (see also Fig. 1); and the effects, particularly at the low agonist concentrations, were susceptible to blockade by the α-adrenoceptor blocker phentolamine (see also Fig. 2). When the atria were cooled to 24 °C however, the reverse order of potency of the three catecholamines on cyclic GMP synthesis became apparent although the effects were again susceptible to blockade by phentolamine. In addition, the β-adrenergic blocking agent propranolol effectively blocked the cyclic GMP increases induced by all catecholamines at the colder temperature

It seems therefore that the same set of β-receptors with its classical structural requirements and blocker susceptibility that trigger the synthesis of cyclic AMP at 37 °C, promoted the

Table 1 Effects of various concentrations of agonists alone and in the presence of antagonists on cyclic nucleotide levels in the rat atrium at 24 and 37 °C

synthesis of cyclic GMP at the colder temperature. Increased cyclic GMP synthesis at the colder temperature could not have resulted from the activation of new α-adrenoceptors that were dormant at 37 °C, as the order of potency noradrenaline > adrenaline > isoproterenol on cyclic GMP generation characteristic of classical α-adrenoceptors did not prevail. Increased cyclic GMP synthesis triggered by the β-adrenoceptor at the colder temperature may be regarded as either a change in substrate specificity of the catalytic subunit of the adenyl cyclase enzyme from ATP to GTP with no change in the discriminator or receptor subunit[18]; or the coupling of the β-adrenoceptor subunit at the cold temperature with the catalytic subunit of guanyl cyclase. A model conforming with

this latter possibility has already been proposed[19]. The continued susceptibility of cyclic GMP synthesis at the low temperature to the blocking effects of phentolamine indicates that this blocker must act as a cyclic GMP-generating site located past the apparently unchanged receptor, as has already been suggested[20]. Propranolol, on the other hand, seems to act at the level of the receptor subunit itself.

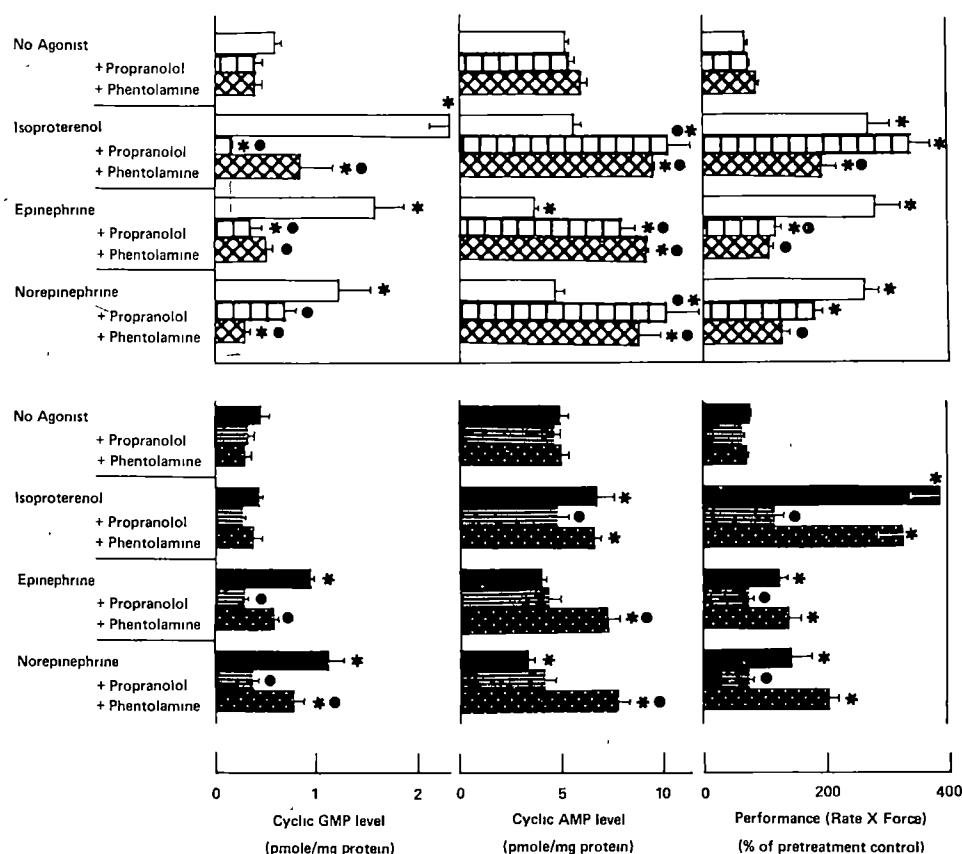
At the colder temperature and low agonist concentrations, the observed propranolol-resistant increases in cyclic AMP in the presence of the β-adrenergic blocking agent could be secondary to blockade of the increases in cyclic GMP (Fig. 2). This may also explain cyclic AMP increases in the presence of phentolamine at both 37 and 24 °C, as both cyclic nucleotides


Fig. 2 Effects of various adrenergic agonists and antagonists on performance, cyclic AMP and cyclic GMP levels in spontaneously beating rat atria at 37 °C (*a*) and 24 °C (*b*). Experimental conditions are the same as for Fig. 1. Column heights represent the averages of 4–6 atria ±s.e m. *Statistically significant differences ($P<0.05$) from control (no agonist) at the same temperature; ● statistically different from agonist alone at the same temperature. Isoproterenol, adrenaline, noradrenaline and propranolol were added in a final concentration of 10⁻⁷ M whereas the final concentration of phentolamine was 10⁻⁶ M. Propranolol and phentolamine were added to the bath 30 min before and the atria were quickly frozen 10 s after addition of catecholamines. Mean (±s.e.) heart rates during the control (predrug) period were 292±6.4 and 105±8.5 beats min⁻¹ at 37 and 24 °C, respectively. Basal contractile forces were 0.29±0.03 g at 37 °C and 0.79±0.08 g at 24 °C.

are known to influence the rate of hydrolysis of one another[18]. The reverse situation may exist in the case of propranolol at the higher temperature, that is, blockade of the changes in cyclic AMP levels induced by the catecholamines may be responsible for the effects of propranolol on cyclic GMP levels. It is unlikely that the effects of these catecholamines on cyclic nucleotide levels involve direct action on phosphodiesterase enzymes[21]. It is not clear from the present study which cyclic nucleotide has the major role of translating the effects of catecholamines into mechanical effects in the heart, particularly in the crucial low temperature–low concentration conditions. The data presented here indicate a possible antagonistic role for cyclic GMP to that of cyclic AMP, a role that seems less prominent at the lower temperature. This is supported by the observation that cyclic GMP seems to mediate the negative chrono- and inotropic effects of acetylcholine on the heart[19].

Two mechanisms for poststimulus hyper-polarisations in cultured mammalian neurones

Long lasting hyperpolarising responses following high frequency spike discharges in neurones from several sub-mammalian species have been attributed to either electrogenic ion transport[1,2] or to a long lasting increase in K^+ conductance[3,4]. These prolonged hyperpolarising responses of whatever mechanism result in alterations of neuronal behaviour which may have important functional consequences for the integrative activity of the central nervous system (CNS). Similar potentials have been reported in studies on the intact mammalian CNS[5–7], but the complexity of these preparations has prevented a thorough analysis. Such phenomena can be studied using intracellular recording techniques in dissociated cell cultures of mammalian neural tissue, and here we demonstrate post-stimulus hyperpolarising responses in cultured spinal neurones and suggest the underlying mechanisms.

Spinal cords were dissected from 13-d-old mouse embryos, mechanically dissociated and plated at a density of about 10^6 cells per dish (35 mm diameter, Falcon). After a brief exposure to a metabolic inhibitor (to suppress the rapid division of fibroblasts) cells were allowed to mature for a period of about 3 weeks. Cells were maintained in modified Eagle's medium with 10% horse serum added as described previously[8]. Experiments were carried out by placing a culture dish in a chamber on the modified stage of an inverted phase contrast microscope. Mature cultures contained two easily distinguishable populations of large neurones (25–50 µm): dorsal root ganglion (DRG)

cells and multipolar spinal cord (SC) cells. These cells exhibited a full range of characteristic neuronal electrophysiology including membrane potentials of -40 to -60 mV, spike electrogenesis, and in the case of SC cells, synaptic transmission, as well as sensitivity to a number of putative transmitters[8,9]. Neuronal somata were impaled under direct vision with 4 M K^+ acetate-filled pipettes (20–40 MΩ). At the time of study $MgSO_4$ was usually added to a final concentration of 10 mM to suppress spontaneous synaptic activity. Standard electrophysiological techniques were used for intracellular recording and iontophoresis. Glutamate (0.6 M, *p*H 8) was iontophoresed on to cell somata from fine-tipped pipettes. Strophanthidin (3×10^{-4}– 7×10^{-4} M, Sigma), dissolved in medium, was leaked on to cells using coarse pipettes (tip diameter 25–50 µm).

Glutamate, a putative excitatory transmitter in the mammalian CNS[10], caused brisk depolarisation, usually evoking action potentials in over 95% of SC cells. Short pulses of glutamate (that is < 1 s duration) elicited responses with roughly exponential falling phases. Longer lasting pulses evoked a more complicated sequence of events (Fig. 1*a*). During the drug application the cells depolarised to a steady plateau level without evidence of desensitisation. Following termination of the iontophoretic current, the membrane potential returned past the prestimulus level resulting in a long lasting (20–200 s) hyperpolarisation of variable magnitude (1–20 mV). The magnitude and duration were related directly to the duration and intensity of the glutamate application. This post-glutamate hyperpolarisation (PGH) was not associated with a change in input resistance (Fig. 1*b*) and did not have an apparent reversal potential. Conditioning hyperpolarisation of the membrane potential (through sustained injection of current) enhanced the PGH response in seven cells tested (Fig. 1*c*). PGH was present at potentials at which the hyperpolarising after-potential of the spike had reversed polarity, implying that the PGH could drive the membrane potential more negative than the K^+ equilibrium potential.

PGH was rapidly and reversibly abolished by the local application of strophanthidin in six cells tested (Fig. 1*b*). In four cells application of the drug during PGH caused an

Fig. 1 Characteristics of PGH. *a*, Response of multipolar spinal cord cell to prolonged glutamate application (50 nA, shown by bar). Trace 2 is a high gain record of trace 1. Membrane potential -38 mV. *b*, Effect of strophanthidin on PGH. Constant applications of glutamate (34 nA, 8 s) were given before (con), during (stroph), and 5 min after (post) the local application of strophanthidin (3×10^{-4} M) to the cell soma Downward deflections are voltage responses to injection of constant hyperpolarising current pulses (0.3 nA for con and stroph, 0.5 nA for post record) Input resistance does not change during PGH The post PGH is longer lasting and smaller than the con PGH probably as a result of a reduction in peak pump rate caused by residual strophanthidin action. Membrane potential -65 mV. *c*, Relationship between PGH amplitude and membrane potential Constant glutamate applications (50 nA, 12 s) were applied while the membrane potential was varied by passing steady polarising current through the recording electrode Membrane potential at rest -38 mV.
Fig. 2 Characteristics of PTH in DRG cells. a, Trains of depolarising current pulses (30 s⁻¹) elicited a spike train of same frequency (shown by bar), following which a slowly relaxing hyperpolarisation is seen. Downward deflections are voltage responses to the injection of constant current pulses (0.2 nA). Note the decrease in input resistance during PTH. Right-hand record in a shows that no change in resistance occurs when the membrane potential of this cell is passively moved in the hyperpolarising direction by steady current injection. b, Relationship between spike after-potential, PTH and membrane potential. After-potential following an action potential (induced by a single depolarising current pulse) and PTH elicited in the same cell by high frequency pulses (50 s⁻¹) are compared at different membrane potentials achieved by polarising current. c, Locally applied strophanthidin (7 × 10⁻⁴ M) does not alter PTH (50 s⁻¹).
Calibration: 20 mV and 60 s (a and c); 0.2 s (b, left).

immediate depolarisation averaging 15 mV. (Strophanthidin application to cells not undergoing PGH led to rapid, reversible, depolarisation averaging 5 ± 2 mV (s.d.; $n = 12$).) Drug application did not cause any detectable changes in input resistance, nor did it interfere with the depolarisation elicited by glutamate.

DRG cells, which are unresponsive to glutamate (B.R.R. and P.G.N., unpublished), also exhibited a form of poststimulus hyperpolarisation. In these cells high frequency spike trains (elicited by depolarising current pulses) were followed by hyperpolarisations lasting several seconds (Fig. 2a). Although this post-tetanic hyperpolarisation (PTH) is similar to the hyperpolarising responses in SC cells with regard to magnitude and duration, PTH has several distinguishing characteristics. During PTH, input resistance was decreased, returning to its control value as the membrane potential returned to the baseline level (Fig. 2a). PTH magnitude was dependent on membrane potential; its reversal potential was identical to that of the spike after-potential (Fig. 2b). Strophanthidin, applied to DRG cells, did not alter PTH (Fig. 2c).

PTH in DRG cells seems to result from a prolonged period of increased K⁺ conductance. This is suggested by the conductance increase during PTH, the reversal potential of PTH being coincident with the reversal potential of the spike afterpotential, and the insensitivity of PTH to strophanthidin. In invertebrate cells a response with similar characteristics follows spike trains and has been shown to depend on Ca²⁺ influx during action potentials with a subsequent increase in K⁺ conductance [3,4]. As the DRG cell has a Ca²⁺ component to its spike (J. Fischbach and M. Dichter, unpublished), it is possible that PTH may result from a similar sequence of events.

PGH in SC cells fulfils many of the electrophysiological criteria which identify potentials produced by electrogenic transport[2]: it occurs without change in membrane conductance, can exceed the K⁺ equilibrium potential (as reflected by the reversal potential of the spike after-hyperpolarisation), and is abolished by the glycoside strophanthidin at a concentration known to inhibit the Na⁺ pump. As the glutamate response has

an equilibrium potential around −20 mV, it is likely that the response involves a substantial increase in Na⁺ permeability (ref. 11 and N. Brookes, unpublished). Prolonged glutamate application therefore would lead to an increase in intracellular Na⁺ concentration, causing an increase in the rate of Na⁺ pumping[12]. In fact, spike amplitude is depressed during PGH, suggesting that the Na⁺ gradient across the membrane is reduced (not illustrated). Other experiments to be reported in detail elsewhere show that Na⁺ injection or tetanic spike discharge in SC cells can result in hyperpolarisations similar to PGH. Thus, we conclude that PGH as well as these other potentials results primarily from the current generated by increases in the rate of electrogenic Na⁺ transport triggered by Na⁺ loading induced by certain chemical and electrical stimuli. The increase in PGH which is seen with hyperpolarisation (Fig. 1c) presumably results from increased Na⁺ loading that would be expected as a result of the increased Na⁺ driving force produced by the hyperpolarisation. Our results also suggest that there is an electrogenic component to the resting potential in SC cells amounting to about −5 mV.

The significance of the potentials reported here is not well understood. Such long-lasting neural signals can have immediate effects on information processing[13,14], and may encode important and unique aspects of previous nervous activity. It is tempting to speculate that these or similar processes may intervene between rapid electrochemical events and more lasting biochemical phenomena. An obvious opportunity for this sort of linkage exists in DRG cells in which both PTH and the initiation of axoplasmic transport[15] may have an important dependency on Ca²⁺. The PGH in SC cells, on the other hand, is clearly associated with an increase in Na⁺ transport and thus ATPase activity. The attendant effects on energy metabolism might be expected to have a variety of biochemical sequellae.

Activation of a voltage-insensitive conductance by inward calcium current

ELECTRICAL excitability is more complex in cell bodies than in axons. In various nerve cells there is a voltage-sensitive permeability to calcium as well as to sodium and potassium. Furthermore, increased calcium in the cytoplasm of nerve cell bodies increases their potassium permeability. In voltage-clamped *Helix* neurones, Meech and Standen[1,2] reported that a substantial fraction of the potassium conductance activated during a depolarisation depends on an inward calcium current.

We have studied the sensory epithelium of the electroreceptor (ampulla of Lorenzini) of the skate. In this epithelium, which

can generate all-or-none action potentials[3,4] of 60 mV, we have found that the repolarising phase of the action potential results from a late outward current initiated when calcium ions enter the cytoplasm of the excitable cells. Because there is no detectable voltage-sensitive outward current, we conclude that a distinct calcium-activated conductance mechanism is involved.

Skate electroreceptor epithelium consists of a single layer of interspersed receptor and supporting cells (Fig. 1b). The epithelium forms a lobulated sac, or ampulla of Lorenzini, which is connected to an external orifice by a long canal (Fig.
Fig. 1 *a*, Skate ampullary electroreceptor and canal (after Waltman[5]). *b*, Details of two receptor cells in the ampullary epithelium. Occluding junctions (zonulae occludentes, Z.O.) occur between receptor cells and adjacent supporting cells. The basal membranes form characteristic ribbon synapses with the afferent nerve fibres[5]. *c*, Experimental arrangement for current clamping, voltage clamping, and internally perfusing an ampulla. The ampulla with its canal (average diameter 1 mm, average length 7 cm) was removed from a skate (*Raja oscellata* or *R. erinacea*). The open end of the canal was placed in one saline pool (S) and the ampulla in another. Little current flows along the external surface of the canal (C) because it was rinsed with a solution of 526 mM sucrose and 350 mM urea before it was placed in the recording chamber. A 100-μm glass cannula was introduced through a nick in the canal wall. The cannulated portion of the canal was in a Vaseline gap. The uncannulated portion was in air. The saline pools contained cerebrospinal fluid from the cranial cavity or occasionally Fühner's[9] elasmobranch saline. The perfusate (P) was under slight pressure. Effluent was aspirated. All perfusates were made from a control solution containing 428 mM NaCl, 13 mM KCl, 50 mM MgCl$_2$, 10 mM CaCl$_2$, 75 mM urea and 5 mM HEPES at pH 8.1. Ionic exchange inside the ampulla was limited by diffusion through the gelatinous material that fills the individual lobules. When the ampulla was perfused with phenol red, noticeable diffusion into all the lobules required about 15 min. Epithelial current was measured by a current–voltage transducer with output *I*. Epithelial voltage was measured at the perfusion cannula, and controlled using an operational amplifier and a voltage source. Constant current pulses were applied by connecting the electrode at the canal orifice to a second voltage source through a 10^8 Ω resistor.

1a). The canal is a core conductor, the wall of which is electrically linear and has a high resistivity[5]. All cell surfaces abutting on the lumen of the ampulla and its canal are joined by occluding junctions which presumably prevent extracellular leakage of current or ions across the epithelium. The occluding junctions separate the excitable lumenal faces of the receptor cells from their basal faces, which are innervated by afferent fibres of the VIIIth cranial nerve (Fig. 1b).

The electroreceptor epithelium was voltage clamped as shown in Fig. 1c. During lumen-positive voltage steps (which hyperpolarise the lumenal membranes), epithelial current was constant after the capacitative transient. When the lumen was made negative (depolarising the lumenal membranes), however, active currents were observed (Fig. 2a). Excitatory (lumen-negative) voltage steps of moderate amplitude evoked an early current which flowed inward across the lumenal membranes followed by a maintained outward current. At voltages less than 30 mV, multiple peaks of inward current sometimes occurred. We attribute active currents to the receptor cells because of the associated postsynaptic potentials that could be recorded in the afferent nerve fibres. The conductance changes responsible for the active currents are attributed to the lumenal faces of the receptor cells because these currents are dramatically altered by ionic substitutions in the lumen (see below), but are only slightly affected by drastic alterations outside the basal membranes, for example, chelation of calcium with EGTA, or 90% replacement of NaCl with potassium acetate.

When increasingly large excitatory voltage steps were applied across the epithelium, onset of the late outward current became slowed and delayed (Fig. 2a). At about 130 mV lumen-negative, activation of the late outward current was totally suppressed. The remaining early current did not inactivate significantly during the clamping pulse. A current–voltage relationship of the electroreceptor epithelium is shown in Fig. 2b. Excitatory (lumen-negative) voltages are to the right of the vertical axis. For excitatory voltage steps, the peak inward and late outward

Fig. 2 *a*, Currents recorded from skate electroreceptor epithelium during perfusion with the control solution. Current flowing inward across the lumenal membranes of the receptor cells and outward across the basal membranes is defined as inward current and shown downward. Voltage displacements that depolarise the lumenal membranes (lumen-negative) are defined as positive. *b*, A current–voltage relationship plotted from the data in *a*. The vertical axis is placed at the holding potential, which is the potential developed by the epithelium when no current is allowed to flow in the canal. The reversal potential for the early current, obtained by extrapolation of the leakage current (long dashes), is also the potential at which the late outward current is suppressed. *c*, Current–voltage relationships obtained from the same preparation after the free calcium concentration in the lumen had been reduced by perfusion with EGTA.
Fig. 3 *a*, Repolarisation tail currents recorded from skate electroreceptor epithelium. Two sweeps with voltage steps of different amplitude are superimposed. The smaller stimulus, 1, evokes a late outward current and a repolarisation tail current lasting 600 ms. The larger stimulus, 2, exceeds the reversal potential for the early current, and evokes no late current and no prolonged repolarisation tail. *b*, Facilitated onset of the late outward current by a conditioning stimulus. Two uniform voltage steps are applied 2 s apart and the currents are superimposed. The early current is identical for the two stimuli, but the late outward current evoked by the conditioned stimulus, 2, occurs at much shorter latency than that evoked by the conditioning stimulus, 1.

currents were linear functions of voltage over a broad range. For lumen-positive steps, current was also linearly related to voltage, the slope of the line being the leakage resistance.

We were able to demonstrate that the resistance immediately after the onset of an excitatory voltage displacement (instantaneous resistance) was equal to the leakage resistance. (This demonstration was possible because the form of the capacitative transient did not depend on the absolute voltage or the epithelial conductance. Capacitative transients could therefore be subtracted from the total current.) Moreover, experiments with superimposed pulses showed that the instantaneous resistance of the epithelium during maintained early and late currents was equal to the corresponding slope resistance. Knowing these instantaneous resistances, it is possible to determine the reversal potential for the early current. This reversal potential, about 130 mV, was equal to the suppression potential for the late outward current.

Early current in skate electroreceptors is carried by calcium as shown by the following observations: (1) The action potential was unaffected when the lumen of the ampulla was perfused with 0.1 mM TTX. (2) The action potential was abolished by perfusion with cobalt. (100 mM $CoCl_2$ was prepared by isosmotic substitution for NaCl in the control saline. Because of diffusion delays, the effective concentration at the ampullary epithelium must have been substantially lower.) (3) Inward current was abolished by a zero calcium solution containing EGTA. (20 mM EGTA and 60 mM HEPES were brought to *p*H 8.1 with NaOH and isosmotically substituted for NaCl.)

The current–voltage relationship of Fig. 2*c* was obtained during perfusion with a solution containing normal (10 mM) Ca, 20 mM EGTA and 60 mM HEPES. The data were taken after about 15 min, before ionic equilibration was complete. Although the free calcium concentration is not known, the reversal potential for the early current was clearly reduced, as was the magnitude of the early current at all voltages. Significantly, the suppression potential for the late outward current still corresponded to the reversal potential for the early current. These observations suggest that the early current is carried by calcium, and that the late current is not activated unless there is a net influx of calcium into the cytoplasm. This interpretation is corroborated by the fact that no delayed rectification was seen when the epithelial action potential was abolished by perfusion of the lumenal membranes with EGTA or cobalt.

When the epithelium is repolarised following activation of the late outward current, a tail current lasting about 600 ms is observed (Fig. 3*a*, trace 1). Prolonged tail currents are not observed when the excitatory voltage stimulus exceeds the reversal potential for the early current and there is no late current (trace 2). Prolonged tail currents are augmented, but

cannot be shortened by repolarising the epithelium to increasingly lumen-positive voltages. These observations suggest that the prolonged tail current flows in a voltage-insensitive conductance that is activated by an early inward current.

The absence of any voltage-sensitive component of the slow current requires that a different type of conductance mechanism, presumably a distinct macromolecule, be responsible for terminating the action potential in skate electroreceptors. An important property of this calcium-activated conductance is that it undergoes facilitation. In Fig. 3*b*, two identical pulses were applied 2 s apart. The conductance of the epithelium returned to normal between pulses and the size of the inward current evoked by the two pulses was uniform. The onset of the late outward current, however, occurred considerably earlier during the second stimulus. This effect of a conditioning stimulus lasted about 10 s. It was not observed when the conditioning stimulus exceeded the reversal potential for the early current. Residual calcium may therefore have been involved. Facilitated onset of a calcium-activated hyperpolarising conductance may mediate sensory accommodation in skate electroreceptors[7].

Evidence for a calcium-activated hyperpolarising conductance has been adduced for each of several nerve cell bodies that have been studied in this respect[6,8]. It seems likely that the underlying molecular basis is the same in these cells as in skate electroreceptors, although in neurones experiments are complicated by the presence of a voltage-sensitive late conductance. Calcium-activated conductances could have a major role in the regulation of electrical activity in cell bodies, particularly if they exhibit the facilitated onset we have described in skate electroreceptors.

Selective elimination of taste responses to sugars by proteolytic enzymes

INTERACTION between taste stimuli and taste receptors has been suggested as the initial event preceding the taste cell excitation, and, based on a number of biochemical investigations, the receptors are presumed to be proteinacious in nature[1–3]. For example, a protein which combines with sweet substances was extracted from bovine[4] and rat tongues[5]. Direct evidence for the ability of the extracted protein to bind with sugars has come from experiments using ^{14}C-labelled fructose and polyacrylamide gel electrophoresis or Sephadex gel filtration[6,7]. The presence of a sugar-binding receptor in taste buds has also been indicated by an experiment in which suspensions of papillae containing taste buds were found to bind more ^{14}C-sucrose than those without taste buds. Furthermore this binding ability could be abolished by heating[8]. Therefore, if taste receptors for sweet substances are composed of a protein, the neural responses to sugars would be eliminated after digestion of the receptor protein by proteolytic enzymes. To check the above hypothesis, various proteases were applied to the rat tongue surface and impulses from the taste nerve were recorded. In addition,
Fig. 1 Integrated responses of rat chorda tympani to stimulation of the tongue with 1 M sucrose, 0.02 M quinine–HCl, 0.01 M HCl, and 0.05 M NaCl before (control) and after treatment with 2 % pronase E for 30 min. The two right-hand columns indicate the responses after rinsing the tongue with water. Female Sprague–Dawley rats (150–250 g) were anaesthetised by intra-peritoneal injection of sodium amobarbital (70 mg per kg body weight). Integrated responses to taste stimuli were recorded from the chorda tympani[9]. In each experiment, the integrated res-ponses to four basic taste stimuli (0.05 M NaCl, 0.01 N HCl, 0.02 M quinine hydrochloride and 1.0 M sucrose) were recorded first as controls. Subsequently, one of the enzymes (with pH adjusted with phosophate buffer solutions at 30–50 °C) was applied to the rat tongue through a glass flow-chamber for 20 min or more, after which the tongue was rinsed with 300–400 ml tapwater and the above series of stimulations repeated. Com-mercially obtained enzymes were used without further purifica-tion.

Fig. 3 Changes in taste thresholds in human subjects by appli-cation of Pronase E (2 %, 10 min, at arrow). Each box indicates the range of the taste threshold concentration (%) for sucrose, NaCl, quinine–HCl and citric acid before and after application of Pronase. Note the recovery to normal of the elevated threshold for sucrose. For sensory examinations a filter paper immersed in Pronase solution at the same con-centration as that applied to the rat tongue was placed on the tongue of human subjects for a period of 10 min. After the filter paper had been taken off, the tongue was rinsed with distilled water, and taste solution applied with a pipette to the same area. The tongue was rinsed with distilled water after each stimulation with a taste solution.

an alteration of the taste threshold produced by the enzymes were also examined in human subjects.

Application of various proteolytic enzymes such as trypsin (pH 7.0), papain (pH 7.0) and neutral (pH 7.0) and acidic (pH 4.7) proteases to the tongue surface for more than an hour did not produce any effect on the neural responses to the four basic taste stimuli (Fig. 2). On the other hand, when Pronase E (pH 7.0) or semi-alkaline pro-tease (pH 8.0) was applied to the tongue for 20 min, the chorda tympani response to 1 M sucrose was suppressed (Figs 1 and 2), whereas responses to the other three taste stimuli were hardly affected (Fig. 1). Similar suppression of responses to various sweet substances was also observed. Responses to 1 M glucose, 1 M fructose, 0.8 M sorbitol

and even 0.005 M saccharin were completely eliminated by the previous application of Pronase E or semi-alkaline protease, and responses to 0.8 M glycine and 0.8 M DL-alanine, which produce sweet taste in man, were also depressed markedly. By rinsing the tongue with water for a period of 30 min or more after the enzyme application, the eliminated responses to the sweet substances were com-pletely recovered to the same magnitude as found for controls (Figs 1 and 2). In contrast, Pronase E, which was
Fig. 2 Integrated res-ponses of the rat chorda tympani to 1 M sucrose and 0.05 M NaCl (left column). The three middle columns indicate the responses after treat-ment with 2 % neutral, acid and semi-alkaline proteases and the right column shows those after rinsing the tongue with water. On–off markers in sucrose response indicate the period of application of taste solution to the tongue.

inactivated by heating at 80 °C for 5 or 10 min, produced little effect on the integrated response to sucrose.

Essentially the same effect for Pronase as that obtained by the neural experiments was demonstrated in the sweet sensation of man (Fig. 3). The mean ($\pm$ s.d.) threshold concentration for sucrose in man treated with Pronase was $2.8 \pm 1.3\%$ (w/v), which is about five times greater than normal ($0.58 \pm 0.32\%$), and the difference is significant ($0.01 > P > 0.001$; Student's t test). The elevated threshold reverted to normal by rinsing the tongue with water for 20–60 min. On the other hand, thresholds for the other three tastes remained within the normal range ($0.44 \pm 0.21\%$ for NaCl, $0.003 \pm 0.0013\%$ for quinine hydrochloride, and $0.099 \pm 0.053\%$ for citric acid) before and after application of Pronase (Fig. 3). The present sensory data confirmed the observations on the neural response in the rat.

In the present study it has been demonstrated that the proteolytic enzyme selectively suppresses rat chorda tympani responses to sweeteners without affecting those to other kinds of taste stimuli. An elevated threshold for sugar by application of the enzyme was also found in the sensory examinations. Thus, the neurophysiological experiments on rats qualitatively duplicate the sensory data in men. Both kinds of study may indicate that the sugar-binding ability of the receptor is depressed, possibly as a result of digestion of the receptor protein by the enzyme. Consequently, our findings support the conclusion, derived from biochemical investigations[4-8], that the sugar receptor molecules are composed of a protein. The recovery of taste responses after rinsing the proteolytic enzyme with water may be the result either of the strong repairing action of the protein or of a rapid turnover mechanism of the receptor protein synthesised in taste cells.

Giroux and Henkin[10] have reported that proteolytic enzymes produce a non-selective increase in the threshold for each of the four basic tastes in man, and that alterations in taste acuities lasted for as long as 12 h after application of Pronase. Their results hardly agree with those from our experiments. This difference may be the result of a difference in the dosages used. In their examinations the total dosage of Pronase was 6 mg in a buffer solution, and the enzyme was thoroughly circulated within the oral cavity, which produced sensations of tingling and burning. In our sensory examinations the total dosage of Pronase absorbed in a filter paper placed on the tongue was about 1 mg. The actual concentration affecting taste buds may be less, because of dilution by saliva. This small dosage produced a light astringent taste and depressed the sugar response alone. Tingling and burning sensations after the enzyme treatment in the former experiments may suggest that not only the protein composing the sugar receptor but also the taste cell membrane responsible for other stimuli would be simultaneously digested by a strong proteolysis, leading to long lasting alteration in the thresholds not only for the sweet taste but also the other three tastes.

Evidence for phosphofructokinase in chloroplasts

ATTEMPTS to demonstrate phosphofructokinase activity in chloroplasts have so far been unsuccessful[1-4], thus raising the question of whether the transitory starch formed in the chloroplast during photosynthesis can subsequently be metabolised to triose phosphates within the chloroplast. Such a conversion would seem beneficial if the products of starch degradation are required to move freely from the chloroplast to the cytoplasm, since triose phosphates, but not hexose phosphates, are actively and rapidly transported across the chloroplast membrane[5]. The apparent absence of phosphofructokinase from chloroplasts was also discouraging since this enzyme is considered one of the principal regulatory enzymes of carbohydrate metabolism[6] and the regulatory properties of the plant enzyme have been shown consistent with the control of starch metabolism[7]. Investigations in this laboratory have now demonstrated that chloroplasts do contain phosphofructokinase activity.

Spinach chloroplasts were isolated by homogenising 24 g leaves for 5 s in 120 ml of the isolation medium described by Lilley *et al.* (ref. 8). The homogenate was filtered through Miracloth, centrifuged at 2,500g for 80 s and the pellets of chloroplasts broken in 30 ml of a solution of pH 7.7 consisting of 5 mM $MgCl_2$, 5 mM dithioerythritol and 1 mM EDTA and containing 1 g Polyclar AT. A sample of the supernatant was collected as representative of the cytoplasmic fraction; dithioerythritol was added to 5 mM, the pH adjusted to 7.7 and 1 g Polyclar AT stirred in. After 10 min these chloroplast and cytoplasmic samples were centrifuged at 22,000g for 20 min, the supernatants collected and that from the chloroplasts was concentrated through a Diaflo XM-50 filter to 4 ml. Samples (2 ml) of each of the concentrated chloroplast extract and cytoplasmic fraction were dialysed for 3 h against 1 l of a solution of pH 7.7 containing 5 mM imidazole-HCl, 1 mM $MgCl_2$, 1 mM dithioerythritol and 0.5 mM EDTA.

The activity of phosphofructokinase is compared in Table 1 with the activities of three marker enzymes: non-reversible glyceraldehyde-3-phosphate dehydrogenase (GAPDH) which is restricted to the cytoplasm[9], the NADP-linked reversible GAPDH found only in the chloroplast[2], and fructose-1, 6-diphosphate aldolase (FDP-aldolase) which occurs both in chloroplasts and the cytoplasm[2]. The specific activity of non-reversible GAPDH in the chloroplast extract was only 2% of that in the cytoplasmic fraction, indicating that cytoplasmic contamination of these chloroplasts isolated in aqueous media was minimal. In contrast, considerable phosphofructokinase activity was detected in the chloroplast extract, the specific activity being 25% of that in the cytoplasmic fraction. The clear difference between the ratios of the specific activities of these two enzymes (Table 1) provides strong evidence that the phosphofructokinase activity detected in the chloroplast extract did not originate from cytoplasmic contamination of chloroplasts during isolation but rather represents an authentic localisation of phosphofructokinase with the chloroplast.

The activities of chloroplast GAPDH and FDP-aldolase (Table 1) show that a considerable number of the chloroplasts were broken during isolation; assuming all the chloroplast GAPDH activity and 65% of the FDP-aldolase activity are located in chloroplasts[2] the results in Table 1 show that enzyme loss from chloroplasts was between 65 and 80%. Consequently the total chloroplast phosphofructokinase activity shown in Table 1 is probably only a fraction of the true value.

Several lines of evidence confirm the presence of phosphofructokinase activity. The enzyme activity was dependent on both fructose-6-phosphate and ATP; no NADH oxidation was observed in the absence of either substrate if the preparation was dialysed before assay. Both phosphoenolpyruvate and

Table 1 Activities of phosphofructokinase and three marker enzymes in a chloroplast extract and cytoplasmic fraction from spinach leaves

| | Chloroplast extract | | Cytoplasmic fraction | | Ratio: |
	Total activity*	Specific activity†	Total activity*	Specific activity†	s.a. chloroplast / s.a. cytoplasm

FDP-aldolase	110	14	310	10	1.4

* Measured as μmol per h per 10 g fresh weight of leaves.
† Expressed as μmol per mg protein per h.

Enzyme activities were determined at 22 °C. The reaction mixtures for phosphofructokinase contained, in a final volume of 1 ml, 50 μmol imidazole-HCl buffer (*p*H 7.7), 2.5 μmol $MgCl_2$, 2.5 μmol dithioerythritol, 1.5 μmol D-fructose-6-phosphate, 0.5 μmol ATP, 0.08 μmol NADH, 1 unit aldolase, 12 units triosephosphate isomerase, 1 unit α-glycerophosphate dehydrogenase and 50–100 μl extract. The composition of reaction mixtures for the determination of FDP-aldolase and chloroplast GAPDH activities were based on those described earlier[2]; the buffers used in the present experiment were imidazole-HCl (*p*H 7.7) and triethanolamine-NaOH (*p*H 8.0) respectively. Non-reversible GAPDH was assayed as described previously for cell-free plant extracts[9]. All assay enzymes were dialysed before use to remove $(NH_4)_2SO_4$. Activities were calculated from changes in extinction of reaction mixtures at 340 nm measured spectrophotometrically. Protein was determined by the Biuret procedure as described previously[9].

relatively high concentrations of ATP inhibited the chloroplast phosphofructokinase activity: phosphoenolpyruvate at 0.1 mM produced more than 70% inhibition, while the activity with 4.8 mM ATP was less than half that with the optimum ATP concentration of 0.1 mM. Inhibition with increased levels of ATP is a common property of phosphofructokinase[6] and sensitivity to inhibition by phosphoenolpyruvate is a notable feature of plant phosphofructokinase[7]. Some of these regulatory phenomena may explain why phosphofructokinase activity was not found in chloroplasts in earlier studies[1-4] particularly if ATP levels used in those assays were too high.

Preliminary experiments in which intact chloroplasts were added to a solution containing the substrates for phosphofructokinase showed that the product fructose-1,6-diphosphate was not formed when the solution was isotonic (containing 0.33 M sorbitol) and the chloroplasts remained intact, but product was formed at a rate of approximately 2 μmol per mg chlorophyll per h when sorbitol was omitted and the chloroplasts were broken. These results not only confirmed that the phosphofructokinase was contained within the chloroplast, but also demonstrated an activity compatible with the amount of starch expected to be metabolised in chloroplasts. It is not inconceivable that chloroplast phosphofructokinase catalyses a regulatory step in the degradation of starch in the chloroplast. Efforts are now being made to separate and partially purify the chloroplast and cytoplasmic phosphofructokinases from leaves with a view to relating their regulatory properties to the carbon metabolism of photosynthesis. Initial results are encouraging.

Localisation of plasma α₂HS glycoprotein in mineralising human bone

THE protein of the organic matrix of bone consists mainly of collagen in association with a small proportion of non-collagenous proteins. When bone is decalcified, much of the non-

collagenous protein can be solubilised in conditions of neutral *p*H but the collagen remains insoluble. Extracts of decalcified bone prepared in this manner contain small amounts of plasma proteins which derive in part from the presence of blood vessels within the tissue[1,2]. There is evidence, however, that some plasma proteins, including albumin, form an integral part of the calcified matrix[3]. When ^{14}C-glucosamine or ^{14}C-glucosamine-labelled rabbit total plasma protein is injected into a rabbit, some activity is incorporated into the bone[4]. Using the procedure of Herring[5] to separate the EDTA-soluble proteins of the bone matrix, most of the activity was shown to be present in the less acidic glycoprotein fraction, much of this in one glycoprotein which was also present as a minor component of blood[4]. This G2B glycoprotein had the electrophoretic mobility of an α globulin and a molecular weight by SDS gel electrophoresis[6] of about 50,000. Studies by Ashton *et al.* (private communication) support the view that the G2B glycoprotein they have investigated in rabbit[4] and bovine bone[6] is the analogue of human α₂HS glycoprotein.

In this report we provide evidence by immunoprecipitation and passive haemagglutination techniques that α₂HS glycoprotein (an α globulin of estimated molecular weight 49,000 by ultracentrifugal analysis[10] present in human plasma at a concentration of about 60 mg dl^{-1}) is concentrated extravascularly in the matrix of normal human bone and can be located in areas of mineralisation in bone using an immunofluorescent antibody-staining technique.

The non-collagenous proteins of normal adult human cortical bone were isolated by sequential extraction of the powdered bone with 0.5 M EDTA at *p*H 7.6. The concentrated extract, dialysed free of mineral salts, and human plasma each gave a single precipitin line of complete identity when they were diffused against the antiserum to plasma α₂HS glycoprotein. The antiserum used in these studies was raised in rabbits against human plasma α₂HS glycoprotein and was specific for the latter, as judged by immunoelectrophoresis and double diffusion against plasma proteins. Tanned sheep erythrocytes, coated with the non-collagenous bone protein as described previously[1], agglutinated in the presence of antiserum to α₂HS glycoprotein but not with antisera to two other human plasma α globulins, α₁ antitrypsin and α₂ macroglobulin (Table 1). The latter two proteins are present in plasma at concentrations approximately three times higher than α₂HS glycoprotein in normal individuals. This suggested that the identification of only the latter protein in bone in these conditions did not derive from the presence of blood within the tissue. The antisera to the three α globulins were each adsorbed with lyophilised bone protein and then incubated with human plasma protein-coated tanned sheep erythrocytes. These preparations had negligible effect (Table 1) on the haemagglutination titres of two of the antisera but the activity of that against α₂HS glycoprotein was destroyed. By radial immunodiffusion in an agarose gel containing antibody, the concentration of α₂HS
Fig. 1 Longitudinal 6 μm thick sections of femur. Frozen sections were fixed for 5 min in formaldehyde as described previously[8]. Sections were then washed in phosphate-buffered saline (PBS) for 30 min. *a*, Stained with von Kossa's reagent and counterstained with haematoxylin and chromotrope. A band of brown/black staining (arrows) in the periosteum (P) overlays staining for calcium in the hypertrophic cartilage which is either heavily ossified (H) or partially ossified (O). *b–d*, Immunohistochemical localisation of α_2HS glycoprotein. Sites of binding of rabbit antibody Fab' to α_2HS glycoprotein in tissue sections were detected by subsequently using fluorescein isothiocyanate-labelled pig antibody Fab' directed against rabbit Fab'. Thus sections were initially treated with pepsin digests (at 1.6 mg ml⁻¹) of 33% (NH₄)₂SO₄ immunoglobulin G-rich fractions isolated from the antiserum to α_2HS glycoprotein (*b* and *c*) or non-immune rabbit serum (control); *d*, as described previously[9]. Sections were washed in PBS and finally stained with Fab' isolated from a pig antiserum to rabbit Fab', and labelled with fluorescein isothiocyanate at a concentration of 2 mg ml⁻¹. Sections were finally washed, mounted and examined (for details see ref. 9). *b* and *c*, Intense green extracellular fluorescence can be seen in the calcified band in the periosteum (arrows) and in the heavily ossified sites in the shaft (H) is magnified region of *b*. Less intense staining is present in sites of partial ossification (O). *d*, No intense green fluorescence was detected and only weak non-specific cellular staining was seen. Comparable sites are indicated as in *b* and *c*. Scales: *a* and *b*, 50 μm; *c* and *d*, 20 μm.

glycoprotein was estimated as 0.1% of the organic matrix of bone.

To establish whether the protein was incorporated into bone during the process of mineralisation, attempts were made to localise the protein by immunohistochemical techniques. The tissue used was the femur of a human foetus aged approximately 12 weeks (obtained after a therapeutic abortion). The femur was placed in a solution of 7% gelatin and 0.09% NaCl at 30 °C and then rapidly frozen in liquid nitrogen before final storage at −20 °C. Frozen sections were fixed and then incubated with a pepsin digest of either rabbit anti-(human α_2HS glycoprotein) immunoglobulin G or a rabbit non-immune globulin as control, and then with the fluorescein-labelled Fab' fragment of a pig antibody to rabbit immunoglobulin G Fab'.

Some sections were fixed and stained by von Kossa's method for calcium, being counterstained with haematoxylin and chromotrope. Staining for calcium revealed a broad band of calcification in the periosteum adjacent to the hypertrophic cartilage of the shaft (Fig. 1*a*). There was also extensive calcification within the shaft and early signs of calcification in the hypertrophic cartilage. Wherever extracellular calcium was detected we observed very intense green fluorescent staining in sections which had been initially treated with the digest of the immune globulin (Fig. 1*b* and *c*). The intensity of this immunohistochemical staining was greatest where staining with von Kossa's reagent was most concentrated. Sections which had been treated with the control non-immune immunoglobulin digest showed almost no staining associated with extracellular

Table 1 Haemagglutination titres of various antisera against three plasma α globulins

| Protein | Plasma concentration | Reciprocal heamagglutination titre | | |
| | | Bone protein-coated cells | Serum protein-coated cells | |
			Control	Adsorbed
α_2 macroglobulin	180 mg dl⁻¹	<4	2048	1024
α_1 antitrypsin	150 mg dl⁻¹	<4	512	512
α_2 HS glycoprotein	60 mg dl⁻¹	512	128	<4

*Average concentrations in adult human plasma of three α globulins. Antisera against those proteins were incubated with tanned sheep erythrocytes coated with human bone proteins; only antiserum against α_2HS glycoprotein caused haemagglutination. If these antisera were first absorbed with protein this inhibited the capacity of the antiserum against α_2HS glycoprotein to haemagglutinate tanned sheep erythrocytes coated with either bone protein (not shown) or serum protein compared with the non-adsorbed antiserum control.

sites, including those where calcification had taken or was taking place (Fig. 1d). These control specimens did exhibit a very low level of non-specific green fluorescent cellular staining of the kind also seen in the test sections.

These results show therefore that a plasma protein, α_2HS glycoprotein, is a constituent of both foetal and adult human bone matrix and is incorporated and concentrated into bone presumably through interactions with one of the other components of the mineralising matrix. The function of this protein in bone tissue has not yet been established but it has been observed[7] that human plasma α_2HS glycoprotein possesses opsonic properties, as demonstrated by its capacity to promote increased phagocytosis of *Staphylococcus aureus* and *Escherichia coli* by human neutrophils *in vitro*. This would account for our own observations that plasma levels of α_2HS glycoprotein, measured by radial immunodiffusion, fall markedly after various surgical procedures (I. R. D., unpublished); in the case of surgical damage to bone, plasma levels of this glycoprotein, corrected for plasma volume changes, fall to as little as half their pre-operative values. There is no evidence that this protein is present in areas where pre-osseous cartilage is degraded so that, if the opsonic property is utilised, it will most likely be in mediating the eventual resorption of the bone.

We thank Dr E. Kodicek for advice and support, and Dr C. Alper and Mr D. Evans for antisera. This work was supported in part by the NIH.

Propagation of human wart virus in tissue culture

HUMAN wart (papilloma) virus (HWV) is an authentic human tumour virus. Based on morphology, it has been classified as a member of the papova group[1] of animal tumour viruses. Using electron microscopy, HWV has been found to be associated with human skin warts[2], laryngeal and venereal papillomas[3,4] and epidermodysplasia verruciformis[5]. Moreover, experiments done with human volunteers at the beginning of this century[6-8], showed that filtered extracts of warts, laryngeal and venereal papillomas can cause skin warts in man. Since these early experiments, there has been little increase in our knowledge of HWV as a causative agent of either benign tumours or those which can progress to malignancy[5,9], mainly because of the lack of a system in which to propagate HWV *in vitro*[10]. This report describes the propagation of HWV in a tissue culture system.
Fig. 1 Isopycnic centrifugation of HWV grown in tissue culture. BE cells were infected with HWV that has been passaged in tissue culture 11 times. ^{3}H-thymidine (2 µCi ml^{-1}) was added to the culture fluid 2 h after infection. Rounded, detached cells along with culture medium were collected 5 d later; cells were disrupted by repeated freeze-thawing, clarified at 800 r.p.m., and virus was concentrated by centrifugation (SW27; 2 h, 25,000 r.p.m.). Resuspended viral pellet was centrifuged in CsCl (ρ 1.32 g cm^{-3}) in an SW50 rotor for 72 h at 40,000 r.p.m.; fractions were collected from the bottom of the tube. Gradient density was determined by measuring refractive index of various fractions.

HWV is epitheliotropic. It infects epidermal cells, a wart probably being a clone of transformed descendants[11] of a single infected cell. Virus progeny are produced in epithelial cells *in vivo*[2]. Our first choice was, therefore, to select a human epithelioid cell strain in which to attempt virus propagation *in vitro*. We have used a cell strain established by Dr M. Bean (Bean epithelial, BE) which, to our knowledge, is unique, as no other epithelioid cell strains have been established from human skin.

Virus was obtained from surgically removed samples of human skin warts, collected in tissue culture medium, incubated at 37 °C for 27 h, and either stored at -80 °C or used immediately. Pooled samples of wart tissue were minced and homogenised with carborundum with a mortar and pestle. Suspensions (10% w/v) were prepared according to a procedure described by Pass and Marcus[12].

To infect BE cells successfully *in vitro*, it was necessary to use cells in the logarithmic phase of growth and to allow the virus to absorb to the cells at low pH (6.5), and then to stress the cells by raising the pH rapidly to an alkaline level (8.0), after which the pH was allowed to fall slowly in a CO_2 incubator to pH 7.0-7.2. Alkaline pH stress was repeated 24 h after infection, and the HWV was thus successfully passaged 14 times in series. Unless cells were treated each time with these three successive pH stresses, serial passage of HWV with cytopathic effect (CPE) failed. The following changes were considered to constitute CPE. At 4-5 d after infection many rounded cells appeared which, in stained preparations, were seen to have intranuclear inclusions accompanied by nuclear vacuolisation. Infected cultures at this time also contained many clear areas surrounded by rounded cells that could be shown by immunofluorescence to contain viral antigens. Rounded cells eventually became detached and died; however, even with continued incubation for 3-4 weeks, only about 50% of the adjacent flattened cells showed similar changes. When the rounded cells were shaken off and examined by indirect immunofluorescence, using hyperimmune rabbit antisera prepared against virus purified from human warts, 90% showed positive nuclear fluorescence. When the remaining attached cells were removed with trypsin and similarly examined, 2-4% were positive. Mock-infected controls treated

in parallel with infected cultures showed neither cytopathic changes nor positive fluorescence.

As progression of the cytopathic changes to complete destruction of all cells in the culture was not observed, a titration method depending on a 50% dilution endpoint could not be relied on. In neutralisation tests carried out with undiluted tissue culture virus, however, cytopathic changes were never found when the tissue culture virus was pretreated with hyperimmune rabbit serum prepared against wart virus isolated from human tissues, or wart virus grown in tissue culture, and some human sera from patients with warts. The cytopathic changes were, however, always observed when tissue culture
Fig. 2 Electron micrographs of HWV stained with sodium phosphotungstate, *p*H 7.0. *a*, Tissue culture virus from passage 7 (10^7 particles ml^{-1} concentrated from 400 ml supernatant). ×102,600. *b*, Virus extracted from human warts (10^{13} virus particles ml^{-1}). ×102,600. Both represent virions that were banded in CsCl gradient at a density of 1.33 g cm^{-3}. BE tissue culture cells were always infected as a suspension, originally with 10% (w/v) extract of pooled human skin warts (5×10^5 cells were infected with 0.5 ml virus suspension containing 5×10^{12} virus particles). After 2 h incubation and *p*H stress, the cells were plated in a 60 ml Petri dish and 4.5 ml of medium added. As cytopathic changes occurred at first rather rapidly, the cells and supernatant were collected after only 5 d. Cells suspended in the supernatant were freeze–thawed three times and then pelleted at 800 r.p.m. for 10 min. The pellet was hand-homogenised in 1 ml original supernatant and the whole sample was centrifuged at 800 r.p.m. for 10 min to remove debris. Final supernatant was then considered as virus stock at passage 0. (The original inoculum was therefore diluted 1:10 and if no virus was lost, its concentration could be 5×10^{11} ml^{-1}.) Fresh cells were treated in the same way as before (but 2 ml of virus stock used for 1×10^6 cells) and the cells plated into 20 ounce plastic bottles diluting the cells in 20 ml medium. Many rounded cells appeared first after 5 d, when the medium was withdrawn and replaced with 20 ml fresh medium. Cultures were then incubated until more pronounced cytopathic changes were observed (up to 16 d) when they were processed as described for passage 0. The supernatant removed after 5 d was not used for further passage in this set of experiments. The procedure was then repeated at each virus passage. (Each virus passage therefore involves a 1:200 dilution factor. Thus, the original inoculum can be expected to be diluted out by passage 5–6.)
Fig. 3 Double immunodiffusion in 0.7% agarose gel. The centre well (C) contains purified HWV isolated from human wart tissue. The peripheral wells 1, 2, 3 and 4 contain rabbit antisera after two, three and four immunisations, respectively, with purified HWV isolated from the wart tissue. Well 5 was filled with rabbit antiserum after three immunisations with purified HWV grown in tissue culture. Purified viral pellet was resuspended in a small volume of Tris–EDTA buffer, *p*H 7.4, and sonicated for 60 s with a Biosonic sonicator. This was used as antigen for immunodiffusion studies. Rabbits were immunised with purified virus, emulsified in an equal volume of complete Freund's adjuvant and given subcutaneously in multiple sites. Four weeks later, the same amount of antigen in incomplete Freund's adjuvant was similarly injected. Subsequent immunisations were started 3 weeks later and given intravenously at 10 d intervals.

virus was similarly treated with foetal calf serum, preimmune rabbit sera, or sera from healthy blood donors.

To show that the virus was actively multiplying in culture and was not merely being carried along passively from culture to culture, we attempted to demonstrate incorporation of ³H-thymidine into newly formed virions (Fig. 1).

Density gradient centrifugation of labelled virions in a CsCl gradient resulted in a split peak of radioactivity at buoyant density approximately 1.31 and 1.33 g cm^{-3} as well as another peak at a density of 1.39 g cm^{-3}. The 1.31–1.33 peak contained typical wart virus particles (Fig. 2*a*), whereas no virus was found in the peak corresponding to $\rho = 1.39$ g cm^{-3}. Interestingly, the later peak contained mainly hexagonal structures with a dense interior, suggesting that they may represent viral cores. Heavier material sedimenting to the bottom of the tube remains to be investigated.

Gradient centrifugation of unlabelled virions, derived from tissue culture as well as from human wart extracts, usually showed three visible bands, two at the above described densities and a third at a density of approximately 1.29 g cm^{-3} which contains mainly empty particles. These findings are consistent with the observations of Pass and Maizel[13] who found three visible viral bands at similar densities in virus preparations made from human plantar warts.

The tissue culture grown virus was identified as HWV by morphological and immunological analyses. The particles shown in Fig. 2*a* are identical in size and morphology to those of the viruses isolated from human warts (Fig. 2*b*). The average diameter of these two groups of particles is 532 Å, a value which is larger than the size (430 Å) of the polyoma SV40 group of papovaviruses. Thus, by virtue of its larger size[14,15], the particles observed in this study may be distinguished from SV40 viruses.

Antisera made against the virus isolated from human warts, as well as antisera made against the virus propagated in tissue culture, gave a line of identity in immunodiffusion when reacted against purified virus from human warts (Fig. 3). Similar results were obtained with virus grown in tissue culture.

A second line of precipitation was occasionally seen in these immunodiffusion tests. None of these sera, however, reacted with SV40 viral antigens. Lack of cross-reactivity was also seen by immunofluorescence when SV40 infected cells were tested against anti-HWV serum and vice versa.

These observations strongly suggest that HWV has been propagated in tissue culture. This study may provide means for: further studies on the identity of viruses causing human warts, venereal warts and laryngeal papillomas[16,17]; and comparing the properties of HWV with those of other human papovavirus isolates[18-20]. Moreover, as warts are common complications in patients with primary and secondary immuno-deficiencies and in patients under immunosuppression[21], we believe that a system for the study of HWV *in vitro* may provide tools for the study of immune mechanisms responsible for the defence against virally-induced tumour in man.

We thank Drs N. Orentreich and B. Safai for human wart tissue, Dr T. Takahashi for help with immunodiffusion, and Drs F. Kingsley Sanders, P. Gomatos and C. Lopez for discussions and critical reading of the manuscript. This research was supported by the US Public Health Service and the National Cancer Institute.

Persistence of viral DNA in human cell cultures infected with human papilloma virus

THE human papilloma (wart) virus produces a transmissible, benign neoplastic disease which is self-limiting and often regresses. Although rare, papillomas containing papovavirus-like particles may undergo malignant transformation. Papil-lomas in epidermodysplasia verruciformis and condyloma acuminatum can become neoplastic[1-4]. Reports of the wart virus replicating in or transforming cells in culture, however, have not been substantiated[5-7]. Butel was unable to demon-strate cytopathic effect, the production of viral antigens or virus replication using a variety of cell lines and culture tech-niques[8]. Mild stimulation of cellular DNA synthesis, however, was observed in contact-inhibited embryonic human kidney cells after infection[8]. We also have been able to induce cellular DNA synthesis in confluent monolayers of a cell line derived from foetal human foreskin (NHP cells) following infection by wart virus.

Induction of DNA synthesis by papovaviruses may be essential for integration of viral DNA[9-12] and thus it is possible that during induction of cellular DNA synthesis by the wart virus, viral DNA was integrated into host DNA. Such genetic
Fig. 1 Induction of cellular DNA synthesis by the human wart virus. Monolayers of NHP cells were grown in 15×60 mm dishes in Eagle's medium containing 10% foetal calf serum at 36 °C. When cell cultures were confluent, the temperature was decreased to 33 °C for 12 h. Duplicate cultures were washed with medium and either infected with 0.2 ml virus or overlaid with 0.2 ml medium for 1.5 h at 33 °C. Cultures were then overlaid with 5 ml medium containing 2% foetal calf serum and maintained at 33 °C. At various times after infection, cultures were labelled for 3 h with 1.0 ml Eagle's medium con-taining 5% dialysed horse serum and 10 μCi ml^{-1} ^{3}H-thymidine (6.7 Ci $mmol^{-1}$, New England Nuclear) followed by a 1 h chase with Eagle's medium containing 10% calf serum. Plates were washed twice with cold phosphate-buffered saline[15], cells lysed and fractions separated according to the procedure of Hirt[16]. Hirt pellets and a portion of the Hirt supernatant fluid were made 1 N with 10 N NaOH and incubated for 60 min at 50 °C. Triplicate samples (0.025 ml) were spotted on filter paper disks (Schleicher and Schuell, 740E) and treated for TCA-precipitable materials using a batch technique[17]. Filter paper disks were counted in toluene scintillation fluid. ○——○, Infected pellet; ○– – –○, infected supernatant; ●——●, control pellet; ●– – –●, control supernatant.

information was detected using wart viral DNA labelled *in vitro* as a probe in DNA-DNA hybridisation studies. We found wart viral DNA persisting in cells 11 months after infection.

Virus was isolated from 5 g tissue homogenised in a Virtis at 45,000 r.p.m. at 4 °C for 30 min in 10 mM Tris-HCl, pH 7.4, 1 mM EDTA, 100 mM NaCl followed by a second homo-genisation (10,000 r.p.m., 4 °C, 5 min) in an equal volume of 1,1,2-trichlorotrifluoroethane[13] (freon). The aqueous phase containing virus was separated from the freon phase and virus pelleted at $54,000g$ for 4 h at 4 °C. Pellets were suspended in CsCl ($\rho = 1.33$ g ml^{-1} in 20 mM Tris-HCl, pH 7.5, 1 mM EDTA) and centrifuged to equilibrium at 35,000 r.p.m. at 25 °C in the SW50 rotor. DNA was isolated following rupture of virions with 1% sodium dodecyl sulphate (50 °C, 15 min) and by extraction with phenol. DNA was precipitated with ethanol and supercoiled molecules isolated by CsCl-EtBr equilibrium centrifugation[14].

Induction of cellular DNA synthesis by the wart virus is shown in Fig. 1. Twenty-four hours after infection there was a

Table 1 Summary of the reassociation of ^{32}P-labelled wart viral DNA in the presence of unlabelled cellular DNA

Experiment	DNA source	Cellular DNA (mg ml⁻¹)	^{32}P-wart DNA (ng ml⁻¹)	Factor of increased rate*	No. of unlabelled viral genome equivalents per diploid cell†
1	NHP	1.6	0.8	—	—

*Increased rate relative to reassociation of ^{32}P-viral DNA in presence of control cellular DNA.
†Calculated by the method of Gelb *et al.*[25].

t
wofold increase in the amount of ^{3}H-thymidine incorporated into Hirt pellets of infected cultures compared with mock-infected controls, followed by a decrease to control levels by 32.5 h. Similar stimulation was observed in Hirt supernatant fluids. Examination of infected supernatant fluids in CsCl–EtBr equilibrium gradients and by CsCl velocity centrifugation, however, revealed neither superhelical DNA nor DNA with sedimentation rates expected for wart viral DNA.

DNA–DNA reassociation was used to show the presence of viral DNA sequences in infected cells which had been maintained in culture for several months. Cellular DNA was partially purified by the method of Meinke *et al.*[17] and was subsequently treated with RNase (13 μg ml⁻¹, 37 °C, 30 min), then Pronase (25 μg ml⁻¹, 37 °C, 30 min) and phenol extracted. Cellular DNA was then sheared to an average single-stranded piece size of 560 nucleotides[18].

To label wart viral DNA *in vitro*, DNA was first nicked with pancreatic DNase I at a ratio of 1,000:1 (w/w) in 50 mM

Tris-HCl, pH 7.4, 50 mM KCl, 5 mM MgCl₂ for 20 min at 37°C. DNase was inactivated by heating solutions to 70 °C for 10 min. Nicked DNA was labelled in conditions of repair synthesis with *Escherichia coli* DNA polymerase I (refs 19 and 20). Specific activities of ^{32}P-TTP and ^{32}P-TTP + ^{32}P-dATP-labelled DNAs were 1.95×10^7 and 4.85×10^7 c.p.m. per μg DNA, respectively. Labelled DNAs had sedimentation rates in alkaline sucrose gradients of 5.9 and 6.3S. Sedimentation rates did not change during experiments. Reannealing of denatured labelled DNAs were at rates expected for viral DNAs with piece sizes as described[21]. ^{32}P-viral DNA reassociated to 90% in the presence of fivefold excess of nicked unlabelled wart DNA. SV40 and wart DNA have the same guanine+cytosine content (41%)[22,23] and *in vitro* labelled wart DNA had a similar T_m (86.0 °C), as determined by hydroxyapatite chromatography[18], as did *in vivo* labelled SV40 DNA (86.6° C).

The kinetics of DNA–DNA reassociation follows the
Fig. 2 Reassociation of ^{32}P-labelled wart DNA in the presence of unlabelled DNA from infected NHP cells, mock-infected NHP cells or *B. subtilis* Nicked viral DNA (1 μg) was suspended in a volume of 1.0 ml containing 66 μmol potassium phosphate, pH 7.4, 6.6 μmol MgCl₂, 1 μmol β-mercaptoethanol, 0.05 μmol each of dATP, dGTP, dCTP, and 2 mCi ^{32}P-TTP (114.8 Ci mmol⁻¹) or 0.05 μmol each of dGTP and dCTP with 2 mCi each ^{32}P-TTP and ^{32}P-dATP (118.0 Ci mmol⁻¹, New England Nuclear). DNA repair synthesis was initiated by addition of 20 units *E. coli* DNA polymerase I (Grand Island Biological) for 75 min at 15°C and terminated with 1% Sarkosyl. Labelled DNA was separated from low molecular weight material by chromatography on Sephadex G-50 equilibrated with 0.1% Sarkosyl, 20 mM Tris-HCl, pH 8.0, 1 mM EDTA and deproteinated by phenol extraction. Solutions of cellular DNA (1.6 mg ml⁻¹) and ^{32}P-labelled viral DNA (0.8 ng ml⁻¹) were denatured in 0.48 M sodium phosphate, pH 6.8, 0.05% SDS, 0.001 M EDTA at 109 °C for 5 min in screw-capped tubes. Solutions of single-stranded DNA were then allowed to reassociate at 64 °C. At various times samples were removed and diluted to 2.0 ml in 0.14 M sodium phosphate, pH 6.8, 0.05% SDS. Single-stranded DNA was separated from reassociated double-stranded DNA by hydroxyapatite column chromatography (10 × 15 mm) at 60 °C[24]. Single-stranded DNA was eluted from the column with five 2.0 ml washes of 0.14 M sodium phosphate, pH 6.8, 0.05% SDS; reassociated double-stranded DNA eluted with four 2.0 ml washes of 0.48 M sodium phosphate, pH 6.8, 0.05% SDS. Radioactivity was determined for each wash by addition of 15 ml toluene–Triton X-100 (2:1 v/v) scintillation fluid containing Cab-O-Sil (Packard). ○, Mock-infected NHP cellular DNA; □, infected NHP cellular DNA; ●, *B. subtilis* DNA; △, *B. subtilis* DNA with 4.0 ng ml⁻¹ unlabelled nicked wart viral DNA. Each point represents about 500 c.p.m.

equation $C/C_0=1/(1+KC_0t)^4$ (ref. 24); C_0 is the total ^{32}P-viral DNA concentration, C is the concentration of single-stranded ^{32}P-viral DNA, t is time, and K is the reassociation constant. A plot of C_0/C against t results in a straight line with the slope proportional to C_0. The rates of reassociation of ^{32}P-labelled wart DNA in the presence of either *Bacillus subtilis* DNA or mock-infected NHP cellular DNA were very similar, indicating that there is no homology between NHP cellular DNA and wart viral DNA (Fig. 2). Addition of 4.0 ng ml^{-1} unlabelled nicked wart DNA (2.0 copies viral DNA per diploid cell) to a solution of ^{32}P-labelled wart DNA (0.8 ng ml^{-1}) and *B. subtilis* DNA increased the rate of reassociation of ^{32}P-labelled wart DNA by a factor of 6.7, which is in agreement with the expected value of 6.0. When denatured ^{32}P-labelled viral DNA was allowed to reassociate in the presence of DNA derived from infected NHP cells, the rate of reassociation was 1.4 times greater than controls. In another experiment, control cellular DNAs consisted of salmon sperm, human lung (Wi38) and NHP. The rate of reassociation of ^{32}P-labelled wart DNA was similar in each instance. The rate of reannealing of ^{32}P-labelled viral DNA in the presence of infected NHP cellular DNA, however, was twofold greater than controls. Interestingly, no wart viral DNA sequences could be detected in Wi38 cells infected in the same manner as NHP cells. The results are summarised in Table 1. The increases in the reassociation rates correspond to 0.18 wart viral genome equivalents per infected NHP cell.

The increase in the reassociation rate could not be the result of the presence of virus inoculum as input virus would have been diluted beyond detection by cell replication by the methods used. Cells used in these experiments had undergone 15 to 60 doublings after infection. The maximum possible multiplicity of infection as determined by particle counts was about 100 virions per cell. After 15 doublings, there would only be 0.003 viral genome equivalents per cell, which is well below the values detected. The stable persistence of viral genetic information in infected cells must, therefore, be the result of replication of viral DNA sequences which may be integrated into the host genome.

As infected NHP cells were not cloned, detection of 0.18 wart viral genome equivalents per diploid cell indicates that each cell contains a portion of the viral genome or that only some cells carry a complete genome. It is possible that cells carrying the viral DNA have no selective advantage over that of uninfected cells in the culture and thus remain in relatively low numbers.

SV40 DNA can persist in abortively transformed mouse cells[26] and recently, it was shown that SV40 DNA injected into the blastocoel of mouse blastocysts resulted in persistence of SV40 DNA sequences through subsequent maturation to adult mice[20]. Our results indicate a similar situation may exist for the human wart virus in that there is a persistence of wart gene sequences in infected NHP cells.

As the human wart virus is the only known tumour agent of man, it is of interest that wart viral DNA can persist in a cryptic state in infected NHP cells *in vitro*. Although cells seem to be normal with respect to growth and morphology the possibility exists that under proper conditions the latent viral DNA sequences could become 'derepressed' and induce cell growth characteristic of transformed cells. These results would indicate that the ubiquitous human wart virus should be given serious consideration as a possible agent of neoplastic disease in man.

Effect of bromodeoxyuridine on redundancy of ribosomal RNA cistrons of *Drosophila virilis*

THERE have been numerous demonstrations that the thymidine analogue, 5-bromodeoxyuridine (BrdU), can affect the progress of cellular events in eukaryotes It has been suggested that the incorporation of the base analogue changes the secondary structure of DNA and/or chromatin recognition sites[1-3]. Support for this view has come from studies which have shown a BrdU substitution effect on the physical properties of isolated chromatin[4,5] and alterations in the patterns of RNA transcription[6-9]. In some instances, a correlation between the onset of DNA synthesis and the effect of BrdU has been observed[1,3]. In addition, several studies have shown that the drug can alter the process of DNA replication[8,10,11]. Thus, it has been argued that changes in the replication of DNA may precede or lead directly to the expression of BrdU sensitivity

We have initiated a study of the influence of BrdU on the redundancy of the ribosomal RNA (rRNA) cistrons of *Drosophila*. The rDNAs have been localised to the nucleolus organiser regions of the *Drosophila* karyotype[12], and can be manipulated genetically. The redundancy of the rRNA cistrons can be measured by hybridisation techniques and evidence of mechanisms which control both the replication[13] and transcription[14,15] of these sequences has been presented. Thus, the interaction of transcriptional and replicational influences of BrdU can be examined with regard to the behaviour of a single DNA sequence. In this report we describe an effect of BrdU on the redundancy of rRNA cistrons of *D. virilis*. *D. virilis* was chosen because a substantial portion of the diploid genome contains A–T-rich redundant sequences. These sequences have been localised to the heterochromatic regions of the *D. virilis* karyotype[16] which also contain the rRNA cistrons It was argued that A–T-rich regions may preferentially incorporate BrdU

BrdU was added to the medium of *D. virilis* larvae on days 5 and 7 after the parental adults had been placed on the food The redundancy of the rRNA cistrons in DNA from the BrdU-treated larval material did not differ significantly from that of the untreated larval control populations (Table 1, experiment 1) When drug-treated larvae from this experimental population were reared to the adult stage, however, a substantially smaller fraction of the DNA hybridised with rRNA compared with controls. Note that the rRNA cistron redundancy is repeatedly

Fig. 1 Thermal stability of ^{3}H-rRNA–DNA hybrids. Denatured DNA from *D. melanogaster*, *D. virilis*, and BrdU-treated *D. virilis* (days 5 and 7, experiment 1, Table 1) adults was loaded on to filters and the hybridisation reactions performed as described in the legend to Table 1. After RNase treatments the filters were washed and placed in glass vials with 3 ml 1 × SSC and incubated in a water bath. Starting at 45 °C, the temperature was raised in 5° increments and maintained for 5 min before removing the solution and replacing it with fresh SSC at the same temperature. Counts released from the filters were determined using Aquasol (New England Nuclear). *D. melanogaster* ^{3}H-rRNA hybrids formed with *D. melanogaster* DNA (△); *D. virilis* adult DNA (●); BrdU-treated (days 5 and 7) *D. virilis* adults (○).

found to be lower in DNA from larval tissues than DNA from adult tissues of *D. virilis*. Similar results have been reported for other species of *Drosophila*[21]. The observation was anticipated because the rDNAs are underreplicated in polytene cells[7,13], and these cells are most prominent in the larval stages.

When the experiments were repeated, two populations were established for drug treatment. In one case, drug was spread on the food on days 5 and 7 after the parental adults began egg laying, as in the previous experiment. Drug was administered to the second group on days 2 and 5, after egg laying had indicated whether the BrdU effect was limited to the postlarval stages. The results obtained from treatments on days 5 and 7 (Table 1, experiment 2) agree with those of experiment 1. There was no substantial difference in rDNA content between larval BrdU-treated and control DNAs, but a significant decrease in the rDNAs from treatments on days 5 and 7 (Table 1, experiment 2) difference in rDNA content between larval BrdU-treated ments 1 and 2 probably reflects variations in the number of larvae grown on the food and the time over which the drug was available to the larvae. DNA extracted from larvae treated with BrdU on days 2 and 5 (Table 1) contained significantly lower rDNA redundancy (18%) than control larvae. DNA from the adults of this population, however, showed about one-half the effect (~9%) compared with DNA from untreated adults. Thus, BrdU influences the redundancy of the rRNA cistrons in both

adult and larval tissues. In the conditions used, however, the effect, if prominent in larval material, was not entirely sustained into the adult tissues.

Note that we have made no effort to screen for any of the development aberrations reported by other workers using BrdU on developing *Drosophila* systems[17,18]. BrdU-treated adults are not phenotypically bobbed The major gross effect of our BrdU treatments on larvae is an increase in the time required to reach adult eclosure. Viability, fertility, and sex ratios of eclosing BrdU-treated adults are not significantly affected by these experimental conditions (D. Durica and H.M.K., unpublished).

Two controls were performed with regard to the artefacts which BrdU might cause in the measurement of hybrids in our heterologous DNA–RNA reactions. In the first, the thermal stability of the hybrids formed between *D. melanogaster* ^{3}H-rRNA and DNA from BrdU-treated and control *D. virilis* adults was compared with homologous *D. melanogaster* hybrids. A typical melting profile from each type of hybrid is presented in Fig. 1, which shows that the thermal stability of the heterologous hybrid is comparable with the stability of homologous *D melanogaster* DNA–RNA complexes. Furthermore, the DNA from BrdU-treated material formed hybrids of comparable quality to those formed by the other DNAs. These thermal stability studies, however, were performed on RNase-resistant hybrids. Thus, it might be argued that BrdU and control *D. virilis* DNAs have the same number of rRNA cistrons, but the hybrids formed by DNAs from BrdU-treated material are more sensitive to RNase. To examine this possibility, the radioactivity (^{3}H) associated with filters was determined before and after RNase treatment for DNAs from BrdU-treated adults (Table 1, experiment 2) and controls. There was no difference in RNase sensitivity of the DNA–RNA hybrids formed by these DNA samples. Thus, the hybrids formed by DNA from BrdU-treated material seem to be neither less stable nor more

Table 1 Hybridisation of *D. melanogaster* ^{3}H-rRNA to DNA of BrdU-treated *D. virilis*

| | Day of BrdU addition | % DNA in hybrid | | % Change |
		Experiment 1	Experiment 2	
Larval	2 and 5	—	0.290	18.3
	5 and 7	0.356	0.351	0–1.1
	Control	0.355	0.355	—
Adult	2 and 5	—	0.352	9.5
	5 and 7	0.212	0.271	45 5–30.3
	Control	0.389	0.389	—

D. virilis were grown on standard corn meal, agar, and sucrose media at 22 °C in half-pint bottles. Adults were placed on fresh media for 24 h, the bottles were then cleared, and at various times 2 ml 10^{-3} M BrdU solution (Sigma) were spread on top of the media. This concentration and means of application was chosen on the basis of other BrdU studies in developing *Drosophila* tissues[17,18], and some preliminary observation communicated by Juan Valencia (University of Wisconsin, Madison). Larvae in the third instar were collected by flotation away from the food with 20% sucrose and washed extensively in distilled water. DNA extractions from larvae and adults were performed as described elsewhere[19]. Nitrocellulose filters loaded with about 20 μg denatured DNA were incubated for 12 h at 67 °C in 4 × SSC (1 × SSC is 0.15 M NaCl, 0.015 M sodium citrate), 0.1% sodium lauryl sulphate, and 3.75 μg ml⁻¹ (68,800 c p.m. μg⁻¹) ^{3}H-rRNA. ^{3}H-rRNA was prepared from *D. melanogaster* cell lines using the technique of Brown and Littna[20] (gift of Dr L. Weber, SUNY, Albany). The filters were washed with 2 × SSC, treated with 20 μg ml⁻¹ RNase A at 25 °C for 2 h, washed again with 2 × SSC, and counted in Liquifluor (New England Nuclear) after drying. Scintillants were removed from the filters by several washings with toluene and ether, and the filter-bound DNA was determined using the procedure of Kissane and Robbins[26]. All DNA preparations were tested in the same reaction vessel. A minimum of six measurements was made for each type of DNA. Untreated larval and adult DNA preparations were used as internal standards to compare hybridisations of experiments 1 and 2. Maximum s.e.; experiment 1, ±0.022; experiment 2, ±0.013.

RNase-sensitive than the hybrids formed by DNA from untreated tissues. Therefore, the differences measured in the hybridisation reactions must reflect changes in the redundancy of the rRNA cistrons associated with the presence of BrdU in the developing larvae.

We may only speculate as to the mechanism(s) which produce this BrdU effect. The redundancy of the rRNA cistrons seems to be subject to control. The number of rounds of DNA synthesis which the rDNA sequences undergo differs significantly from other nucleotide sequences in polytene chromosomes[7,13,22]. Further, the cells of *D. melanogaster* which bear a substantial deletion of the rDNAs when diploid, possess nearly wild-type levels of rRNA cistrons in polytene tissue[13]. In addition, alteration in rDNA redundancy of non-polytene cells can occur in *D. melanogaster*[23]. It has been suggested that such rDNA magnifications occur through unequal exchange events between sister chromatids before formation of meiocytes[24]. The presence of BrdU in developing larvae may affect any of the events normally associated with establishing and maintaining the redundancy of rRNA cistrons in polytene and diploid cells. To date we have no direct evidence that the BrdU effect described here is limited to particular tissues or cell types; nor is it clear that the effect is limited to rRNA cistrons. Preferential incorporation of BrdU into highly and intermediately repeated DNA sequences has been observed in tissue culture cells grown at low drug concentrations[6,25]. Such preferential incorporation may explain the specificity of the action of BrdU in this case, and further suggest that the A–T-rich redundant sequences which surround the rDNA may also be influenced by the drug. Experiments designed to examine some of these possibilities are in progress.

Inhibition of myogenesis in a rat myoblast line by 5-bromodeoxyuridine

5-BROMODEOXYURIDINE (BrdU) at very low concentrations inhibits the expression of cell or tissue-specific characteristics of several differentiating systems (for reviews see refs 1 and 2) including myoblasts[3-6], and was postulated to cause its anti-differentiation effects by being incorporated into DNA segments[2-6]. Available data show, however, that in some cell types, the primary effects of BrdU may be mediated by means other than its incorporation with the genome[7,8]. To determine whether template modification by BrdU *per se* is the cause of inhibition of myogenesis, we have investigated the reversal of inhibition by BrdU by various naturally occurring nucleosides, and show that deoxycytidine (and deoxyuridine) reverses the inhibition of myogenesis caused by BrdU without affecting its incorporation into cellular DNA. It seems likely, therefore, that template modification by BrdU may not be the sole cause of the inhibition of fusion of myoblasts brought about by this compound.

A clone, L6B, which was isolated from Yaffe's[9] rat skeletal muscle myoblast cell line, L6, and which was stable with regard to its fusion properties, was used throughout. Concentrations of BrdU higher than 1 μM during growth and division of the myoblasts completely abolish their differentiation into myotubes (Fig. 1). Below 1 μM BrdU has very little effect on myogenesis. As with the chick myoblasts[5] and other cell types[10], L6B cells reach confluence in the presence of 3.5–16 μM BrdU but are very much flattened. The doubling time and plating efficiency of L6B myoblasts remains unaltered at concentrations of BrdU which completely inhibit fusion (Fig. 1a). The inhibition of differentiation by BrdU is reversed
Fig. 1 Effect of BrdU and deoxycytidine on growth (a) and fusion (b) of myoblasts. a, About 10[5] cells of clone L6B were grown in 250 ml Falcon culture flasks in 20 ml Dulbecco modified Eagle's (DME) medium supplemented with 10% horse serum, 50 μg ml⁻¹ gentamycin and the nucleosides to be tested. The cells were incubated at 37 °C in an atmosphere of 10% CO_2 in air. The culture medium was replaced after the first day of plating and every 4th day thereafter. For growth measurement the cells were dissociated using 0.1% trypsin and counted in a haemocytometer b, To obtain the fusion index cells were plated in 6 cm diameter plastic tissue culture dishes at a density of 3.5×10[3] cells per cm² in 4 ml DME containing 10% horse serum and the required additives. At the indicated times, cells were washed with citrate saline, fixed with methanol, dried, and stained with Ehrlich's eosin–haemotoxylin. Fusion index was determined according to the procedure of Morris and Cole[17] by counting nuclei in single cells and myotubes in 32 fields (0.084 mm² per field) in early stages of fusion, and in 15–20 fields later A cell was scored as a myotube if it contained three or more nuclei within the same cell. ●, No additions; ○, 3.2 μM BrdU; ▲, 3 2 μM BrdU plus 400 μM deoxycytidine; △, 16 μM BrdU plus 400 μM deoxycytidine.
Fig. 2 Effect of nucleosides on the incorporation of BrdU in cells. L6B myoblasts (10⁶ cells) were grown for 3 d in 35 × 10 mm, 6-well Linbro dishes in 5 ml DME containing 10% horse serum. Cells were washed consecutively with phosphate-buffered saline and citrate saline and then exposed to 3 ml growth medium containing 3.2 µM (0.1 µCi) ^{14}C-BrdU (50.6 mCi mmol^{-1}) and other nucleosides at 37 °C. At the indicated intervals the cells were washed twice with saline and then treated for 15 min with 0.5 ml cold, 10% TCA. Cells were once again washed with saline to remove the TCA, dissolved in 0.5 ml 2 N NaOH, and counted. ○, BrdU alone; ●, BrdU plus 0.4 mM deoxycytidine; △, BrdU plus 1 µM thymidine; ▲, BrdU plus 2 µM thymidine.

to a large extent by the presence during growth of deoxy-cytidine, deoxyuridine or thymidine (Table 1).

Tested by themselves or together with BrdU at concentrations listed in Table 1, the nucleosides effective in restoring fusion do not cause any significant alterations in growth and plating efficiency of L6B myoblasts (Fig. 1a). Inhibition caused by higher concentrations of BrdU (16 µM) is also reversed by 400 µM deoxycytidine but the time required for maximal fusion is prolonged (Fig. 1b). Note that not only is the fusion potential of myoblasts restored in the presence of deoxycytidine, but the myotube-specific enzyme, creatine phosphokinase (CPK) also appears and increases in the fused myoblasts. As an example myoblasts in the presence of 3.2 µM BrdU show a specific activity (µmol product formed per min per mg protein) for CPK of less than 0.02, but in myotubes produced in the presence of BrdU and 400 µM deoxycytidine the specific activity rises to about 0.35.

The simplest way to explain the reversal by the nucleosides of BrdU-induced inhibition of differentiation is to assume that they inhibit the entry and subsequent incorporation with DNA of BrdU inside the cells. Steck et al.[11] have demonstrated that

Table 1 Effect of various nucleosides on myoblast differentiation in the presence of BrdU

Addition	Concentration (µM)	Fusion index
None	—	0 2
Deoxycytidine	4	21 ± 2
	40	46 ± 5
	400	46 ± 6
Deoxyuridine	33	31 ± 4
Thymidine	0.5	12 ± 2
	1	52 ± 5
Thymine	1	17 ± 3
Cytidine	400	19 ± 3
Uridine	400	1 ± 0.4
Guanine	400	5 ± 2
Adenine	400	4 ± 2

Cells of clone L6B were plated in the presence of 3 5 µM BrdU and the nucleoside to be tested. Fusion index was quantitated on day 10 after growth. Fusion index in the absence of BrdU was about 50. Details of experimental procedures are given in Fig. 1.

in various cultured cell lines uptake of any given nucleoside is inhibited by other heterologous nucleosides. In L6B myoblasts, however, only thymidine (but not thymine) inhibits the uptake of BrdU into the acid-insoluble material of the cell. We have ascertained that this material is probably DNA because treatment with DNase releases radioactivity in an acid-soluble form. Deoxycytidine (400 µM), however, has no effect on the uptake of BrdU (Fig. 2).

This suggests that thymidine and deoxycytidine reversal may occur through a pathway which is independent of the level of incorporation of BrdU in DNA. To investigate these possibilities further we carried out the following experiments. Myoblasts were grown for one to four generations (in different experiments) in the presence of 3.2 µM ^{14}C-BrdU, 3.2 µM ^{14}C-BrdU plus 1 µM cold thymidine, and 3.2 µM ^{14}C-BrdU plus 0.4 mM deoxycytidine. ^{14}C-BrdU (50.6 mCi mmol^{-1}) was used at a level of 1 µCi in each case. At the end of the required time the cells (about 10⁶) were collected using EDTA, and nuclei were isolated and lysed in 0.5% SDS as described previously[12]. The DNA was banded by centrifugation in neutral CsCl density gradients and the specific activities (sum of c.p.m. in each DNA-containing fraction divided by the sum of A_{260} of the same fractions) computed[12]. The DNA of control cultures (without BrdU or other additions) banded at a density of 1.703 g cm^{-3} and that of cells grown with BrdU (3.2 µM) for two generations at 1.708 g cm^{-3}. The amount of BrdU substitution of DNA was thus not more than 1–2% (ref. 13). The small amount of BrdU incorporated in our experimental conditions may be caused by the presence internally of sufficiently large pools of nucleotides in L6B myoblasts which interfere with the uptake or further metabolism of BrdU.

Whatever the reasons for the low incorporation of BrdU the significant finding was that the specific activity of DNA from cells grown in the presence of 3.2 µM BrdU in different experiments was approximately the same in myoblasts grown without (4.3 × 10⁴), or with 0.4 mM deoxycytidine (4.7 × 10⁴). We conclude that inhibition of fusion of myoblasts and reversal of this inhibition was not dependent on the substitution of thymidine residues in DNA by BrdU. A decrease in the level of BrdU incorporation in the presence of thymidine was found in our experiments (specific activity 3.2 × 10⁴) and was expected in view of the BrdU uptake experiments presented earlier (Fig. 2). It is likely that differentiation of myoblasts is restored in the presence of thymidine (Table 1) either because inhibitory amounts of BrdU are not able to accumulate inside the cells (see later) or thymidine itself is able to counteract, like deoxycytidine, the inhibitory effect of BrdU on the yet unidentified events leading to fusion.

If it is agreed that BrdU substitution in DNA is probably not the cause of inhibition of myogenesis, as the results at least with deoxycytidine show, what are the conceivable mechanisms for BrdU inhibition of fusion? We propose that BrdU in a phosphorylated form at low concentrations inhibits some of the glycosyltransferases of the myoblasts which are responsible for the biosynthesis of fusion-specific glycoproteins or glycolipids and this inhibition is reversed by several pyrimidines related to the sugar donors (UDP-glucose, CMP-N-acetylneuraminic acid, and so on) of macromolecular synthesis. In support of this proposal it may be stated that several nucleoside analogues, such as puromycin[14] and cytosine arabinoside[15] have been shown to inhibit some glycosyltransferases in mammalian cells. In addition, it has been reported[16] that chick embryo fibroblasts grown in the presence of BrdU become agglutinable by concanavalin A, which again suggests that alteration of sugar-containing macromolecules does occur in the presence of BrdU.

Reduction in sympathetic nervous activity as a mechanism for hypotensive effect of propranolol

THE β-adrenoceptor antagonist propranolol is an effective antihypertensive drug in man[1] but it is not known how the fall in blood pressure is produced[2]. There is a decrease in plasma renin activity[3] and in cardiac output immediately on starting propranolol therapy but neither of these effects can explain fully the hypotensive action of the drug which is delayed in onset and associated with a reduction in peripheral vascular resistance[4]. It has been suggested that the fall in blood pressure after propranolol results from blockade of β-like adrenoceptors within the central nervous system[5]. Thus, intracerebroventricular injection of propranolol lowers blood pressure in conscious cats[6] and rabbits[6], an effect which is specific for the β-blocking (—) isomer of the drug[7]. The effective concentration of propranolol achieved in the hypothalamus by this route of administration is within the range predicted for hypertensive patients after chronic oral therapy[8]. We now present direct evidence that propranolol diminishes sympathetic nerve activity in the rabbit and that this central effect contributes to the hypotensive action of the drug.

Electrodes were implanted in the greater splanchnic nerve of rabbits weighing 3–4 kg (ref. 9). After a recovery period of at least 4 d a catheter was inserted under local anaesthesia into the central artery of an ear and used for measurement of blood pressure. Another catheter was inserted into the marginal vein of the other ear for administration of drugs. Each conscious unrestrained animal was placed in an individual cage and left undisturbed for 1 h. Integrated splanchnic nerve activity and arterial pressure were then recorded continuously for a 3-h period. The first hour served for control observations. After these, intravenous infusion of one of four solutions was begun and continued at a rate of 3 ml h^{-1} for the remaining 2 h. The solutions used were saline, (±)-propranolol, (+)-propranolol and sodium nitroprusside, sufficient of each drug being dissolved in saline to enable an infusion rate of 1 mg kg^{-1} h^{-1}. Each treatment was given to eight animals. Splanchnic nerve

Table 1 Effect of intravenous (+)- and (±)-propranolol, sodium nitroprusside and saline on mean arterial pressure (MAP) and splanchnic nerve activity (SNA) in conscious rabbits

Infusion	No. of animals	First hour MAP	First hour SNA	Second hour MAP	Second hour SNA
Saline	8	97±2	111±5	99±3	104±16
(+)-Propranolol	8	101±2	122±17	99±4	132±24
(±)-Propranolol	8	94±3	68±11*	87±2†	52±9*
Sodium nitroprusside	8	74±1†	178±30*	73±2†	199±38*

Values are the mean ±s.e.m. of the average during one hour expressed as a percentage of the average during the hour pretreatment. Significant differences from saline control group: *$P < 0.05$; †$P < 0.01$ (Student's unpaired t test).
Fig. 1 Effect of (±)-propranolol infusion (1 mg kg^{-1} h^{-1} intravenously) on sympathetic nerve activity and arterial pressure in a conscious rabbit. *a*, Splanchnic nerve discharges as original oscilloscope records and as integrated activity over 6-s periods (*b*); *c*, arterial pressure (each record was taken at the end of the time period indicated); *d*, mean values of integrated splanchnic nerve activity per hour and of mean blood pressure measured over the complete hour by planimetry (*e*).

activity during each hour was summed by planimetry of the record, and the values during the infusion hours expressed as a percentage of that during the pretreatment hour. The systolic and diastolic arterial pressure traces were treated similarly except that the results were expressed in terms of mean arterial pressure, calculated as diastolic pressure plus one third of the pulse pressure.

Table 1 shows the effect of the four treatments on splanchnic nerve activity and mean arterial pressure. Neither saline nor (+)-propranolol, the non-β-blocking isomer of propranolol, altered these parameters significantly. Sodium nitroprusside, a vasodilator drug which relaxes vascular smooth muscle[10], reduced arterial pressure. An increase in preganglionic sympathetic nerve activity accompanied the fall in blood pressure, indicating that the preparation is sensitive enough to detect reflex changes which are the expected response to a peripherally mediated hypotension.

By contrast, a different pattern of response was seen with (±)-propranolol which decreased both blood pressure and splanchnic nerve discharges. Figure 1 shows the original record of such an experiment, illustrating the parallel fall in preganglionic sympathetic nerve activity and blood pressure during (±)-propranolol infusion.

As sympathetic nerve activity was recorded from a preganglionic nerve, the site of the sympatho-inhibitory action of propranolol must be in the central nervous system. The only other possible explanation—that the drug increases the sensitivity of the arterial baroreceptors—seems very unlikely. Therefore, we suggest that blockade of central β-adrenoceptors brings about a reduction in sympathetic nervous tone and that this action could explain the antihypertensive effect of propranolol.

reviews

Is research management really as boring as this book makes it sound? "Finally he should desirably exercise some flair which stamps his department with an identity, making it recognisable as a unit with a reputation for excellence", writes Mr White at the end of less than a page devoted to the attributes of a research leader. Flair is the ingredient conspicuously missing from what is really a rather expensive handbook of information for the research manager, long on lists of research laboratories but very short on convincing examples of either successful or mismanaged research.

Never has there been a greater need than now for a book on the effective management of an inherently labour-intensive activity. Never has there been greater need for advice on how to make maximum use of scientific talent, by example and inspiration, and by providing scientists with efficient tools and support. Yet I looked in vain for specific examples of people who have succeeded in making better use of a scientist's time, or examples of balanced (and unbalanced) research portfolios. Where, at a time when those responsible for granting or rejecting applications for research funds are so well aware that funds are flowing not to the most deserving areas of research but to scientists who can write a convincing proposal, is advice on how to put forward your case for research? What are the differences between a good and a bad research proposal? To be more chari-

Competent if not inspired

David Fishlock

Effective Management of Research and Development. By P. A. F. White. Pp. x + 295. (Macmillan: London and Basingstoke, May 1975.) £10.00.

table, the author's most recent experience of research management, as a divisional head at the atomic weapons factory at Aldermaston, one of the most secret enclaves of science in Britain, has probably had an inhibiting effect on his readiness to supply or seek out the kind of details and examples that could have enlivened his book so much. But it scarcely excuses him from the charge of publishing out-of-date information. The long lists of research laboratories in Britain, given presumably to help the research manager with a problem to select a contractor who might help, contain names that no longer exist, and record budgets of four or five years ago, even for a public corporation such as the National Research and Development Council whose annual reports are readily available. One table offering the ratio of research funds spent in-house to those subcontracted, for 11 industries, is dated 1966-67.

When, however, the author drops the pretence of providing a handbook of up-to-date research data and concentrates on writing a textbook of research management, he stands on firmer ground. The latter half of his book starts with a chapter on the choice of a research and development portfolio—"probably the most important task of research management"—in which he sets out the principles, basically three, and reviews the sophisticated techniques which nowadays can help the manager to calculate economic benefit. Here I would cavil only at the brevity of the section on the stopping of research projects, acknowledged to be "one of the most difficult of a director's activities" yet commanding less than four pages when a whole chapter would have been fully justified. But it leads into further chapters on the control of projects, on efficiency and productivity in research and development, and on choosing research staff.

At the end of each chapter the author provides a brief but lucid summary of the points he has been trying to make. Rereading this review I think that the point I really want to make is that Mr White has almost totally neglected the human factor in an activity where, perhaps more than in any other field of endeavour, the difference in terms of success between competent and inspired research management—as between competent and inspired research—is a very big factor indeed. □

SINCE the previous volume in this series of symposia devoted to virology was published in 1968 progress in the field has been considerable. This compilation of 14 articles on the theme of control processes in virus multiplication is, therefore, an invaluable source of information for students and would-be students of animal virology.

Like other symposia in the series this is a collection of specially written review articles, rather than research papers, aimed at a readership of general microbiologists. This symposium deals principally with animal viruses. Only 4 of the 14 articles are concerned specifically with bacteriophages, and none of them considers the multiplication of plant viruses though there is a mention of certain structural aspects of these in an article by Showe and Kellenberger. The editors have to a large extent succeeded in keeping the articles within

the stated theme. Reviews which are not so confined include the first three which are intended to provide back-

Latest virology

Control Processes in Virus Multiplication. (25th Symposium of the Society for General Microbiology, London, April 1975.) Edited by D. C. Burke and W. C. Russell. Pp. viii + 449. (Cambridge University Press: London, New York and Melbourne, 1975.) £9.00; $27.50.

ground information to the subsequent reviews. Indeed, Dressler in a very readable article admits that very little is known about the control of DNA replication but explains the advantages available to DNA molecules which adopt a circular form for replication, and goes on to describe the way the

T7 bacteriophage genome replicates without adopting a circular form.

Some of the articles are not easily assimilated perhaps because they each deal with a different aspect (or closely related aspects) of control for all the main classes of animal virus; they may have been easier to assimilate if each had dealt with a different class of viruses but had explored all aspects of control known within that class.

I strongly recommend this comprehensive collection of authoritative review articles on a theme of great significance in the field of virology, and will conclude with a quotation from the editors' preface: " . . . it has been our intention to describe the 'state of the art' at the time of writing, and if the reader is more impressed on occasions by our lack of knowledge, then we trust he or she may be stimulated to repair the deficiency!" **A. C. R. Samson**

Tropical landforms

Tropical Geomorphology: A Study of Weathering and Landform Development in Warm Climates. (Focal Problems in Geography Series.) By Michael F. Thomas. Pp. xii+332. (Macmillan: London and Basingstoke; distributed in USA and Canada by Halsted Press.) £2.95.

THE terms bornhardt and inselberg reflect the keen interest taken by German scientists in tropical landforms during the late 19th century. The British came in strongly in 1911 with J. D. Falconer's account of the geology of northern Nigeria. Comprehensive summaries appeared later, the chief being S. Passarge's *Panoramen afrikanischer: Inselberg-landschaften* (1928) and Karl Sapper's remarkable *Geomorphologie der feuchten Tropen* (1935), and recently the French have produced much literature on tropical landscapes, including Jean Tricart's *Le modelé des régions chaudes, forêts ét savanes* (1965) which was translated into English by C. J. K. de Jonge in 1972.

Now Dr Thomas, having published numerous percipient articles, has produced the first full treatment of tropical geomorphology written originally in English. He balances the results of his own wide-ranging field studies against the findings of other warm-climate geomorphologists, and summarises carefully the issues that are fundamental to an understanding of the development of tropical landforms and regoliths. In addition, by analysing in detail weathering processes and their relationships to common morphometry, he ensures that the reader understands geomorphogenesis anywhere under warm bioclimatic conditions in which the work of wind, frost and waves is absent.

Part 1 contains five chapters on weathering and in these the author stresses the increased tropical rate of endothermic chemical reactions, the stability of vast horizontal surfaces, and the frequent occurrence of silicate minerals in rock exposures. The description of the processes are set out clearly and concisely, particularly the eluviation of silica and the formation of duricrusts and of deep-seated profiles.

Part 2 discusses the character and development of the tropical terrain and includes chapters on distinctive individual landforms, on hill-slopes, and on pediments and pediplanation. The text ends with a bibliography and three indexes.

Throughout, the author recognises that the processes undergo complex variations in intensity and that inherited or relict forms may be part of the general picture. The landforms characteristic of the tropics are shown to experience a continuity of sub-aerial morphogenesis over a prolonged period during which interruptions by tectonic and climatic pulses are localised in space and time. Dr Thomas makes the reader aware of the many problems ahead and of the great progress made during the last few decades. His concise analysis combines clarity of exposition with clear-cut diagrams and ample quantification so successfully that it deserves to become straightaway the standard text on the geomorphology of the humid tropics.

Robert P. Beckinsale

Thereby hangs a tail: a highly placed leopard watches for prey. From *Tigerland.* By Kailash Sankhal. (Collins: London, May 1975.) £3.50.

Antibiotic agents

Mechanism of Action of Antimicrobial and Antitumor Agents (Antibiotics, vol. 3.) Edited by J. W. Corcoran and F E. Hahn. Pp. xii+742. (Springer: Berlin and New York, 1975.) DM.188; $77.10.

THIS volume is the third of a series and provides up to date information on many of the classes of antibiotics described in the first volume published eight years ago. In spite of the inclusion of 46 chapters, it is not a complete review and classes of antibiotic such as the actinomycins and nitrofurans, which are missing, will form the basis for a future volume. Among the 3,500 or so references are to be found a sprinkling of 1973 quotations, so the book is reasonably up to date, which is a good achievement for a publication of this complexity.

The book deals with antibiotics defined in the broadest sense of the word and chapters are included on alkaloids and synthetic chemicals which are clearly like antibiotics in their mechanism of action. Descriptions are given of a great variety of agents which have properties ranging from antibacterial and antiparasitic, to antitubercular and antitumour, and agents which are primarily useful as laboratory probes for investigating biological processes are also discussed. Indeed, some chapters contain accounts of chemicals which seem to have no practical value and which, presumably, are still looking for some disease to cure.

A clear sign of the emerging interest in antibiotics as antitumour agents is evident from the first section of the book on agents that interfere with nucleic acid biosynthesis. The majority of the compounds described in this section have some antitumour properties, and though only bleomycin and members of the anthracycline group are of proven clinical value, it is apparent that this is an area in which new discoveries may well be made. A second section deals with agents that interfere with protein biosynthesis and a miscellaneous final section is devoted to agents that interfere with specific enzymes and with membrane or cell wall biosynthesis and with agents whose mechanism of action is unknown.

The editors have obviously given a lot of thought to the design of the book and to the selection of authors. What emerges is a pleasingly uniform series of chapters dealing with the mechanism of action of various antibiotics. With few exceptions, the chapters are authoritative and provide critical accounts rather than just a catalogue of reported work.

Mechanisms of selectivity are discussed in a few of the chapters. Ethidium, for example, is an antiparasitic agent probably because it interacts specifically with closed circular molecules of extrachromosomal DNA. The characteristic sensitivity of squamous cell carcinoma to bleomycin is explained by the fact that this tumour type concentrates the drug and is also unable to convert it to its non-toxic form. Unfortunately, many authors, having described the probable mechanism of action of a compound, make no effort to explain the basis of its selectivity. Why, for instance, should one intercalating agent be an antimalarial, another antitumour, and yet another just a poison? Perhaps the reasons for selectivity are still little understood, but a few comments by each author, even if only of a speculative nature, would have rounded off a good book.

All in all this is a fine volume which, combined with the promised volume dealing with agents not covered in this book, provides a comprehensive and critical survey of our present day knowledge of antibiotics and related compounds.

T. A. Connors

Natural and Synthetic Polymers: An Introduction. By Henry I. Bolker. Pp. xiv +688. (Dekker: New York, November 1974.) $29.75.

THE great increase in the number and type of synthetic polymers during the 25 years since the publication of K. H. Meyer's book under almost the same title as this one, and the great deal more that we now know about both synthetic and natural polymers, would make it a daunting task for anyone to follow precisely in Meyer's footsteps. Dr Bolker does not attempt to do so. Instead, he maintains wide coverage by making only brief statements about many of the polymers with which he deals, each of which could often be expanded into a whole book in itself; though, with his commendable conciseness, he manages to pack a surprisingly large amount of information into a small space.

His account differs from others I have read in basing the sequence in which the polymers are considered, not upon their chemistry or function, but upon the molecular geometry of their structure, passing from linear through branched to cross-linked architectures and, therefore, from simple to complex. This gives some natural polymers somewhat awkward neighbours but it has a logic about it which is appealing, which leads students gently by the hand (and this is why the book was written), and has a great advantage in bringing together in a unified way matter normally taught separately by 'natural product' chemists, by polymer chemists and by biologists. The upshot is a very readable book.

Linear polymers are dealt with in four chapters of which the longest (and the longest in the book) is the first, dealing with cellulose as the type linear homopolymer upon which polymer chemistry was for so long based. The discussion of branched polymers, also covered in four chapters, includes considerations of heteropolysaccharides and nucleic acids as well as the multitudinous synthetic copolymers. Cross-linked polymers include proteins (and the genetic code) and lignin. For each group of polymers, attention is paid to structure, to properties, to synthesis or biosynthesis, and to the use by man or the function in nature. Each chapter carries its own reference list and many of the great names of polymer science will be found here though the almost completely chemical approach has meant that some of the non-chemists are, sadly, not mentioned.

In the sections covering those aspects about which I know best the book is not up-to-date—the explosion of knowledge of polysaccharide structure during recent years, for instance, is hardly touched upon—but it would be surprising if every part of a book with such wide coverage could be 'stop press'. I personally would have been happier to have had more diagrams of the ball-and-spoke type rather than chemical formulae; they give a better appreciation of the three-dimensional geometry. And some of the diagrams could have been drawn more tidily. These are, however, minor criticisms of a book which skilfully takes students through a complex series of discoveries, which turns a maze into a garden path. It is to be recommended strongly to students not only of polymer chemistry but of physics and biology, and indeed mature scientists in these disciplines might profit from reading it. I have certainly profited myself. **R. D. Preston**

Polymers

Ionic Polymers. (Materials Science Series.) Pp. xii+416. Edited by L. Holliday. (Applied Science : London, 1975.) £14.00.

AFTER reading this book I not only share the editor's view that materials like the inorganic borates, phosphates and silicates should be regarded as polymers of a particular (ionic) type, I feel that the very existence of the book will make it impossible for authors of future texts on polymer chemistry to resist the inclusion of these inorganic compounds in what is clearly their proper context. The text, taken in order, gradually passes from comparatively orthodox—in polymer science terms—discussion of the synthesis and properties of certain predominantly organic macromolecules to descriptions of the sheet-like and three-dimensional structures of the inorganic polymers. I am left with more than a sneaking suspicion that if history had permitted organic polymer chemistry to precede the study of the silicates, the intentional preparation of the latter would have been hailed as a substantial achievement in polymer synthesis.

The eight chapters, taken together, give a pretty comprehensive view of ionomers, from detailed structural studies of the group to their commercial utilisation. The first chapter provides a general discussion, dealing with nomenclature and general properties. After that the text covers ionomers of the thermoplastic and elastomeric types and moves on through a range of materials of increasing ionic content to the longer standing polyelectrolytes and inorganic silicates, and so on. In the middle range, cements and soil-conditioning materials are found together with the metal dicarboxylates, for which the name 'halatopolymers' is coined—are they salts or polymers, or both?

Naturally, the various articles vary in approach but the important thing is the book as a whole : it not only fills a void in the literature of polymers, it also teaches a valuable lesson which should leave its mark on all future contributions. **A. D. Jenkins**

Molecular Behaviour and the Development of Polymeric Materials. Edited by A. Ledwith and A. M. North. Pp. 553. (Chapman and Hall : London, February 1975. Distributed in the USA by Halsted Press.) £12.00.

AT the research level a large proportion of new books consist of collections of review chapters, contributed by different authors. Where such collections are aimed at the specialist in a particular discipline, they are easily judged by the standards of that specialist. The present volume is more difficult to judge, since it has a different motivation, being compiled as a richly deserved tribute to Professor C. E. H. Bawn, on his retirement from the University of Liverpool. The review articles which form the book have been written by friends and former colleagues of Professor Bawn and their only other unifying theme is that they all lie within the boundaries of polymer science. The result is a somewhat heterogeneous book with topics that cover a very wide range of interests.

The 14 chapters comprise three reviews of polymerisation mechanisms, four broad reviews of specific polymer types (polybutadienes, other elastomers, polyolefins and polyurethanes), two reviews on the chemical reactions of polymers and five reviews on the structure and physical properties of polymers. All of the chapters have been written to a high standard and editorial monitoring has been good. I found the chapter by Small, on polyolefins, and the chapter by Ledwith and Sherrington, on polymers as catalysts, especially interesting, the former for its critical discussion of why so few polyolefins are commercially successful and the latter for its treatment of an underdeveloped area of great potential.

This is a book which is unlikely to be read by the specialist looking for new insight into his own discipline. Certainly in those areas where I can claim expertise, there is little which has not already appeared elsewhere. But for those wishing to get a feel for what is going on in a selection of other areas of polymer science this volume will provide much of interest. At the price (which is high but not excessive) few individuals will find enough of sufficiently urgent interest to wish to buy a personal copy but the book can be highly recommended as a library purchase. **N. C. Billingham**

Understanding of the developing child

Learning and the Development of Cognition. By Barbel Inhelder, Hermine Sinclair and Magali Bovet. Translated by Susan Wedgwood. Pp. xiv + 308. (Routledge and Kegan Paul: London, February 1975.) £4.95.

PIAGET'S theory is frequently presented as a rigid maturational system in which stage follows stage, more or less regardless of the child's social milieu, so that specific training procedures to speed up intellectual development are ineffective and pointless: either the child has the developmental structures to assimilate the material, in which case nothing substantially new can be acquired, or else those structures are not yet developed and no useful learning can take place.

No wonder that psychologists and educators alike, in their efforts to understand and to instruct the developing child, recoil from this altogether pessimistic picture and put it aside as irrelevant. No wonder, either, that any experimental evidence of successful intervention programmes in teaching mental operation at a younger age than commonly expected is flaunted as proving Piaget's theory wrong. Fortunately, the interpretation I have mentioned is but a caricature of the theory, born out of the unquestioned assumption that between a hereditarily given, unchanging potential and learning in the form of storing and coding environmental information there are no other factors contributing to the growth of intelligence. Piaget rejects both extremes of the heredity–environment controversy without lapsing into an interactionist stance in which one is locked in interminable arguments about the correct statistical proportions, but by proposing mental development as a psychological process altogether different from the learning of information or the unfolding of instinctual patterns.

This book, if nothing else, is a reminder that Piaget's theory is not at all aversive to a study of environmental input as it affects children's efforts at understanding their world. On the contrary, the investigations reported are predicated on the idea that developmentally suitable encounters will bring about intellectual progression; yet there is no concomitant desire of speeding up, rather of observing the developmental process in a concrete setting. The authors, who are Piaget's closest collaborators of many years, conceptualise this progression as a construction on the part of the child in the face of

fluctuations and conflicts between apparently divergent schemes of thinking. The encounters are devised precisely to expose children, if possible, to an awareness of this conflict and thus to bring about a restructuring of these schemes; in other words, a progression from a base of less or conflicting understanding to a stage at which the conflicting views are subsumed as nondisturbing facets of a more adequate understanding. As an illustration, in the comparison of a W-shaped line and a straight line, the length of the lines and the number and configuration of segmental units making up the lines can create a conflict in a child who does not fully coordinate the concept of length in relation to segmentation and unit element.

In all experiments the children were carefully selected as being in a transitional phase and tested before and after training; each child's performance was individually analysed and tentative categories of progress—or lack of it—were proposed. Though the methods of experimentation include the use of such familiar concepts as assessment of the quantity of a liquid, numbers, inclusion, conservation of substance and weight, the thinking activities to which the children were exposed are ingenious and original, not only in helping the child's progress, but also in helping us to understand and observe the process of development. In the foreword Piaget singles out some of the more important theoretical insights to be gleaned from this research which is frankly acknowledged to be but an exploratory beginning in the search towards the unravelling of the process of development.

Thus the book is another milestone in Genevan research and contains the clearest exposition so far of Piaget's elusive concept of developmental equilibration. One may add to this that the translation was supervised by one of the authors and is not full of mistranslations as are, unfortunately, many other works on Piaget's theory. But make no mistake, like other Genevan writings it is not easy reading and it does have weaknesses for which the Genevans can be so easily criticised: points of empirical and methodological inadequacy, incomplete protocols, theoretical overinterpretations. A reader who cannot see beyond these will no doubt be dissatisfied. But those who want to understand better the nature of environmental occasions leading to intellectual development, and who search for guidelines in worthwhile psychological research will find here an exciting theoretical framework, all the more so on account of its obvious practical and educational applications.

H. Furth

obituary

Joseph Hewitt, designer of the Hewitt satellite camera, died on May 21 at the age of 63.

Born at Leicester in 1912, Hewitt took a first degree in Botany at University College, Leicester in 1933, but after some research on the colorimetry of cells, he became convinced that optics was his métier, and he took a postgraduate course on technical optics at Imperial College, London in 1939. In 1942 he joined what is now the Royal Radar Establishment at Malvern, where he remained for the rest of his career, becoming leader of the photographic unit and also working on lasers. Hewitt will be particularly remembered as the designer of the Hewitt camera, a Schmidt-type instrument of 600 mm aperture with a 900 mm mirror and a field-flattening lens. Two of these cameras were made and are at present owned by the Ordnance Survey, for whom Hewitt acted as consultant for the past three years, after retiring from RRE in 1972. The cameras have proved to be the most accurate in the world for observation of artificial satellites, and the observations have been extensively used in geodetic and geophysical researches.

Sir William Hodge, FRS, ScD, FRSE, who was Lowndean Professor of Astronomy and Geometry and Master of Pembroke College, Cambridge, from 1958–70, has died at the age of 72.

Born at Edinburgh and educated at St John's, Cambridge, Sir William spent most of his working life in Cambridge, with the exception of five years as a lecturer at Bristol and a year at Princeton. After holding a research fellowship at St John's he became a staff fellow of Pembroke, until in 1936 he became Lowndean Professor. In 1958 he was elected Master of Pembroke, and, together with Lady Hodge, did much to preserve a friendly atmosphere in the college. Hodge's main mathematical contributions were in the field of algebraic geometry. His theory of harmonic integrals has had a profound influence on the development of geometry in the past 30 years. After the war he played a leading role in the formation of the International Mathematical Union, serving as vice-president from 1954–58. He was one of the instigators of the British Mathematical Colloquium, and was also president of the London Mathematic Society, the Mathematical Association and the Cambridge Philosophical Society. He was elected a fellow of the Royal Society at the early age of 35, and was physical secretary from 1957–65 and a vice-president from 1959–65. Recognition for his public services came in 1959 when he was knighted. The Royal Society awarded him its Royal Medal in 1957 and the London Mathematical Society gave him the de Morgan Medal in 1959.

Whitlam, Connor and Cameron

AUSTRALIAN scientists have been through a deeply traumatic period, as Peter Pockley reports (p. 448), and it is by no means clear that the somewhat ambiguous statement of Mr Whitlam on July 1 will be the end of the matter. The issues at stake deserve to be understood internationally, if only because they exemplify the sort of problems that are bound, sooner or later, to beset a country whose policy for the support of science has placed emphasis on unity by means of the large, some say monolithic, CSIRO (Commonwealth Scientific Industrial Research Organisation) with 6,600 staff spending £50 million annually, and a ministry trying to coordinate science.

CSIRO has traditionally enjoyed a high degree of autonomy in the running of its affairs. It reports direct to the Minister for Science, not through the ministry's secretariat, and thinks of itself as 'scientists run by scientists'. Promotion tends to be more by merit than by seniority. All of this has made CSIRO scientists wary of their status; to be moved into the public service sector and to report into the bureaucracy of a sectoral ministry would, they believe, seriously alter their style of doing things. It would also choke the inter-disciplinary links which have been carefully nurtured in the last few years.

By themselves such arguments might simply be seen as defences of a cosy *status quo* and if used in normal times would have to be offset against other considerations. But in this instance the removal of roughly 500 staff from the jurisdiction of the Minister for Science (Mr Cameron) to that of the Minister for Minerals and Energy (Mr Connor) has some more disturbing aspects.

First, the tasteless manner in which it was done gives no confidence that any type of consensus politics was being practised. To act unilaterally and hastily is, of course, Mr Whitlam's privilege as Prime Minister, but it is one which inevitably leaves a feeling that the multilateral discussion has had to be short-circuited because the logic doesn't stand up too well to examination.

Second, the ambitions of Mr Connor, although relatively little mentioned in the furore that followed the decision, are not those that endear him to many scientists. His low profile throughout the affair, his failure to speak out on his own reasons for wanting to annexe portions of CSIRO and his undoubted aspirations to run a very large and very Australian resources empire have left him with few supporters in the scientific community, even though his fascination with technology is unquestioned.

Third, and undoubtedly most important, there is much despair that the careful exercises during the past two years of Mr Bill Morrison (former Minister for Science) in attempting to enunciate a science policy for Australia could be so easily ignored. Only in January 1975, Mr Whitlam, on introducing the White Paper establishing the Australian Science and Technology Council (ASTEC), harangued scientists on the need to take science policy more seriously. And yet this decision was made without reference to ASTEC, in the absence of any indication in last year's OECD report on Australian science policy that CSIRO should be carved up, and without even the chairman of CSIRO being notified in advance. It will be difficult to get Australians to give up their time to thinking about the governing of science in future. And if the Department of Minerals and Energy is allowed to annexe what it wants, this could be a precedent for similar acquisitions by at least half a dozen other departments who have scientific needs close to CSIRO's interests.

In the midst of all this, Australia acquired a new Minister for Science and Consumer Affairs in Mr Clyde Cameron. There could only be sympathy for him at first at arriving to find a burglary had just taken place. But since then he has been travelling and his first major speech in the new job was delivered in New Delhi to the Indian National Science Academy. It gives grounds for concern. He declares " . . . science and technology is now responsible for activities that are polluting and poisoning the world's atmosphere, ionosphere and even stratosphere. . . . At the rate we are now moving, it will soon be possible to fix a timetable for the ultimate end of human life itself. . . . Australia wants its scientists to do two things: one to concentrate on those areas which will improve the quality of human life, not just in Australia, but everywhere. And secondly, to [concentrate on] research that will enable Australia to help remedy the incalculable damage which the abuse and misuse of scientific knowledge has already caused to nearly every country in the world. ASTEC will direct its attention to these two objectives." ASTEC, CSIRO and the academic community are in for a difficult time ahead.   ☐

international news

THE Australian Government and public, and not least the scientists themselves, have been amazed by the intensity and unanimity of the fight by CSIRO staff to retain the integrity of their organisation following the raid by the Minerals and Energy Department to take over the CSIRO's Minerals Research Laboratories and Solar Energy Energy Studies Unit. At the time of writing, a compromise appears to have been reached, albeit one open to alternative interpretations, and CSIRO has at least held its ground.

Among the many problems faced by the CSIRO Executive and supporters in the wider public in mounting their fight has been the simultaneous battle of Mr. Whitlam's government to survive in power. Politics in Australia has been turbulent in Labour's 2½ years in office, but the last few weeks have been remarkable for the severity of the battering taken by the government, mostly of its own making. No sooner had Mr Whitlam finalised his new ministry on June 6, by persuading Mr Clyde Cameron to accept the Science and Consumer Affairs portfolio (and, at the same time, announced amputation of CSIRO), than the byelection campaign began to go sour in the safe Labor seat of Bass in Tasmania vacated by Mr Lance Barnard whose resignation had precipitated the Cabinet reshuffle. Labor lost the seat in a landslide to the Liberals at a time when the CSIRO fightback was gathering great momentum.

The Prime Minister and his Minerals and Energy Minister, Mr Rex Connor, were hardly approachable on anything, let alone the CSIRO affair and the scientists' campaign was waged largely at arm's length against a silent adversary. Without a day's respite from their drubbing in Bass, the government was pushed into its greatest crisis when a long-simmering row about unorthodox ways of raising overseas loans of "petrodollars" (to the tune of $4,000 million) came to a head. The bulky Mr Connor (who does not delight in his popular nickname of "The Strangler") and the nice but naive Deputy Prime Minister, Dr Jim Cairns (demoted from the Treasury to Environment), were the central targets of attack from the Liberal Opposition and the media.

Finally, Mr Whitlam sacked Dr Cairns, a drastic enough move in itself, but this was insufficient to keep the

CSIRO holds ground in fightback

from Peter Pockley, Sydney
Connor : hardly approachable.

wolves at bay, and Parliament was recalled for a special session. One of the dozens of members of Parliament and Ministers who came scurrying back from overseas to support their sides in the crisis debate on July 9, was Mr Cameron who had been visiting Delhi, Moscow and Paris, far from the madding crowd of CSIRO staff. He had not been missed, though, for the Acting Minister for Science and Consumer Affairs, Dr Moss Cass, a quietly persuasive politician with a knowledgeable and sympathetic record on science policy matters, had taken up the scientists' case with drive and some effect.

Before Mr. Cameron arrived back in Australia, Mr Whitlam had issued a brief statement on July 1, which went some way to meeting the scientists' demands for autonomy in staffing conditions from the Australian Government Public Service. The Prime Minister said "that he wanted to make it clear that the fact that the Minister

for Minerals and Energy was responsible for those aspects of CSIRO's research work (minerals and solar energy) did not entail the transfer of the CSIRO's staff concerned to the Public Service. These staff would remain employed under the Science and Industry Research Act and it is not proposed that they should be transferred."

That this statement leaves much open to doubt is shown by the cautious statement issued the following day by the CSIRO Chairman, Dr Jerry Price, who has worked with great energy to defend his organisation. Dr Price said that CSIRO welcomed the announcement, and then went on to say: "The Executive of CSIRO is now examining the administrative machinery involved to put into practice the division of ministerial responsibility as outlined in the administrative arrangements order." For the first time CSIRO formally accepted that the administrative order "makes clear the movement of ministerial responsibility for matters relating to minerals and solar energy research from the Minister for Science and Consumer Affairs, Mr Clyde Cameron, to the Minister for Minerals and Energy, Mr R. F. X. Connor".

But, the puzzlement over how CSIRO can work to two Ministers remains. Mr Whitlam's announcement could be consistent either with CSIRO remaining intact as an organisation, or with a separate CSIRO-like organisation being formed, under the Minister for Minerals and Energy, from the transfer of the relevant CSIRO staff without change in their working conditions. The Minerals and Energy Department are understood to have worked on draft legislation to give effect to the latter alternative, but, to date, they have not showed their hand. Showing hands is not part of that Department's style, and in any case their energies have been consumed by the defence of their Minister and their equally redoubtable Departmental Head Sir Lenox Hewitt, who, apart from the tragic Dr Cairns, have been the central figures in the row over the petrodollars loans (which never were —such is the fate of unsuccessful borrowers).

Mr Connor could also obtain a stake in CSIRO's operations through nominating members of the Executive—the next full-time vacancy will arise in January 1976, but whether Mr

THIS account would be incomplete without a survey of the two years leading up to the raid on CSIRO. This story is only beginning to emerge as CSIRO collectively gains confidence to speak a little louder than before the crisis.

Mr Connor is one of the few Australian politicians to proclaim a personal interest in science. Modern technology is said to fascinate him deeply—his vision of a national pipeline grid, under public ownership, for the distribution of Australia's none-too-plentiful natural gas supplies has been one expression of his apparent belief that to apply technology on the grand scale is to control the development of society. Mr Connor and Sir Lenox Hewitt have shown single-minded dedication to their aim of coordinating, through government or legislative controls, all principal aspects of mining and energy policy, but their ways of achieving these ends have not been marked by their encouragement of public information and discussion. Perhaps they planned from the outset that gaining the control and exercising close direction of major research facilities in the minerals and energy fields were essential elements of their strategy—in many ways a sensible aim if considered in isolation—but they played their cards close to their chests.

In 1973 (the first year of Labor rule) mining appeared to be out of favour with the government. Overseas ownership and "rape of national resources" were the bogies. The CSIRO leadership, struggling hard to read the new government's mind and not finding itself closely in tune with the Science Minister Mr Morrison, decided to slow the rate of growth of their minerals research effort. This effort had flourished in the late 60s in the wake of Australia's mining boom; CSIRO had created new mining-oriented Divisions, such as Mineral Physics, and had grouped old and new Divisions together as the Minerals Research Laboratories under a Director, Mr Ivan Newnham.

Research into energy was partly located in these laboratories, for example, investigations into coal, but such areas of work were largely dispersed throughout the CSIRO organisation. However, a separate Solar Energy Unit was formed, under Mr Roger Morse, early in Labor's first term of office, a move popular with Mr Morrison and the environmental lobby. This was a modest operation, and Mr Connor was able, unbeknownst probably to CSIRO, to start building a case for a single minerals and energy research organisation, a case which he may have thought politically unbeatable because of the brakes put by CSIRO on minerals research (demonstrable from budget figures) and the organisation's supposed neglect of energy research (demonstrable from the CSIRO establishment chart and some inside information).

From early 1973 CSIRO began to make a series of formal approaches to the Minerals and Energy people seeking joint meetings between senior researchers to define areas of cooperation and rationalisation for the achievement of government objectives. The reception was cool—in the case of the original letter no acknowledgement was received for six months, in marked contrast to the response from other new Departments established under Labor with whom scientific cooperation was rapidly and substantially put into effect, e.g. with Environment, and Urban and Regional Development.

Within a year, CSIRO convened its own in-house conference on solar energy with papers from researchers both at the centre and periphery of problems of energy conversion and storage, ranging from photosynthesis to wind machines and low grade heating devices. Minerals and Energy gained the list of delegates and their topics, and later (after the June 5 announcement) used it as a check list on CSIRO's willingness to relinquish their staff in these areas.

Meanwhile, the OECD examiners arrived to analyse Australia's science and technology policies in March and April 1974. They were given extensive cooperation by the Ministers and Departments of Science, Health and En-vironment, but they let it be known that Minerals and Energy did not seem to welcome them, Mr Connor and Sir Lenox Hewitt are reported to have declined to see the OECD team who, in their August 1974 report, recorded that they were unable to identify any energy policy at the national level. This bald statement was well considered by the politically oriented OECD people, but it drew a vitriolic Parliamentary attack on their report from Mr Connor, which at least had the virtue of spelling out what the Minister believed to constitute a policy for energy.

By September, Mr Connor had begun to show his hand. He wrung a joint statement out of Science Minister Morrison to the effect that Minerals and Energy was "to become involved in the implementation of the results of solar energy research". While CSIRO would continue its research in low-grade heat conversion, Minerals and Energy "would take over the development phase of those CSIRO research results which were approaching practical realisation".

Around this time, the Minerals and Energy Department asked that CSIRO provide a list of staff working in the minerals and energy field (they already held what they believed was the solar energy part of this list). For this purpose, Sir Lenox Hewitt paid a visit to the Canberra headquarters of CSIRO; Dr Price, the Chairman, was absent and he was given no satisfaction by the two members of the Executive who received him.

By November 1974 some contact was restored but not at the level of the CSIRO Executive. Discussions, which the Executive later said they thought were of an informal, exploratory nature leading to possible liaison, were held between the Director of the Minerals Research Laboratories and Minerals and Energy. By this time, Professor Harry Messel, an Atomic Energy Commissioner, had become Mr Connor's adviser on nuclear and other scientific matters; he became involved in the build-up to the Prime Minister's announcement on June 5, which so stunned the CSIRO staff.

Whitlam's government can survive until then is now open to daily speculation. Even if the government survives, Mr Connor's power base may be eroded because of his part in the loans crisis.

When the next history of CSIRO is written, the researchers will have unaccustomed ease in obtaining documents for the 25 crucial days for CSIRO spanning the period June 5 to July 1, the dates of the Prime Minister's two statements. The official communication network and the un-official grapevine within the organisation worked overtime to keep the scattered staff up-to-date with latest developments.

The press came to realise that this aspect of science policy at least was big news—probably the first time in Australian history that science policy has rated front-page and editorial treatment. Australian scientists, notable for their caution about dealing with the press (there are no full-time science correspondents on Australian papers), began to brief journalists like long-lost allies. The crisis created a flood of general information about CSIRO which should never have been so cautiously damned up for so long. But, while the press were remarkably generous in their coverage of the CSIRO side of the story, it was notable that the reporters who covered it—necessarily only political and general journalists—were struggling to find in their memories or files any arguments about scientific achievements to support their reports.

In passing, it should be noted that

whatever the final outcome, CSIRO's approach to its publicity must now surely change to a more open, if not aggressive stance. Some (but by no means all) of CSIRO's present troubles with the government could have been averted by a more accurate reading of the political cimate over the past two-and-a-half years. On the other side, some of the government's embarrassment from a public confrontation with an essentially non-political body like CSIRO could have been avoided by a better understanding of the nature of scientific endeavour and researchers themselves. Facts about Australia's achievements and potential in research are not common currency, even among local scientists, let alone politicians and bureaucrats. Each side of the confrontation has lacked information and comprehension of the other. Despite its debilitating effects on the short-term, then, it is possible that the open fight over 25 days did a power of good in bringing political realities sharply home to the scientific community.

Once placed in the fire, CSIRO staff learned fast the tough business of political pressure. For instance, once they noticed that the government-financed Australian Broadcasting Commission, despite a swag of science programmers on its staff, had given scant attention to the CSIRO story at a time when the press were headlining it daily, direct pressure was placed on the ABC hierarchy. A special radio programme followed, with unanimous statements of support for keeping CSIRO intact from some unlikely but influential sources. As implied already, CSIRO is not immune to criticism, but not a whiff of this emerged in the public debate.

Reportedly, Mr Connor, Sir Lenox Hewitt and their adviser Professor Harry Messel (of Sydney University) had been assured during the planning of their raid on CSIRO that the Minerals Research and Solar Energy staff subject to transfer to the Minerals and Energy Department would welcome the charge. (It is difficult, at this stage, to be certain of the origin of this advice, but fingers have been pointed sharply in only one or two directions.) That such advice was catastrophically wrong, and that the CSIRO staff have a solid if quiet pride in their organisation, has been shown by the complete lack of statements of support for the Connor/Hewitt/Messel move from within or without CSIRO. Such was the anger generated among some CSIRO people that there were underground moves to turn the raid back on the raiders. It is remarkable that, if there were good arguments in favour of consolidating all minerals and energy research, none have emerged publicly, even from the Minister involved or,

indirectly, by the much-favoured technique of off-the-record leaks to the press.

From June 12 onwards, meetings in laboratories and groups of laboratories regularly drew hundreds of staff from across the board of CSIRO employment barriers, namely research scientists, technical officers and administrative support staff. The respective unions were at one on the issue. They decided to take strike action on June 18, but this was deferred at the last moment (as was a later stop-work meeting) by reports that negotiations were in hand to restore the *status quo*. There was, though, considerable uneasiness among the staff for they had already been advised from their Head Office that "discussions are proceeding to identify the officers, employees and physical facilities that will be so transferred" (to the Department of Minerals and Energy). In a meeting on June 10, Mr Connor had left Dr Price and Mr Cameron without any doubt that he expected the transfer to occur.

Dr Price went public the following day with a press conference, and by June 16 the CSIRO Executive had briefed the Acting Minister for Science, Dr Cass, that the transfer of staff and facilities from CSIRO was "wholly unacceptable" to CSIRO. Dr Price does not find public debate easy; he is essentially a quiet person, but he showed that if scientists are slow to ignite, they can be devilishly long in burning.

Attempts by Dr Price and the CSIRO Advisory Council to see the Prime Minister failed, but Dr Cass had some effect with a well-publicised telegram to Mr Whitlam. The CSIRO Officers Association took out a writ in the High Court seeking to block the transfer on grounds of illegality related to their much prized working conditions which are independent of strict public service rules. On June 18, the 40-odd Chiefs of CSIRO Divisions had met in emergency session—always some achievement in Australia due to the distance and cost of travel to Canberra. The Chiefs unanimously (including the various Minerals Research Chiefs) telegraphed a stinging protest to Mr Whitlam. On June 20, a massive petition gathered hurriedly from 4,000 CSIRO staff, from technicians through to Chiefs and Executive, was presented to the Prime Minister's office. Six days later, the staff took out a large advertisement in the national press, timed to precede by two days the Bass byelection.

The points common to all protests included the arbitrary manner of handing down the decision without previous consultation, the value of CSIRO's unique model of organisation, its formula of freedom from political interference, and concern for morale.

Appeals to the 1974 OECD report on Australian science which recommended that CSIRO be kept intact were added to requests that the question be referred to the new Australian Science and Technology Council.

Genetic manipulation and the WHO

THE involvement of the World Health Organisation in the controversy that at present surrounds genetic manipulation experiments is welcome for a number of reasons, not all of them immediately obvious. It is true that Dr Halfdan Mahler, the WHO's Director General, has not himself made a direct statement of the position he is taking on behalf of the Organisation. But the publication of the recommendations made to him by his Advisory Committee on Medical Research (ACMR) is sufficient indication of the firm intention to become involved, the more so since one of these recommendations suggests that "the Director General pursue appropriate means" for publicising the committee's conclusions on this subject.

The hazards involved in genetic manipulation, the need to ensure that every possible precaution is taken in controlling research, and the importance of keeping the public aware and as well informed as possible, have already aroused discussion and violent debate worldwide, and such matters were already high on the agenda of this year's meeting of the ACMR. It is to that committee that the Director General would naturally turn for advice, in particular in the form of a lengthy and comprehensive statement from Dr Joshua Lederberg of Stanford University School of Medicine.

Extreme opponents of the work in this field will certainly be concerned at the very positive nature of the committee's first recommendation, which is to the effect that "The continuation (under appropriate safeguards) of microbiological research, including genetic manipulation and cell fusion studies, is of the utmost importance for progress in medicine and public health".

Other recommendations make it quite clear that the committee sees the WHO as playing a leading part at the international level, in keeping all concerned—in the scientific community as well as governmentally—continually aware of developments in this field and of the implicit dangers. On a more positive note, priority should be given to research aimed at the development of the safest possible biomaterials for such research, and to the evolution of techniques that reduce the hazards of working with them. Internally, the

WHO itself is recommended to co-ordinate all activities (at present scattered among a number of different departments) dealing with subjects in any way connected with this field. The organisation, too, will need to establish itself as "the international focus for information and its dissemination at the national level; "collaborating centres" for work in this field should be designated; and the WHO will need to play a leading part in the training and inter-country liaison that must be part of the essentially global approach to research and development of this kind. □

UNESCO science in S. E. Asia

from Yoshinobu Kakiuchi, Tokyo

AT its 17th General Conference UNESCO adopted a resolution aimed at the promotion of research and advanced training on the basic sciences with special emphasis on the needs of developing countries, and to this end UNESCO headquarters in Paris and the Field Science Office for South-East Asia in Jakarta have been working with the Japanese National Commission for UNESCO.

The meeting on regional cooperation in basic science in South-East Asia was held in Tokyo last year to consider approaches, and scientists from nine countries from South-East Asia (in-cluding Korea and Japan), and observers from Australia and New Zealand and representatives of international organisations joined the meeting. Taking the survey report prepared by two UNESCO consultants into consideration, the meeting agreed to select the field of the chemistry of natural products including microbiology as the first approach to the project.

The second meeting on regional cooperation was held in March this year in Tokyo and Osaka, and the meeting confirmed the establishment of the "Regional Network for Microbiology of Natural Products in South-East Asia" and the name of the interim points of contact of each participating country (a university involved in studies in the field) was suggested by the participant representing the country. The meeting also scheduled a meeting some time in late 1975 to discuss a more detailed picture of the similar network in chemistry, the establishment of which has already been agreed upon in the first meeting.

UNESCO is trying to mobilise all possible means available within the existing framework of its regular budget, but there is a need for more resources for this purpose. Japan has agreed to contribute cash in the form of a fund-in trust designed for use for specified objectives. There has been a fairly long experience in Japan of running UNESCO international graduate courses, one for chemistry and the other for microbiology (this is actually a one year course for foreign students, not necessarily those from Asian countries) and Osaka University is operating the course for microbiology, with the full consultation and cooperation of microbiologists from universities and research institutions all over Japan. Japanese scientists recommended Osaka University to serve as the Japanese point of contact, after consultation with Professor Kei Arima of University of Tokyo, who is at present a member of the International Cell Research Organisation (ICRO).

For the fiscal year 1975, Japan contributes $50,000 in the form of fund-in trust, and also donates approximately $18,000 equivalent of research equipment. Similar contributions will be expected in 1976. Funds and equipment are to be used exclusively for the academic activities of the network both in microbiology and chemistry, but the amount is by no means sufficient.

At the last Tokyo-Osaka meeting, Mahidol University in Bangkok, Thailand, agreed to serve as the regional centre for microbiology. It also functions as the national point of contact of Thailand, and Professor Pornchai Matangkasombut, who is in charge of research in microbiology in Mahidol University, is at present heavily involved in detailed planning of the structure and activities of the regional network. □

"It is undoubtedly a misnomer to speak of a British technological strategy". That's the harsh verdict of Dr Robert Gilpin, Professor of Public and International Affairs at Princeton, delivered in a mammoth report to a Congressional committee last month. Gilpin suggested that for various reasons, the British "on the whole have made very poor use of their rich scientific and technological resources", and he warned that the United States may make the same mistakes.

Gilpin's observations on Britain's technology policy were contained in a special report to the Joint Economic Committee on the hoary problem of how to integrate science policy and economic policy. Noting that "underlying the British malaise has been the problem of making the adjustment from the status of a global imperial power to that of a middle-sized European state", Gilpin suggested that the relative industrial decline of the United States poses similar problems to that country. The US, he suggested, should learn from the mistakes of the British.

"In the first place", Gilpin suggests, "British Government expenditures, like those of the US have been overly concentrated in a relatively few areas such as defense, space and atomic energy. The government has taken upon itself the role of entrepreneurship and has concentrated upon commercial development instead of on research, exploratory development and related activities. In substituting its judgment for that of private entrepreneurs with respect to the commercial 'ripeness' of particular high technology projects, the government has assumed a responsibility and tasks which governments do not do well. As a consequence of this neglect of the market very few of these costly projects have had commercial success".

Gilpin goes on to suggest that "the British government in a number of significant cases has made commitments to full-scale commercial development of particular technologies too early and on too big a scale" and notes that "there has been a neglect of more traditional sectors of the economy which for historical and institutional reasons tend to under-invest in R & D."

Finally, he suggests that "the British have failed to integrate sufficiently the three estates of science and technology; universities, government and industry. They have failed to create the necessary mechanisms to bring together the sources of new scientific and technical knowledge and the industrial users of knowledge. A disproportionately high fraction of British research and development has been conducted in government laboratories or in industry-wide cooperative laboratories catering to specific industrial sectors . . . While this latter set-up has served to improve the state of the several technical arts . . . the spill-over of government-supported military, and related research into the private industrial sector has been minimised".

The underlying failure of British science and technology policy, Gilpin asserts, is that "the government has tried to supplement rather than complement the private market . . . As a consequence, although the British are among the most technologically rich and resourceful people in the world, they have been unable to harness these resources to generate a sufficiently high rate of economic growth and competitive imports".

Canadian science: the golden era

from David Spurgeon, Ottawa

IN his final annual report as chairman of the Science Council of Canada, Dr Roger Gaudry looks back to a "golden era" of science policy in 1966, when the council was created, and forward another nine years to the problems of 1984. And in passing he comments on the crises of today, in which "the comfortable academic debate over science policy has largely become a thing of the past for most of us."

The former rector of the University of Montreal, who recently took over as first president of council of the new United Nations University, was the Science Council of Canada's second chairman, after Dr Omond Solandt, the founding chairman. His terms expired this summer.

The "science policy era" had barely begun when the Council was created in 1966, Dr Gaudry recalls. The Glassco Royal Commission Report on Government Organisation was barely three years old, the Senate special committee on science policy had not yet been established, and Canada had not yet been investigated in the OECD series of national science policy studies.

Before 1966, the country's science policy was, in the terminology of the Senate committee report, a "hidden" one. This, said Dr Gaudry, was because the greatest portion of policy work was not close to the point of application and thus was of interest only to the scientific community; most federally-supported science was housed in government laboratories and the universities and was largely self-determined; and because federal funds were largely given without strings, their allocations were not politically important. "Rarely did science or science-related items become public issues," says Gaudry.

By 1966, however, three sets of issues related to science and technology surfaced in public discussions and the press: the controversy over four Big Science projects; arguments over the scale and distribution of growing national research and development expenditures; and discussions over mechanisms for policy formulation and implementation.

The four Big Science projects were: Atomic Energy of Canada Limited's plea for construction of an Intense Neutron Generator (ING), which was opposed by many in the academic engineering community; the withdrawal by the federal Department of Industry of support of McGill University's High Altitude Research Project (HARP); the federal Department of Energy, Mines and Resources' plan to construct the Queen Elizabeth II Telescope in British Columbia, in the face of divided support from astronomers; and the proposal by three (later four) universities in western Canada to build a Tri-university Meson Facility (TRIUMF). The latter was the only one of the four projects destined to be funded to completion.

"Viewed in retrospect," says the Science Council chairman, "the mid-sixties were a golden era for science and technology, an era of enthusiasm, of rising budgets and of rising hopes. Canada's gross national expenditure on R & D was 15 per cent higher than in 1965, and that at a time when the annual rate of inflation was about 3.6 per cent."

Gaudry: looking back, looking forward

Science policy discussion of the era focused heavily on matters of research *per se*, as opposed to questions of the uses of science or the effects of technological programs, says Dr Gaudry. Even the Big Science projects had scientific, not technological goals. The participants were drawn almost exclusively from the scientific community itself.

By contrast, "the nature of today's discussion is both more technological and more political in character . . . many of the political issues of today revolve around what technology is, or is not, doing for us." The arguments now surround the James Bay Hydro Project, the Mackenzie Valley Pipeline, the Alberta Oil Sands Project, and the establishment of a second international airport near Toronto, at Pickering, Ont. And these arguments are over the validity of the economic objectives, the environmental impact and the costs, which are expressed in billions rather than millions of dollars.

"The adversaries in these discussions come from all segments of our society rather than from the confines of the scientific community *per se*. What has changed materially, it seems to me, is the nature of the public's attitude to technological development. Our outlook has matured considerably, we realise that 'bigger' is not necessarily 'better', we have recognised the concept of external costs which can spring as side effects from major projects, and all in all we take a more circumspect view of potential technological changes. What remains to be seen is the extent to which scientific evidence will be given due weight in decision making."

Thus the perception of what science policy is all about has changed since 1966, as well as the substantive issues. Environmentalism, anti-economic growth thought, economic nationalism, and the emergence of the provinces as significant factors in technological areas, have all come to the fore.

In the background, there has been a small but articulate "anti-science" movement, and demands for technology assessment. Debate concerning industrial strategy has also arisen. And through it all runs the thread of social responsibility, "the growing recognition that our technologies can be made either to serve or to dominate our society."

Looking ahead, Dr Gaudry sees three international problems as important: population growth and inadequate food supplies; resource supply problems due both to depletion and the action of international cartels; the possibility of nuclear proliferation.

He suggests Canada should consider participating in international technological ventures, and says she should avoid being isolated in the face of increasingly organised trade blocs. Domestically, there will have to be some form of national long-range planning in order to solve some problems, such as that of energy supply.

Changes in the structure of the population will have to be coped with, as well as chemical assaults on the environment. Industrial strife may follow technological change if not handled properly, and more public attention may have to be paid to defence technology. And "we will be forced to pay more attention to the concepts of a 'conserver society' and will move away from the maxim that any 'demand' must be satisfied, irrespective of how the demand is generated."

On the technological front, Dr Gaudry sees growing concern over increasing dependence on systems so large that redundancy in them cannot be afforded. And on the basic research front, the moral and ethical dilemmas of progress in some areas of biology, particularly genetics, will influence policy. □

A PROTOTYPE British-built rice mill, costing £10,000, is on its way to Indonesia, where the government plans to tackle inefficiency in rice milling by introducing modern mills of a sufficiently small scale to suit the needs of the country's predominantly subsistence rural economy. At present Indonesia's crop is processed largely on a small scale, either by hand pounding or by milling in wasteful machines (the most widely used being a modification of the 19th century Engleberg coffee grinder, which only produces 500 kg of edible white rice—more than half of which is broken grain—from a tonne of paddy). However, official statistics rate milling efficiency at an inflated level of 60% probably because extrapolations from a few large, modern mills are applied to the total paddy crop, although, as a 1972 UNIDO survey pointed out, these mills only handle a small percentage of the Asian paddy harvest.

Rice constitutes the staple diet of more than a third of the world's population, in particular, of 90% of the low income families in the densely populated regions of tropical Asia. Discussions of rice production are sometimes obscured by the fact that—unlike the other staples, wheat and maize, with which rice is often bracketed—there is a substantial difference between the weight of the harvested, threshed and dried paddy, often called rice, and the final yield of edible milled rice. Avoidable mechanical damage during this milling process could be destroying 20–25% of the potential yield of edible rice from paddy, according to surveys carried out in Indonesia and the Philippines by British consulting engineers and agronomists, under the auspices of the British Agricultural Export Council and the Department of Trade and Industry.

In the milling process, the inedible outer hull, which makes up about 20% by weight of the harvested dried paddy, is removed, and the final yield of edible white rice, separated from the bran—which makes up a further 10% of the paddy weight—is, ideally, 70%. Milling efficiency in the various countries of tropical Asia is said to vary between 60% and 70%, but some British experts believe, on the basis of observations in Indonesia and the

Grain gains

by Eleanor Lawrence

Philippines over the past few years, that the published figures for milling efficiency are over optimistic.

A large modern mill which deals with the paddy in several steps—hulling, separating the bran, and polishing the grain—can produce up to 700 kg of milled white rice per tonne but these large mills, capable of handling anything up to 100 tonnes of paddy an hour do not fit into the social pattern of a predominantly subsistence rural economy. The small farmer and his family, who in Indonesia, produce on average 1.5 tonnes of paddy from two crops on their half-hectare small-holding each year will eat the rice from about 1,200 kg of this, which will be milled locally or hand-pounded on the farm and will only send the surplus to the modern mills which are often far away and often inaccessible at certain times of the year.

The Indonesian government is now remedying this situation and has introduced a programme of small, more efficient local mills which can deal with the paddy at all stages from the initial threshing of wet paddy from the straw. The mechanically-dried paddy can be stored in silos until needed. These mills will incorporate a more efficient huller, which is being developed in Britain at the moment, and would be able to recover about 65% of the paddy as edible milled white rice of good quality, as well as conserving the oil and protein-rich bran for use as an animal feed and producing clean hulls which will be used to power the mechanical driers (specially converted from oil-burners). With traditional milling, either in the Engleberg mill or by hand pounding, an unusable melange of hulls, bran and powdered rice (20%, 10% and 20% respectively of the original paddy weight) is left either to smoulder or to be dumped in nearby marshy land. Each mill would serve about four square miles bringing it within easy reach of all the farmers in the area.

For Indonesia, with an annual paddy production of upwards of 23 million tonnes, a real milling efficiency of 65% covering the total paddy crop would provide an extra 3 million tonnes of edible milled rice. A preliminary survey in the Philippines has also indicated that milling efficiency over the total paddy crop is much lower than officially assumed. If the situation in Indonesia and the Philippines is paralleled throughout tropical Asia, more than 16 million tonnes of edible milled rice are being lost each year in dust, several times the entire world exports of rice each year—a substantial contribution to the 'food crisis' endemic amongst the peoples of tropical Asia who need the rice only they can produce.

A little knowledge . . .

from Vera Rich, London

" EVERYONE has won", announced Mr Brezhnev at the end of the recent Helsinki talks on detente and arms limitation. According to the rules of Lewis Carroll's caucus race, everyone should therefore have prizes. But although the agenda of the conference included not only political and economic issues, but also human rights, the free flow of information between east and west, and the possibility for all citizens to travel freely, one group at least stands to gain no benefits from the Helsinki agreement—the ever-growing group of Soviet Jewish refusniks. Hardly was the ink dry on the agreement, when the Moscow cyberneticist Aleksandr Lerner was informed "officially" that Helsinki will mean "no change" in the rules governing the emigration of Soviet Jews.

The problems involved in visa applications are particularly acute for scientists, since it is easy for the authorities to claim that they have had access to classified information. With the new atmosphere of detente, this may lead to some curious anomalies. One such case is that of Aleksandr Druk, who was working on the electronics of the space programme before he applied for a visa and was subsequently dismissed some three years ago. Although he had never visited the Baikonur cosmodrome or even seen a spacecraft, he has been informed that the question of his emigration "will be decided only in 1980". Yet, as Druk himself has pointed out, the Apollo–Soyuz mission has led to the sharing of information of far more potential importance than any which he could divulge to the West.

In other fields, too, the clamp down on Soviet Jewish scientists continues. A number of them are at present under considerable pressure because of their connection with the *samizdat* journal *Jews in the USSR*. This journal, founded by Professor Aleksandr Voronel (the founder of the "Sunday Seminars" for refusniks), carried articles on historical, philosophical and religious topics, and was intended, according to Voronel, to explore the meaning of Jewish traditions and culture against the background of tacit discrimination in which Soviet Jews must live. A number of prominent scientists were connected with the journal; those under pressure at the moment include the physicists Aleksandr Lunts and Eitan Finkel'shtein and the cyberneticist Grigorii Rosenshtein. □

IT came to the table accompanied by the limp, succulent bacon and hard toast for which English breakfasts are famous, and it was so delicious that I bought a jar to take back to the States. The label said, "Contains Sugar, Oranges, No Preservatives, No Colouring". Now sugar is, of course, one of the most ancient and universal of food preservatives, and is certainly the one used in largest quantities. The colour of oranges makes them glow like lamps against the dark green leaves in the citrus groves of California. Colourless marmalade without sugar is difficult to imagine. The label was written, of course, to quiet the fears of those who are convinced that they are being harmed by food preservatives and food colouring; that they are hapless victims of malevolent concocters of artificial viands. These fears are even voiced by the Neuberger Report which says "Flavouring agents and other food additives may have harmful effects" (p. 6) . . . "Food additives may be converted into carcinogens" (p. 138). Presumably the authors were talking about nitrites, but generalised accusations are easy to make and difficult to pin down. Rainwater during a thunderstorm contains nitrites, too.

The skin of an orange is its protection against invaders. I have no idea whether orange oil would pass all of the elaborate safety tests that are used for new food additives but I think it is quite unlikely. It contains forty-two

Peel meal
THOMAS JUKES

chemical entities including 12 alcohols, 9 aldehydes, 2 esters, 14 hydrocarbons and 4 ketones. One of the entities is a phenolic compound called tangeretin. When tangeretin was injected subcutaneously into pregnant rats at a level of 10 mg per kilo of body weight, 83% of the offspring were born dead, or died within three days. Foods are tested for toxicity, of course, by feeding rather than by injection, but one can imagine what a hullabaloo would start if a "synthetic" food additive gave such a response. There are hundreds of "natural" components of foods that

have not been evaluated for toxicity in human subjects, and probably never will be. If we believe the assurances of analytical chemists that traces of a substance are present, we must also learn to accept the findings of toxicology that there are thresholds of toxicity that can be experimentally defined. But we tend to trust Mother Nature, and suspect the organic chemist, so that "synthetics" are examined much more stringently than natural compounds. Our lives are a curious mixture of rejection and acceptance of science, and this shows prominently in attitudes towards food.

Somehow there is a feeling that human beings have developed the ability to cope with injurious substances in common foods by an evolutionary process, but that a "new" chemical is quite likely to be unmanageable. This assumption is unwarranted as a generalisation. The process of alimentation consists of devouring plants and small animals that have always contained numerous "chemicals" that are more or less toxic. These are dealt with by excretion or metabolism unless the amounts ingested become too high for comfort. So, most literally, we may have a "gut feeling" that orange marmalade is a great food; and in this I would include even the less fancy brands to which extra amounts of citric acid and pectin, two normal ingredients of oranges, have been added. □

The waiting game

SIR,—I wish to bring to the attention of all university departments the problems of one section of the scientific community; UK postdoctoral fellows currently engaged in research at overseas institutions, which I feel will add to the current discussion of the future structure of the UK university system. Other than the ridiculous practice of setting deadlines for the receipt of applications for university positions which expire before the particular advertisement reaches foreign shores, there is a much more serious problem involving the time frame.

In my own experience university lectureships tenable from October 1975 were advertised in your columns starting in May. Allowing three months for the receipt of applications and testimonials, the short-listing of candidates and finally the acceptance by one candidate, this means that perhaps several

hundred unsuccessful applicants are kept in limbo until August to hear their fate. Amongst these the applicants from overseas are often worse off because, due to visa problems they cannot retain their fellowships indefinitely. Often such candidates will also have applied to universities in other European countries where things are decided more rapidly; this can mean being faced with the decision to accept or reject a firm offer from, say a German laboratory, by the middle of July, or risk everything and wait upon the deliberation of the ponderous UK system.

It is apparent that to ensure that UK university appointments are made from the best pool of candidates available there must be radical changes in the hiring system. Since this would require advance information of budgets and staff needs, government and university cooperation is needed.

RICHARD JAMES
Princeton University, New Jersey

Close relatives

SIR,—Gold (*Nature*, July 10, 1975) has shown how two individuals (a mother and baby) may be differentially aged by a general relativistic effect. However, the method chosen involves the mother going out to collect masses from afar, since the act of 'going out' cannot be achieved without the mother experiencing an acceleration, then the mother like the baby will also age more slowly than an inertial observer situated at a large distance from the mass shell. Indeed, during her nightly travels it is possible for the mother to age more slowly than the baby.

I therefore question whether it is at all possible for a person to construct such a mass shell without experiencing acceleration.

Yours sincerely,
L. A. KING

Mercury since Mariner 10
from a Correspondent

> The First International Colloquium on Mercury was held at the California Institute of Technology on June 25–27, 1975. It was chaired by Bruce Murray of Caltech.

COMPARATIVE terrestrial planetology is an interdisciplinary field which has come of age as a result of satellite studies of the Moon, Mars and, most recently, Mercury. In the last decade, a number of complex, unmanned devices has investigated these objects and man himself has personally inspected one of them. The most remarkable result of these studies has been the identification in the photographs obtained of a universal process of cratering. The consensus is that most, if not all, craters are due to impact bombardment by planetesimals, some of which come from beyond the orbit of Uranus. Combined with the returned lunar samples, providing age dating, it now appears certain that early in the history of the formation of the Solar System, the terrestrial planets were subjected to an intense, cataclysmic bombardment process which has mainly shaped their surfaces unless they

possess substantial atmospheres. These matters and other new results concerning the innermost terrestrial planet, Mercury, were discussed and debated at the recent colloquium.

Understanding of Mercury is based primarily upon the USA Mariner 10 spacecraft results. They were obtained during an unprecedented celestial sequence of three successful fly-bys of the planet on 29 March 1974, 21 September 1974 and 16 March 1975. In view of current economic conditions, the space technology community can take great satisfaction in the multiple re-encounters achieved because they permitted a unique synergistic study of unexpected results obtained at first encounter. Any future return to Mercury seems unlikely for at least the next decade.

The most unexpected result of the first encounter was the identification of a strong solar wind interaction with the planet. This leads to the development of a detached bow shock wave as the solar plasma is deflected around the planet and the occurrence of intense bursts of energetic particles in the magnetosphere of the planet. The third fly-by unequivocally confirmed the

existence of the modest magnetic field (about 1% of Earth's intensity) and solar wind interaction. The consensus at the colloquium was that the field origin is most probably due to an active dynamo in the planetary interior. It was noted that from a magnetohydrodynamic fluid viewpoint, Mercury and its interior are rotating rapidly and thus could sustain such a dynamo.

In spite of its great success, it is doubtful if Mariner 10 will provide a precise measure of the moments of inertia and hence the distribution of mass within the planet. Nonetheless, the indirect evidence for a large, dense core seems compelling based upon theoretical models of the thermal history of the planet, global expressions of compressional features, and the existence of a modest magnetic field. The uncertainty in geochemical characteristics, especially of the radiogenic isotopes, leaves many degrees of freedom in predicting the present thermo-mechanical state of the interior. Some think that convection is inevitable in order to account for the unique synchronisation of the spin period and orbital periods of Mercury (T_{orb} = $3/2 \, T_{spin}$). One specific issue unresolved is distribution of heat sources which would be responsible for forming a large core (70% of the surface radius) and maintaining it sufficiently fluid-like to permit convection up to the present time.

One of the significant results of the high fidelity photographic reconnaissance of Mercury was the identification of heavily cratered terrains and large basins readily evident in all photographs, the largest of these being Caloris with a diameter of 1,300 km! The development of a cratering chronology was one of the principal challenges to comparative planetologists studying impact bombardment of the terrestrial planets. The higher gravity on Mercury limits the radial extent of ejecta blankets and permits a more pristine view of the cratering sequence than on the Moon, with its lower gravity, or on Mars, where alteration by Aeolian weathering occurs extensively.

The extent of volcanic processes, in both space and time, was debated as offering the most logical explanation
Intercrater plains (ic) and heavily cratered terrain (hc) typical of much of Mercury outside the area affected by the formation of the Caloris basin. Abundant shallow elongate craters and crater chains are present on the intercrater plains. Prominent scarp Santa Maria Rupes cuts both intercrater plains and old craters. Scene is 200 km across.

of the smooth plains, wrinkle ridges and lobate scarps observed. Unquestionably to some, the plains areas appear filled as a result of internal activity. But yet how is it possible for younger craters to be floored with plains-like looking material which the cratering process should have obviously disturbed? The view was also expressed that the intercrater plains represent a process contemporary with the cratering and occur as a result of impact melting. The debate is reminiscent of the lunar questions in the mid-1960s following the early lunar orbiter photographs but prior to the Apollo landings.

It is readily admitted that it is not yet possible to consider development of a single model of evolution of this planet. In addition to its anomalously high average density, we now know its surface to be very Moon-like and yet with its modest magnetic field its interior must be more Earth-like. Where Mercury fits in the grand scheme of the origin of the terrestrial planets is not certain. It can reasonably be expected that future studies of these results and comparisons with the Moon and Mars (with the USA's Viking 76 landers) will shed light on this fundamental question.

Human cytogenetic registries

from a Correspondent

THE astonishing success of human cytogeneticists in communicating their discoveries in a standardised and comprehensible way is due to their early recognition of the need for a standard system of nomenclature. To this end, participants at four international meetings have made recommendations and devised systems of nomenclature, each of which has extended and modified the previous one and thus successfully kept pace with rapid technical advances. The meetings were arranged on an *ad hoc* basis and had no authority save their broadly based international representation and the excellent reports which resulted. Their recommendations have been followed by virtually all workers in human cytogenetics.

The question of an international registry of abnormal human karyotypes was first raised in 1966 because many people felt that unpublished data on individuals with abnormal chromosomes (and all laboratories of human cytogenetics have such data) could, if collected and pooled, be used in some worthwhile way. The topic was first considered in depth on April 7 and 8 of this year when a standing committee on human cytogenetics, set up after the 1971 international meeting held in Paris,

sponsored a workshop in Edinburgh on human cytogenetic registries. The meeting was attended by nine individuals who run such registries, by consultants and by members of the standing committee.

The workshop first considered cytogenetic registries generally. It was agreed that it was absolutely essential that the aims and goals of a cytogenetic registry be clearly defined and that the output of useful data from such a registry was dependent upon, and limited by, the methods of ascertainment employed in the registry and by the quality and uniformity of the information within it. Subsequent to discussion of the methods of intake into a registry, the question of patient confidentiality, the rigorous quality control needed for data in the registry and the necessity for the continued surveillance of patients for certain types of registries, the participants turned their attention to the question of an international registry of abnormal human karyotypes. After considering a variety of problems to which cytogenetic registries might address themselves, the participants decided that their solution would not be helped by an international registry.

Therefore, with one dissension (Dr D. S. Borgaonkar: see *Nature*, **253**, 591; 1975) they recommended that an international cytogenetic registry should not be set up at this time and that if, at some future date, an international registry should be considered of value, it should be established only after careful planning and under the guidance of an international advisory committee. They also recommended that the establishment of regional and national cytogenetic registries should be encouraged, as should cooperation between them and existing registries. They further advised, again with one dissension, that an international advisory committee on cytogenetic registries should be set up by the standing committee of the Paris conference and, lastly, that the standing committee should advise international organisations and appropriate national agencies of these developments and solicit their cooperation and support.

The workshop report was accepted by the standing committee who will publish it later this year as part of a supplement to the Paris Nomenclature. In the light of the recommendations the standing committee has already established an advisory committee on human cytogenetic registries under the chairmanship of Dr James R. Miller, Department of Medical Genetics, University of British Columbia, Vancouver.

At a time when few regional or national registries have yet shown their worth, it seems that the Edinburgh

workshop report reflects a very sensible decision not to support at present the establishment of an international cytogenetics registry which would, in all probability, turn into a cumbersome, expensive and unproductive way of disposing of unpublished data.

Label triangulation becomes feasible

from a Correspondent

A Brookhaven Symposium on neutron scattering in biological research was held on June 2–6 at the Brookhaven National Laboratory, New York.

INVESTIGATING the topography of ribosomal proteins by the chemical methods discussed recently in *Nature* (**254**, 555; 1975) can only lead to a qualitative model of a ribosome. The standard methods for structure determination are diffraction methods. At the symposium two groups showed independently that the application of the 'label triangulation method' to ribosomes has become an experimental reality. This method is in principle capable of giving the complete quaternary structure of the 54 proteins in a ribosome in a quantitative and unambiguous way. It is based on low-angle scattering in solution and was first proposed for X rays (Hoppe, *Israel J. Chem.*, **10**, 321; 1972) and shortly thereafter for neutrons (Engelman and Moore, *Proc. natn. Acad. Sci. U.S.A.*, **69**, 1997; 1972).

Scattering in solutions can be treated like gas diffraction. Using the corresponding theory it can be shown that the linear combination of four scattering curves $u = a + b - c - d$ (scattering of solutions of equal amounts of a, the molecular complex to be studied; b, the molecular complex labelled with two additional scatterers A and B; c, the molecular complex labelled with A only; d, the molecular complex labelled with B) corresponds to a damped sine curve with a wavelength inversely proportional to the distance AB (see also Kratky *et al.*, *Mh. Chem.*, **76**, 281; 1946; **78**, 295; 1948). A systematic labelling is possible by disaggregation of the ribosome (respectively of the 30S or 50S subunit) and by reaggregation, replacing unlabelled proteins by labelled proteins. In the case of X rays labelling can be done by introducing heavy atoms; in case of neutrons by replacing deuterium (in a completely deuterated subunit) with hydrogen. A triangulation of the distances leads to the quaternary structure. Approximately 200 distances can be measured in the 30S subunit and 500 in the 50S subunit.

It is evident that not only a considerable amount of diffraction work but also a great amount of biochemical work is necessary for a triangulation.

The difference scattering curve u=a+b—c—d can be measured in two different ways· one can prepare and measure four solutions of the derivatives (as proposed by Engelman and Moore, 1972) or one can prepare two mixed solutions, which deliver respectively a+b and c+d. It was shown in the X-ray triangulation paper (Hoppe, 1972), that in the latter case all inter-particle effects (even if stemming from aggregations) will be cancelled (see also Hoppe, *J. molec. Biol.*, **78**, 581, 1973). This is a very unusual situation in solution scattering. It is easy to see how important—even essential—this cancelling is for the label distance measurement in such a giant assembly as the ribosome. The averaged label concentration in a 50S subunit is only 1%. One is therefore forced to work on highly concentrated solutions (11% of the 50S subunit and more than 20% of the 30S subunit in the later mentioned measurements). Moreover, the additional determination of the shapes of the proteins in neutron work—which requires accurate scattering curves—would be entirely impossible.

The experimental results reported in Brookhaven have been achieved on the protein pairs S3–S7 (115 Å), S2–S5 (104 Å), S5–S8 (38 Å) in the 30S subunit (D. M Engelman, P. B. Moore, B. P. Schoenborn, and collaborators) on the Brookhaven reactor and on L7/L12–L10 (100 Å), (W. Hoppe, H. G. Wittmann, H. L. Crespi, and collaborators) on the Grenoble reactor. In the latter case the two proteins L7/L12 are identical—except for a N-terminal group in L12. It has been deduced from other experiments that the pair L7/L12 should be a dimer. It can therefore be treated as a single protein. Both groups have used the mixture method; both labelled by replacement of hydrogen with deuterium (instead of *vice versa* as originally proposed in the neutron paper) in order to economise on deuterated material. The intensity differences are very small (with an order of magnitude of ~ 1%) and could only be measured using low angle diffraction matrix instruments as first developed in Grenoble by K. Ibel.

Replacement of hydrogen by deuterium was first used in membrane work (Kirschner and Caspar, *Ann. N.Y. Acad. Sci*, **195**, (ser. 5), 309) and it is therefore not surprising that much effort was reported in Brookhaven to use this type of isomorphous replacement not only for myelin membranes (D. Kirschner, University of Basle, and D. L. D. Caspar, Brandeis University) but also for other biological systems:

for example M. J. Yeager (Yale University) and M. Chabre, retina; V. Luzzati (CNRS, Gif-sur-Yvette), lipoproteins; A. Miller (University of Oxford), collagen, E. M. Bradbury (Portsmouth Polytechnic), chromatin; J. Randall (University of Edinburgh), catalase. All work has been done by exchange of water or of hydrogen ions by respectively heavy water or deuterium ions. It is evident that the non-exchangeable replacement of core hydrogen by growth of microorganisms (as used in the triangulation work) will open up new possibilities. It is therefore of great practical importance that *E. coli* with nearly fully deuterated proteins can grow from hydrogenated substrates like glucose (P. Moore). Interesting applications of direct methods were reported, originating from earlier work of Hosemann and Bagchi (see Matter, *Direct Analysis of Diffraction*, Amsterdam, 1962). Of further interest is the fact that the first projects were aimed at the use of neutron spectroscopy in biological systems (J. White and W. L. Peticolas). A report on the Brookhaven Symposium would be incomplete without mention of the elegant work on protein crystal structure determination of haem proteins (B. P. Schoenborn, Brookhaven National Laboratory).

Tektites and their origins

from David W. Hughes

TEKTITES are small glassy objects which are found in certain localised areas on the Earth's surface. They are one of the enigmas of science, a cuckoo in a nest of meteorites.

There is still considerable doubt as to whether tektites are meteorites because they have never been seen to fall to ground. Meteorites are found randomly over the whole Earth whereas tektites only occur in certain areas, all at relatively low latitudes: the southern half of the Australian continent, Indomalaysia, the Ivory Coast in Africa, Czechoslovakia and North America (Texas, Georgia and Martha's Vineyard). They do not arrive at Earth continuously either: the separate arrival events all occurred during the last 34 Myr.

About 650,000 tektites had been discovered by 1960. The Czechoslovakian Moldavites are dark green whereas all the others are jet black, their surfaces usually having a dull lustre due to abrasion and weathering. The glass is isotropic and brittle with a refractive index between 1.48 and 1.52 and a density around 2.4 g cm^{-3}. Tektites have weights up to 300 g and shapes varying from spheroidal to pear-, lens- and disk-shaped. Many of them show ablation

features and contorted flow structures as if their surfaces had been heated while travelling at high speed through a gaseous atmosphere and subsequently quickly cooled. The chemical composition is that of a silicic igneous rock with high SiO_2 (70–80%) and moderate Al_2O_3 (11–15%), the composition being relatively independent of the formation with which the tektites are associated. There are, however, distinct minor variations between the different groups and also systematic minor variations across the individual strewn fields. Tektites also contain minute shred-like inclusion of pure silica glass (lechatelierite) which can only form at temperatures in excess of 1,710 °C. Tektite composition is quite different from that of any known meteorite. The age of solidification of the primary object was found to be close to 400 Myr by using $^{87}Rb/^{87}Sr$ decay, and measuring the $^{87}Sr/^{86}Sr$ ratio. The range of values obtained is much smaller than that found for terrestrial igneous rocks and there are only slight differences between specimens from different localities. By using the $^{40}K/^{40}Ar$ ratio, the age of solidification of the glass during ablation can be found. This is equivalent to the age of arrival on Earth and varies considerably between locations, being 0.61 Myr for Australites, 1.3 Myr for Ivory Coast tektites, 14.7 Myr from Moldavites and 34 Myr for American Bediasites.

The origin of tektites is still unknown Theories can be divided into two main categories. terrestrial and lunar. One of the favoured terrestrial theories is that tektites were formed by the fusion of terrestrial material during the impact of giant meteorites. These meteorites also produced large craters in the Earth's surface such as the Ries Kessel structure in West Germany, 250 km away from the Moldavite strewn field, and the Bosumtwi crater in Ghana. The potassium–argon ages of the tektites and of the cryptic glass from around these craters agree surprisingly closely. However, these impactite glasses found near the craters are markedly different from tektites, being slaggy and porous and having abundant inclusion of partly fused material; also the problems of moving the tektite a distance of 200–300 km against air resistance and accounting for the 10^3 difference in H_2O content between terrestrial rocks and tektites are not trivial. The fact that large impacts have occurred throughout the history of the Earth and not just in the last 34 Myr must also be explained.

Another terrestrial theory advocates a crypto-volcanic origin McCall (*Meteorites and their Origins*, David and Charles; 1973) states that Reis Kessel and Bosumtwi might be extinct volcanoes and not impact craters, the

A hundred years ago

Mirage on Snowdon

On Monday, July 12, I, with a party, ascended Snowdon. The atmosphere was clear until we had reached within half a mile of the summit, when a light cloud rising stealthily from amongst the southern peaks enveloped it. Drifting towards us, when very near, the cloud dropped over the eastern shoulder of the mountain just where it dips towards Capel Curig. As we stood watching, great was our surprise and delight as we beheld painted upon it, not the *arc-en-ciel* with which we are familiar, but a complete and brilliant prismatic circle, apparently about thirty feet in diameter, in the very centre of which we ourselves were depicted, the image being somewhat enlarged but clearly defined; as we arranged the party in groups, or bowed to each other, every form and movement was faithfully reproduced in the picture. It was now about 8 o'clock, with the sun nearly in a line with us. Our guide, who had made some hundreds of ascents, had never witnessed such a sight before.

H. J. WETENHALL
from *Nature*, 12, 292; August 12, 1875

tektites being produced by fusion between volcanic emanations and country rocks. A simpler theory postulates that tektites are shed melts derived from ablating meteorites. But tektites are acidic and all known meteorites are basic.

Lunar theories propose that the tektites are ejected from the Moon in a molten form during the formation of craters by meteorite impact and during periods of lunar volcanic activity. The composition of tektites is hard to account for as most of the material brought back from the Moon has been basaltic rather than acidic. The fact that there are only four age groups of tektites, although the hundreds of thousands of lunar craters were created at many different times, counts against the impact ejecta theory. Also impact craters mainly eject matter at low angles.

Lunar volcanic ejecta as a source of tektites is strongly advocated in the recent paper of Cameron and Lowrey in *The Moon* (12, 331; 1975). Reliance on a volcanic ejection process can explain the rarity of tektite falls on Earth and their composition. The velocity of escape they need to leave the Moon requires the volcanism to be of the explosive type which terrestrially is usually associated with acidic suites. (Acidic lavas, which have very high viscosities of 10^{12}–10^{13} poise, can sustain very high pressures before disruption. This leads to massive rock and lava ejection, as with Krakatoa, which ejected 18 km^3.) As the youngest tektite is only 0.6 Myr old, lunar volcanic activity must have been very recent—and the authors tie this in with observations of lunar transient phenomena—mild degassing observed from time to time around certain craters. The lack of H_2O in lunar samples is also echoed in tektites.

Tektites ejected vertically from the Moon at a speed of 3 km s^{-1} will only reach the Earth if they start from a small area on the eastern hemisphere within 6° of the lunar equator. The orbits are hyperbolic with respect to the Earth–Moon system so if the tektite misses the Earth on the first pass it goes into a heliocentric orbit. In searching for the exact point of origin Cameron and Lowrey regard 'lunar transient phenomena' sites within the specified boundaries as prime suspects, provided, however, that other evidence of volcanic activity can be found in their vicinity. The sites are all ray craters—Censorinus, Taruntius, Messier and Messier A (the old Pickering) and it is postulated that the rays are whitened exposed rocks which have had their dust covering blown off by gases emanating from the craters. Censorinus AB has a central mound with a funnel-shaped crater similar to those of terrestrial diatremes, fumaroles and explosion pits, all manifestations of volcanism. The hummocky bands in Messier, some of which have summit craters, are also pointers towards volcanism. Steep sloped ridges inside Taruntius indicate that volcanism could have post-dated the impact explosion.

The source of tektites must lie deep within the Moon because tektites differentiated in the last 10^9 years when the Moon's heat was confined to very deep regions. Cameron and Lowrey postulate that diatremes coming from these depths discharged their ejecta vertically; and that craters such as Messier were formed by impact and then suffered volcanism because the craters were formed on mare surfaces, the scenes of original volcanic flows.

So old lunar volcanoes, the present day sites of transient lunar phenomena, provided they are in the right area of the Moon, can eject tektites which will hit the Earth. But why have these only erupted in the last 34 Myr? Why are the tektites so tightly bunched in space that they only produce small strew fields on Earth? How does such pure differentiated material get produced on the Moon? Where are all the tektites that missed the Earth the first time, only to fall to Earth an indeterminate time later? Many questions remain unanswered; these enigmatic tektites have been bothering scientists since the eighteenth century and I am sure will continue to do so long into the future.

Far infrared astronomy

from M. Rowan-Robinson

The first international conference devoted exclusively to far infrared astronomy was held at Cumberland Lodge, Windsor Great Park on July 9–11. It was organised by Queen Mary College, London, and sponsored by the Royal Astronomical Society.

THE far infrared is usually taken to mean the wavelength range 30 μm to 1 mm which, being almost inaccessible from the ground, is observed from aeroplanes, balloon platforms or (for the future) satellites. One of the most interesting discussions was of the relative merits of NASA's proposed Large Space Telescope (LST), a satellite-borne 60-cm telescope which will operate in the optical and ultraviolet as well as the infrared (plans were reported at the meeting by D. E. Kleinmann of Harvard), and balloon-borne telescopes working at an altitude above 30 km. One advantage of balloon-borne systems is that they are already in action. The University College, London group reported the latest results of their broad-band (40–300 μm) survey of the galactic plane and maps of some individual sources, while G. G. Fazio of Harvard described 70 μm studies of several galactic HII regions and some external galaxies. K. Shivandan of Naval Research Laboratories, Washington, described multicolour photometry of the Orion nebula, and several groups described interferometer systems to be flown on aircraft or balloons giving detailed spectra of strong sources in the far infrared.

Another area of outstanding interest was the microwave background, with reports of Queen Mary College's balloon-borne interferometric observations in the range 0.7–2 mm and of Leeds's forthcoming experiment. Although the Berkeley group, who have recently successfully repeated the experiment, were not represented, much of the discussion centred on the conflicting atmospheric measurements and interpretation of the Queen Mary College and Berkeley groups. The issue remained unresolved, partly due to ignorance about the amount of ozone at altitudes above 30 km, and it is to be hoped that the Leeds experiment this summer will help resolve the issue. However both groups agree on the major issue, that the cosmic background spectrum turns over shortwards

of 1 mm as expected if it is the 2.7 K black-body relic of the fireball phase of a big bang Universe. The efforts of J. V. Narlikar (Tata Institute, Bombay) to explain this background as starlight thermalised by large graphite 'whiskers' ran into heavy criticism.

Ground-based astronomy had its moments too, with F. F. Gardner of CSIRO, Australia, L. T. Little of the University of Kent, and A. Gillespie of QMC reporting on molecular line studies (formaldehyde, H_2O and CO respectively) and P. E. Clegg reporting on Queen Mary College's 1 mm continuum studies of galactic sources, galaxies and QSOs.

The theoreticians produced a variety of models of dust-clouds and HII regions, disagreeing wildly over the composition, shape and size of the dust grains, ranging from ice and silicates to formaldehyde polymers, from spheres to whiskers and snowflakes, and from 0.1 μm to 1 mm in size. Clearly much work remains for both observers and theoreticians in this exciting field.

Rock fabrics

from Robert W. Cahn

THE British Standard Conference is organised by a learned or professional society, lasts 2.5 days, has two parallel sessions, costs £25 in registration fees alone, involves a pricey conference dinner, is attended mostly by academics and industrial scientists whose institutions are still willing to pay up, and evokes a British Standard Response to the effect that, with luck, just one paper will be really interesting to the British Standard Conferee. I claim a little artistic licence—the British Standards Institution has not yet, so far as I know, laid down a standard for the BSC—but all seasoned scientists will recognise the gestalt.

Some weeks ago, in mid-May, I had the good fortune to take part in a very different kind of conference in the Geology Department at Imperial College, London. It lasted one day, cost £0.50 to attend, had a single session, and was organised entirely by a graduate student, K. McClay, on behalf of a group of graduate students and university staff (the Tectonic Studies Group); the audience consisted of a sprinkling of British and foreign academics and a lot of students, post- and undergraduate alike. The topic was "Fabrics and Textures in Rocks".

The term 'fabric' in a petrographic context denotes both preferred orientations in populations of crystal grains (what metallurgists term 'texture') and the shapes and mutual dispositions of matrix grains and subsidiary phases (what metallurgists term 'morphology').

Texture arises from mechanical deformation of rocks under pressure and resultant recrystallisation when the temperature is high enough. The processes involved must be related to those that generate deformation textures and annealing textures in metals; the Tectonics Group evidently recognise this, because the two opening speakers (I. L. Dillamore of the British Steel Corporation and R. W Cahn of Sussex University) were invited to outline the present state of metallurgical knowledge on the two kinds of textures. The geologists present showed an impressive familiarity with the mathematical techniques used to interpret the genesis of deformation textures or the processes that arise during annealing of deformed metals. Thus G. Lister of the Geological Institute, Leiden, dealt with deformation textures in quartzite and S. White of Imperial College with recrystallisation mechanisms in the same rock, both drawing extensive metallurgical parallels.

Other contributors (E. Rutter and W. Shaw of Imperial College and R. G. C. Bathurst of Liverpool University) reviewed textures and fabrics of limestones, dolomites and marbles. D. J. Barber and H. R. Wenk (Essex University) applied electron microscopy to these rocks; this technique has only recently proved feasible for petrography, following the introduction of the ion-beam thinning technique, and it seems likely to prove as fruitful here as it has done in metallurgy.

The petrographer has the advantage over the metallurgist that he can examine his (optically anisotropic) minerals by transmitted polarised light, with the aid of a universal stage. Students of quartzite use this approach to determine a 'partial texture', that is, the distribution of the orientations of *c* axes both from one grain to another, and between different parts of the same grain : in this way, detailed textural and morphological information on a population of over 100 grains can be obtained within a day's work—information that would take a metallurgist, working with X rays and optical microscopy, or with electron microscopy, many weeks to assemble. Dr White in particular, using the *c*-axis technique, was able to draw on metallurgical experience to prove the close similarity of the processes that generate high-temperature textures in quartzite.

The remaining speakers, from Leeds and Leiden, dealt with more complex minerals, such as slates and peridotites. Here again, metallurgical processes such as strain-induced grain-boundary migration were identified.

One of the quartzite specialists spoke a few weeks later at a British Standard

Conference (good of its type!), devoted to textures in metals : to a witness who was able to compare the two occasions, it was plain that the geologists were much more ready to learn from metallurgical insights than metallurgists were willing to interest themselves in geologists' problems and techniques. This is a pity, because the two groups have much to contribute to each other.

Nuclear pores

from J. R. Tata

ONE of the many mysteries surrounding the organisation and function of the cell nucleus is how this organelle maintains concentrations of ions and small molecules (especially nucleotides) higher than those in the surrounding cytoplasm, while, at the same time allowing the large ribonucleoprotein precursors of polyribosomes to pass into the cytoplasm. The characteristics of the double nuclear envelope are such that some specialised site at the nuclear surface must regulate the nucleo–cytoplasmic transactions. A likely candidate for this function is the 'nuclear pore complex' (see Franke and Scheer in *The Cell Nucleus*, vol. 1, 219, 1974 for an excellent review). Although cytologists have for a long time known about the existence of pores on the surface of the nucleus, virtually nothing is known about their chemical nature and function.

Ultrastructurally, the size (diameter 600 ± 150 Å), but not the number, of nuclear pores is remarkably constant in all eukaryotic cells. Franke's group have done considerable work in defining optimal conditions for observing these structures by electron microscopy of intact cells and of isolated nuclei and nuclear membrane preparations. A well known ultrastructural feature of the nuclear pore is the 'annulus' of non-membranous material surrounding both the inner and outer rims of the pore (Callan and Tomlin, *Proc. R. Soc.*, B137, 367; 1950; Afzelius, *Expl Cell Res.*, 8, 147; 1955). What is particularly interesting about the annulus is its characteristic eightfold symmetry arising from eight 'annular granules' with diameters of 100–250 Å (Roberts and Northcote, *Nature*, 228, 385; 1970; Franke and Scheer, *J. ultrastruct. Res.*, 30, 288; 1970). The space within the pore is often seen to be filled with varying amounts of an 'amorphous' material as well as fibrils of about 50 Å diameter, themselves sometimes studded with smaller granules of 50–100 Å. Not surprisingly, several models for the structure of this complex ensemble have been proposed.

Blobel's group at the Rockefeller

University have undertaken to isolate and characterise the nuclear pore complex as a prerequisite for exploring its function. Recently, Aaronson and Blobel (*Proc. natn. Acad. Sci. U.S.A.*, **72**, 1007; 1975) have succeeded in isolating the nuclear pore complex of rat liver nuclei and giving a preliminary account of the composition and structure of this isolated subnuclear fraction. The procedure involves, first, the preparation of nuclear envelope, not by a method based on treatment with high concentrations of Mg^{2+} as previously used in Blobel's laboratory (Monneron, Blobel and Palade, *J. Cell Biol.*, **55**, 104; 1972), but one based on the use of DNase I (Kay, Fraser and Johnston, *Eur. J. Biochem.*, **30**, 145; 1972). The isolated nuclear membranes are then treated with detergent (Triton X–100) to solubilise phospholipid and remove the membraneous components; any residual chromatin is removed by precipitation of the nuclear pore complex with 0.3 M $MgCl_2$.

When examined in the electron microscope, Aaronson and Blobel's isolated nuclear pores were found to be associated with stretches of the peripheral lamina of the nucleus. The latter structure, which is distinct from the inner nuclear envelope, has been previously described in intact nuclei from other sources but not from rat liver (Fawcett, *Am. J. Anat.*, **119**, 129; 1966; Kalifat, Bouteille and Delarme, *J. Microsc.*, **6**, 1019; 1967). The lamina in the isolated preparation is 150 Å thick and connected to well preserved pores of diameter 700–900 Å whose lateral profile is 650 Å in diameter and 'goblet-shaped'. An interesting feature of these isolated structures is the absence of any membraneous material, which confirms an earlier suggestion by Aaronson and Blobel (*J. Cell Biol.*, **62**, 746; 1973), based on the preparation of 'nuclear ghosts', that the membrane of the double nuclear envelope is not essential for imposing or maintaining the structure of the pore complex. As regards its composition, the isolated rat liver nuclear pore complex is almost 94% protein with traces of RNA and DNA but no detectable phospholipid. The sugar content has not been determined and it would be interesting to know whether any glycoproteins are present. Electrophoresis on sodium dodecyl sulphate–polyacrylamide gels resolved the proteins of the isolated nuclear pore complex associated with the lamina into three major components of molecular weights 66,000, 68,000 and 69,000 with a minor component of much higher molecular weight. This simplicity of protein composition is, indeed, surprising in view of the complex structural elements of the nuclear pore.

What could be the functions of the nuclear pore complex in the intact cell? That the number of pores per nucleus is not constant, but is directly related to the rate of protein synthesis or ribosome accumulation (as during amphibian oogenesis), suggests a role in the nucleo–cytoplasmic transport of ribonucleoprotein particles. Isolated nuclear pore complexes do not offer any advantage in studying such a transport function, which can best be tackled by a combination of indirect methods of cell biology and cytology. But the advance made by Aaronson and Blobel offers the possibility of directly testing the role of the pore complex in carrying out terminal modification step(s) in the biogenesis of messenger and ribosomal RNA and the assembly of corresponding ribonucleoprotein particles. Thus, it would be interesting to see if the isolated nuclear pore complex has enzyme(s) for specific cleavage, polyadenylation or methylation of RNA, or whether it could somehow facilitate the terminal addition of protein(s) to 'immature' ribonucleoprotein particles just prior to their release into the cytoplasm. However, the extremely simple protein composition of the isolated nuclear pore complexes makes it likely that they retain few, if any, of such activities as they may possess in the intact cell.

Links between core and plates

from Peter J. Smith

IN a series of articles published about a decade ago, Wilson and his colleagues (see, for example, Wilson and Haggerty, *Endeavour*, **25**, 104; 1966) reported that they had established a statistical correlation between magnetic polarity and the degree of oxidation of the iron–titanium oxides in a wide variety of basalts Specifically, they showed that the higher the average oxidation state of the oxides within a basalt, the greater was the chance of the rock having reverse magnetisation. This result was, and remains, a mystery. The magnetic polarity of a rock depends on the polarity of the geomagnetic field at the time the rock formed; and the polarity and polarity changes of the field are presumably governed by processes in the Earth's core. Lava flows, on the other hand, originate in the upper mantle. The Wilson correlation thus seemed to imply an unlikely connection between core and upper mantle processes.

Since then, the so-called 'oxidation state–polarity paradox' has been largely ignored, partly because some workers have disputed its validity and partly because even those who accept the cor-

relation have been unable to decide whether or not it is significant enough to follow up. But the question of links between core and mantle was later revived by Hide and Malin (*Nature*, **225**, 605; 1970) who found a significant correlation between the Earth's gravitational field and the non-dipole geomagnetic field. This they attributed to undulations of the core–mantle interface, which would presumably influence, and be influenced by, both core and mantle motions. It also seemed to bear out in part Hide's (*Science*, **157**, 55; 1967) earlier prediction that "it would not be surprising to find that 'reversals' are correlated to some extent with other phenomena that may be affected by motions in the mantle, such as tectonic activity (mountain building, ocean-floor spreading, continental drift, and so forth) . . .".

The conceptual difficulty raised by the Wilson correlation of the mid-1960s had thus given way by 1970 to one possible physical model whereby core–mantle interaction could be achieved; since then other connections between mantle and core processes have been proposed. Won and Kuo (*J. Geophys. Res.*, **78**, 905; 1973), for example, have suggested that great earthquakes could cause the solid inner core to oscillate. Any such oscillation could be expected to influence fluid motions in the outer core and hence affect the apparently delicate mechanism of field reversal. Closer to the Earth's surface, on the other hand, the exciting earthquakes are intimately related to plate tectonic processes. The Won–Kuo hypothesis thus implies that correlations between geomagnetic field behaviour and events in the crust and upper mantle are not only possible but probable.

The near-surface phenomena envisaged here are altogether more conspicuous—Vogt (*Earth planet. Sci. Lett.*, **25**, 313; 1975) calls them 'first order' events—than the previous polarity–oxidation and gravity–magnetic field correlations. But the motion of lithospheric plates is also complex, making it difficult to define a general plate tectonic 'index' with which to compare geomagnetic behaviour. Any attempt at a general worldwide comparison is thus out of the question for the time being. As an alternative, however, Vogt has examined the four principal plates for particular examples of correlations between plate tectonic activity and geomagnetic phenomena, and has discovered enough of them to suggest that core–upper mantle coupling is real.

The first comes from the Hawaiian–Emperor chain of volcanic islands in the Pacific—a chain which comprises two more or less linear sections joining at an angle. Because these islands

increase in age from one end of the chain to the other, they have been attributed to the motion of the Pacific plate over a stationary hot spot, possibly related to a mantle plume (although other explanations are possible). The bend in the chain is then thought to be due to a sudden change in the direction of Pacific motion which can be dated from the monotonic age pattern of the islands at 42–45 Myr. But the geomagnetic reversal frequency also changed significantly at that time. Thus within the errors of dating, the only conspicuous changes in Pacific plate motion and reversal frequency during the last 70–80 million years coincide Moreover, other tectonic changes took place at the same time in other parts of the world. In the Reykjanes ridge area south of Iceland, for example, the 45 Myr isochron marks the largest change in the direction of motion between Greenland and Europe, a change which gave rise to the generation of numerous small transform faults

The second magnetic event examined by Vogt was the ending 70–77 Myr ago of the Mercanton interval, a 30–40 Myr period during which there were few or no reversals At this time, seafloor spreading first began south of the Rockall Bank in the northeast Atlantic and the Meteor and Corner Rise seamount groups were formed. In addition, there was a major change in the trend of the fracture zones in the central North Atlantic, a reflection of what appears to be the most prominent change in spreading direction between North America and Africa during the whole 180 Myr existence of this ocean basin Other major plate tectonic changes also took place about 115 Myr ago when the Mercanton interval began and the earlier Keathley sequence of reversals (150–115 Myr) ended

But if these correlations are manifestations of core–mantle coupling, the problem of precisely how the coupling occurs remains. Vogt clearly favours a return to the idea of mantle-wide convection, the most obvious and traditional physical link between the core–mantle boundary and the near-surface processes In this case, the geometry of the convection would change from time to time, thereby directly influencing the plate motions above and at the same time changing the boundary conditions at the core–mantle interface and hence the reversal frequency within the core. Whole-mantle convection has not received much support in recent years. Since Wilson's basalt correlations (which are not mentioned by Vogt) were discovered, however, an alternative form of mantle-wide motion has been proposed in the form of mantle plumes. These would seem to offer a connection between core and

plates which is both more direct and perhaps more attractive to today's earth scientists.

Convergence of information in thermal pathways

from Shin-Ho Chung

NEUROPHYSIOLOGICAL studies of different sensory systems have shown that incoming information undergoes drastic modification as it proceeds along the pathways of the nervous system, the degree of modification increasing as messages proceed centrally. Such hierachical organisation is a general principle upon which all the nervous system is constructed, and understanding the transformation of information at each level has been the dominant preoccupation of sensory neurophysiologists over the past two decades. Two recent articles by Hellon, Hensel and Schafer (*J Physiol, Lond.,* **248**, 349–357, 1975) and Hellon and Mitchell (*ibid,* 359–376) describe the successive steps taken by the nervous system in processing the information generated by thermoreceptors.

Primary sensory fibres arising from 'cold' and 'warm' receptors in the rat scrotum show action spectra resembling bell-shaped curves when frequency of impulses is plotted against scrotal temperature. The size of each receptive field is about 1 mm². These inputs are integrated by cells in the spinal cord; however, cells in the cord no longer have spot-like receptive fields but are sensitive to temperature changes over the entire extent of the scrotum Alteration of the response pattern is most clearly seen in the behaviour of cells in the thalamus. Unlike the bell-shaped action spectra of primary afferents, thalamic cells exhibit an on–off pattern of firing (see figure). A cell remains silent until a critical temperature is sensed, after which it fires at its maximal discharge frequency.
Action spectra of 'warm' receptors in the rat scrotum (broken line) and of thalamic neurones (continuous line). From Hellon and Mitchell, *J. Physiol., Lond.,* **248**, 349–357; 1975.

Different cells in the thalamus have different critical temperatures (Hellon and Misra, *J Physiol, Lond.,* **232**, 389, 1973) Thus, at the expense of spatial discrimination, activities of primary afferents are integrated by the central nervous system and, as thermal assault on the testes intensifies, more neurones are recruited in their defence. This is a sensible physiological arrangement, for the ability to discriminate which side of the scrotum is warmer is unlikely to serve any useful biological purpose

Language understanding by computer

from Arnold G Smith

A conference at MIT on June 10–13 entitled "Theoretical Issues in Natural Language Processing" was aimed at scientists working on computer models of language either in order to study the human mind, or with the more pragmatic goal of "teaching computers to speak English"

ATTEMPTS to create computer systems which understand English raise issues which reach deeply into linguistics, computer science, psychology and even philosophy. Earlier work in this field led to the realisation that a reasonable model of language comprehension would require the active use of a potentially vast amount of 'common sense'. Common sense is called upon continually though often unconsciously in making sense of what we hear, but how does one design a computer program to function analogously, organising a large corpus of knowledge so as to have the appropriate facts available at the appropriate moment? Marvin Minsky's concept of frames is the currently fashionable approach to answering this question, although it generated a great deal of controversy at the meeting.

Minsky (from MIT) was there to explain his ideas. He uses the term 'frame' basically in the sense of frame of reference, in the light of which one makes sense of a sentence, a story or a scene. An intelligent person presumably has a very large number of such frames stored away in a richly interconnected structure. At any point one of these frames is in charge of interpreting and interacting with the current environment. It has its own procedures which look for evidence to confirm its relevance to the situation at hand and, when something turns up which is inconsistent with or beyond the scope of the current frame, it has

links to likely alternative frames which will have a good chance of making sense of the input. Each frame has slots for the kinds of information it expects to find and, until these slots are filled, they are likely to have default assignments. My frame for bedrooms, which will be evoked if you start to tell me what happened in your bedroom, has defaults for things like the size of the room, and the style of the bed. In the absence of specific information, I will simply assume the presence of a normal bed to supply the default. If you then say that ten people slept in your bed last night, I will expect them to have been very crowded. On the other hand, an earlier description of your particularly huge bed would have displaced the default and so have led to different inferences. As long as a particular frame is in charge, it coordinates the information that comes in, making inferences to connect what might otherwise look like unconnected bits of evidence, and calling on other frames with narrower expertise to work with details of the situation. In this way, frames supply an interpretive context and constitute their owner's model of the world

Some critics regard the frame theory as a re-statement of ideas long current in philosophy and psychology. In fact Minsky explicitly disavows claims of formal precision for his theory, but it is oriented specifically towards computer models of cognition. Terry Winograd of Stanford pointed out various ways in which frames were suggestive of, but not merely equivalent to, a variety of other paradigms from artificial intelligence—scripts, patterns, decision trees, semantic nets, actors, and production systems. He suggested that frames share important characteristics with each of these, but that you miss part of the point of frames by limiting your perspective to any one. I see the frames concept not as a unified theory but as a vantage point for discussing the shortcomings of present systems and pointing to some of the properties that better cognitive models must have.

A workshop session on methodological issues considered the difficult problem of evaluating and comparing the contributions of different projects in the field. Two factors seem to exacerbate the situation. One is the notorious lack of perspicuity of large computer programs. The other is the fact that language is so inextricably involved with everything we do that it is hard to gain the perspective needed to see how a particular piece of work fits into the whole domain. W. A. Woods, of Bolt, Beranek and Newman, presented a particularly, well-reasoned paper on this subject. He argued,

among other things, the need for cognitively efficient representations—models whose explicit structure can act as a guide to understanding the theory they incorporate.

There was somewhat less than one might have expected in the way of new results reported at the meeting. Several people were in the process of working out some of the implications of their version of the frames idea. Roger Schank and his colleagues at Yale, for example, described initial work with a program which knows what to expect when it hears a story about someone going to a restaurant. A few sentences relating John's experience eating a lobster dinner will trigger off a variety of inferences about who cooked the lobster, how it arrived at John's table, that if he gave the waiter a large tip it was probably because he enjoyed the lobster, and so on. And Sheldon Klein, of the University of Wisconsin, passed out copies of a seven page murder story generated by his computer in nineteen seconds! But there was more emphasis on what people had been thinking about methods and paradigms than on what they had learned about language.

Motion of muscle proteins

from a Correspondent

THE dynamic behaviour of proteins—their rotation and internal flexibility—are important for many aspects of their biological function. This is particularly true in the actomyosin system of muscle, where these phenomena are intimately related to the mechanism of contraction.

In such a situation, it is obviously necessary to be able to study the behaviour of individual components of the system, and in practice this means they must be labelled in some way. Two such labelling techniques have been widely used over the last few years. In the first, the protein is labelled with a strongly fluorescent group; the time course of the decay of the anisotropy of the fluorescence after excitation with a short flash of polarised light can then yield a value for the rotational correlation time, τ_c, of the label. The second approach, known as spin-labelling, involves the attachment of a stable nitroxide free radical to the protein. The value of τ_c is obtained by careful analysis of the shape of the electron paramagnetic resonance (EPR) spectrum of the nitroxide. Both of these methods are at their best in the study of relatively rapid motions—those with correlation times shorter than a few times 10^{-7} s.

Recently a new EPR technique has been developed (Hyde and Dalton, *Chem. Phys. Lett.*, **16**, 568; 1972; Hyde and Thomas, *Ann. N.Y. Acad. Sci.*, **222**, 680;

1973) which promises to extend the application of the spin-labelling method into the time range 10^{-7}–10^{-3} s. This technique, known as saturation transfer EPR spectroscopy, depends upon the use of partially saturating microwave fields and out-of-phase detection to obtain a spectrum whose shape depends critically on the rate of rotational diffusion. The theory of the method is discussed by Thomas and McConnell (*Chem. Phys. Lett.*, **25**, 470; 1974); the maximum sensitivity to motion occurs when $\tau_c \sim 1/\omega_m \sim T_1$ ($\sim 10^{-5}$ s), where ω_m is the modulation frequency and T_1 the electron spin-lattice relaxation time.

This technique has now been applied to myosin and its interaction with actin (Thomas, Seidel, Hyde and Gergely, *Proc. natn. Acad. Sci. U.S.A.*, **72**, 1729, 1975). The spin label was attached to a thiol in the globular 'head' (subfragment 1) of the myosin molecule. The correlation time of the isolated subfragment 1 was 1.8×10^{-7} s, and for myosin this increased to 3×10^{-7} s. Thus there is only about a 40% decrease in τ_c when subfragment 1 is cleaved from myosin, although the molecular weight decreases by a factor of more than four. There must therefore be considerable internal flexibility in the myosin molecule; the same conclusion was drawn earlier from closely analogous fluorescence experiments by Mendelson *et al.* (*Biochemistry*, **12**, 2250, 1973). The saturation transfer EPR technique can also be applied to supramolecular complexes of myosin, which are essentially beyond the range of previous methods. Aggregation of myosin into filaments led to a ten-fold increase in correlation time, indicating that there was still considerable flexibility of the 'heads' of the myosin molecules. In contrast, addition of actin to either subfragment 1 or myosin led to a very substantial immobilisation of the label, giving a correlation time of 10^{-4} s. This indicates that the globular 'head' of myosin is essentially irrotationally bound to actin.

The saturation transfer EPR method shares two problems with the other labelling methods. Motion of the label relative to the protein to which it is attached will obviously lead to erroneously short values of τ_c for the protein. Though this does not seem to happen in the case of subfragment 1, it may limit the application of these methods to some systems. In addition, for a non-spherical protein, rotational motion cannot strictly be described by a single correlation time, and the value obtained will depend on the orientation of the label relative to the hydrodynamic axes of the protein. But notwithstanding the difficulties in precise quantitation, it is clear that this new method is a valuable addition to the armoury of the physical biochemist interested in supramolecular structure.

review article

The origin of nuclei and of eukaryotic cells

T. Cavalier-Smith*

A new theory not involving symbiosis is proposed for the origin of eukaryotic cells. It explains how the evolution of phagocytosis by a wall-free blue-green alga would have created selection pressures leading directly to the formation of all characteristic eukaryote organelles and cell properties including mitosis, meiosis and sex.

THE problem of the evolutionary origin of eukaryotes has been a major one in biology ever since the fundamental distinction between prokaryotic and eukaryotic cells[1-3] became clear. It is generally accepted that eukaryotes evolved from prokaryotes, but how this happened is unknown[4-5]. Certain similarities between mitochondria and bacteria and between plastids and blue-green algae have led to the recent revival[6-8] of old theories[7-11] suggesting that these eukaryote organelles are derived from intracellular symbiotic prokaryotes and also to the suggestion[7,12,13] that microtubules, centrioles and flagella are similarly derived. This "serial endosymbiosis theory of the origin of eukaryotes", which supposes that eukaryotes evolved as a result of the symbiosis of from three to six[7,14-16] genetically different prokaryotes, has received more support[2-19] than the alternative theory that they evolved from a single prokaryote species by intracellular differentiation[20-22].

My strongest criticism of the symbiosis theory is that it fails to explain how the eukaryote condition itself (that is, the nucleus) evolved[24] Most proponents of the symbiosis theory[5-19] do not seriously discuss the origin of the nucleus, but assume it to have evolved gradually from a prokaryote nucleoid

Eukaryote nuclei differ in at least three fundamental ways from prokaryote nucleoids. They are surrounded by a double-membraned envelope bearing characteristic pores; they contain several non-identical chromosomes which are linear and not circular; segregation occurs by mitosis which always involves spindle microtubules. Here I show how these differences could have arisen and argue that the same selective forces would also have led to the formation of mitochondria, plastids and other characteristic eukaryote organelles and properties.

Like Stanier[5] I consider the evolution of endocytosis (phagocytosis and pinocytosis) to be of key importance in eukaryote evolution. But this is not because it enabled them to harbour endosymbionts. (I believe endosymbiosis to be one of many secondary and almost inevitable consequences of phagocytosis, but not the cause of the eukaryote condition.) It is because phagocytosis provided not only the selective pressure but also the physical mechanism (membrane budding and fusion) for cell compartmentation by intracellular membranes. Cell compartmentation explains not only the origins of mitochondria, plastids and nuclei, but also their characteristic properties more simply than does the symbiosis theory.

I assume that the ancestor of all eukaryotes was a single-celled, facultatively phototrophic, blue-green alga, unable to fix nitrogen but possessing oxygen-evolving photosynthesis and oxygen-using respiration based on cytochromes and other electron transport molecules borne on intracellular thylakoid

*Address: Department of Biophysics, University of London King's College, 26-29 Drury Lane, London WC2B 5RL, UK

membranes (Fig. 1a). The first step leading to eukaryotes must have been the loss of the cell wall by such an alga living in a shallow bacteria- and detritus-rich benthic environment (Fig. 1b). Cell wall degrading enzymes like those abundantly secreted by soil myxobacteria[3] may initially have produced a blue-green algal "L-form" which subsequently became a stable L-form. Whatever the mechanism, wall loss was essential for phagocytosis and explains the complete absence of peptidoglycan cell walls in eukaryotes.

Many blue-green algae (in contrast to bacteria, whose minute size would make the evolution of phagocytosis difficult) have cells as large as those of unicellular eukaryote algae[3,25], so size would be no barrier to the acquisition of phagocytosis—they would already be large enough to engulf bacteria. A strong selective force would favour any blue-green algal L-form able to develop phagocytosis and so become a "pre-alga". A phagocytic pre-alga could photosynthesise by day or during the Arctic summer, and phagocytose by night or during the Arctic winter (or in any dark environment). This versatility would give it a clear advantage over other blue-green algae (mostly obligate phototrophs) as well as over bacteria since it would seldom lack food.

Evolution of phagocytosis

I suggest that there is a fundamental similarity between the mechanism of plasma membrane budding to form a phagosome and the mechanism of eukaryote cell cleavage during cytokinesis. Both involve invagination, breakage and resealing of membranes. Clearly they differ in the timing and location of these processes. But I think these reflect differences in control rather than in the basic mechanism, and that the blue-green alga evolved cleavage first and endocytosis evolved subsequently from it.

Phagocytosis, like division, reduces the surface area of the plasma membrane but, unlike division, creates separate intracellular phagosome membranes. Extensive endocytosis is therefore not possible unless the phagosome membrane can refuse with the plasma membrane after absorption of its contents. Thus phagocytosis could not evolve in the absence of this reverse process (exocytosis—frequently the basis of secretion in eukaryotes). Since, in growing (but not in non-growing) cells, limited exocytosis is possible in the absence of endocytosis, exocytosis probably evolved before endocytosis (either as a mechanism of membrane growth additional to the insertion of individual molecules into an existing membrane, or more probably for secretion of extracellular digestive enzymes). Any blue-green alga possessing both cleavage and exocytosis would be preadapted for the evolution of phagocytosis. Figure 1 shows a possible evolutionary sequence.
Fig. 1 The evolution of phagocytosis A blue-green alga loses its cell wal (*a*) and evolves an acto-myosin dependent cell cleavage mechanism (*b*). The resulting L-form develops extracellular digestion (*c*) by direct secretion of digestive enzymes across the plasma membrane and/or by exocytosis by protolysosomes (L) derived from thylakoids specialising in the intracellular storage of digestive enzymes. Efficiency is increased by partially (*d*) or completely (*e*) surrounding the prey before liberating the enzymes. Finally in the fully phagocytic "pre-alga" only the plasma membrane engulfs the bacterium (B) and the protolysosome fuses with the resulting phagosome. DNA (D), with its attached polysomes, and most thylakoids (T) remain unchanged.

I suggest that not only exocytosis, endocytosis and cleavage but all cases of controlled membrane budding and fusion in eukaryotes (for example, budding of smoth vesicles from rough endoplasmic reticulum or Golgi apparatus, or the fusion of transmitter vesicles with presynaptic membranes) have a common basic mechanism, which I call cytosis. Since much of eukaryote cell evolution can be understood in terms of a diversification in the uses of and increased control over the timing and positioning of cytosis it is a pity that so little is known of its mechanism. Conceivably membranes containing polyunsaturated fatty acids (found in blue-green algae and in eukaryotes but not in bacteria[3]) were a prerequisite. Although phospholipid membranes have a natural tendency to bud and fuse I suggest that cytosis also universally involves a calcium-activated contractile actin–myosin-like microfilament system[26]. The smplest explanation for the universality of actomyosin in eukaryotes[2] is that it was the essential molecular innovation which made the origin and evolution of eukaryotes possible, and that it originated when our blue-green algal ancestor lost its cell wall and the prokaryote type of cell division by located growth of a semi-rigid membrane was

superseded by actin–myosin mediated cleavage by furrowing, that is by cytosis.

Subsequently, modifications led to exocytosis and then phagocytosis. Then selection for greater phagocytic efficiency would occur. Cells would be selected for greater size and for the ability to phagocytose over their whole surface. The actomyosin system would diversify independently to produce amoeboid movement—greatly increasing predation efficiency—and cytoplasmic streaming and organelle movement—speeding up contact between phagosomes and protolysosomes.

Origin of the spindle

Such a highly mobile cell surface would interfere with chromosome segregation (dependent in prokaryotes on attachment to a stable semi-rigid membrane[2]). Endocytosis of the chromosome attachment site would be especially serious, so there would be strong selection for a new rigid non-membrane segregation mechanism—the microtubule. Initially microtubules joined the two membrane attachment sites (Fig. 2*a*) and pushed them apart as they grew (like pole-to-pole spindle microtubules, the only universal components of modern spindles[24,29]; or like the reverse of sex pilus retraction (microtubules and sex pili are both tubular and interact with chromosome attachment sites—are they related or just functionally similar?)). This ensured that one chromosome ended up on each side of the cleavage furrow (a mechanism to ensure that cleavage was at the equator was also essential).

Efficient segregation by microtubules ended the selective advantage of chromosome attachment to the plasma membrane; the attachment site would soon be endocytosed and thereafter remain inside the cell as a protonuclear envelope (Fig. 2*b*), making the entire cell surface available for phagocytosis. The origin of mitosis was not a consequence, as commonly supposed, of the greater size or greater number of eukaryote chromosomes but was instead the essential prerequisite for these changes.
Fig. 2 The evolution of spindle microtubules (M) in the amoeboid pre-alga, as a device to push the two circular daughter chromosomes (here shown twisted into supercoils) apart to opposite poles of the cell to ensure that one is present in each daughter cell produced by the cleavage furrow (C). Initially chromosomes were attached to the cell membrane (*a*) but later (*b*) the attachment sites were endocytosed to become protonuclear envelope, N. Phagosomes (P), protolysosomes (L) and thylakoids (T) are also shown
Fig. 3 Diversification of the (ribosome-covered) protolysosome (a) (originally derived from a ribosome-bearing thylakoid). The evolution of membrane budding by cytosis allowed differentiation and specialisation between the "rough" ribosome-bearing membranes and their various smooth-membraned products (b)

Cytosis and origin of sex

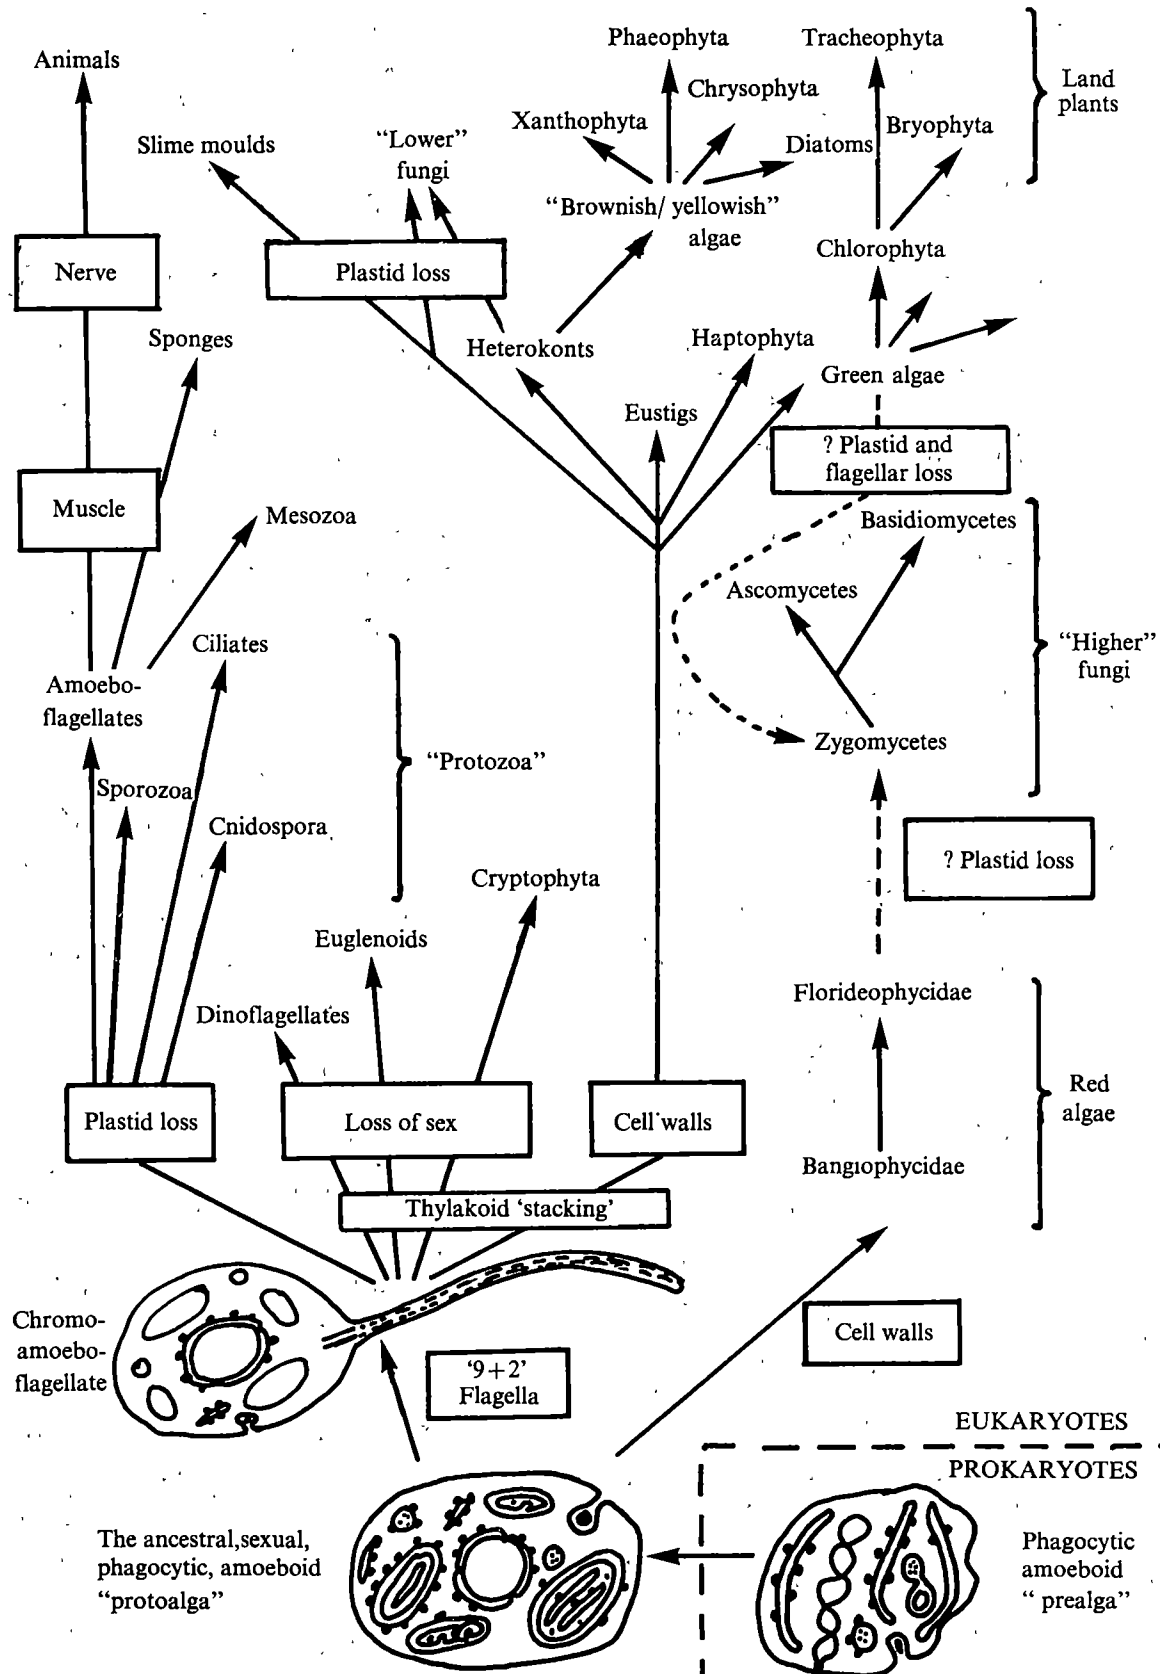
Cytosis also provided the mechanism for cell fusion, which must have evolved in a wall-free cell, and initially was probably poorly controlled and more frequent than today. Its initial selective advantage would be greatest in times of starvation (starvation still triggers sexual differentiation in many algae and fungi) when fused cells would have twice the internal food supply of unfused competitors. I suggest that it originated in this way in the amoeboid pre-alga before even the development of the nuclear envelope; many properties of eukaryote chromosomes are best explained by the simultaneous evolution of mitosis and meiosis.

With only one circular chromosome per cell meiosis was unnecessary; the primitive mitosis described above would ensure segregation Recombination was easy in the absence of a nuclear envelope. Assuming reciprocal and random recombination (as in the *rec* system of *Escherichia coli*), an even number of crossovers would produce two recombined daughters but an odd number would produce double length circular DNA. This increase in genome size and redundancy would immediately provide raw material for rapid evolution of new functions and create multiple replicon origins. The random release of spare copies of genes from stabilising selection pressure would break up operons. But an indefinite increase in DNA would be disadvantageous (and double-sized DNA molecules would often be broken during segregation because of their two membrane-microtubule attachment sites), and so selected against—most simply by the chromosomes becoming linear by the mechanism I previously suggested[30]. With linear chromosomes odd as well as even numbers of crossovers will give normal reciprocal recombinants thus terminating the explosive burst of new genome creation.

Selection for increased recombination efficiency would lead to chromosome pairing mediated by a synaptinemal complex. Efficient pairing would remove the necessity for having all the DNA in one molecule (previously necessary to prevent aneuploidy). Indeed, positive selection for chromosome fragmentation by the mechanism previously suggested[30] is likely because this will give increased recombination by independent assortment of non-homologous chromosomes. Thus the most distinctive features of eukaryote chromosomes, mitosis, meiosis and sex probably all evolved in a very short space of time, during the earliest stages of eukaryote evolution as a direct consequence of the evolution of cytosis. Chloroplast fusion[31] was probably a late development.
Fig. 4 The evolution of plastids, mitochondria and nuclei by fusion of DNA-associated thylakoids or endoplasmic reticulum cisternae. a, Plastids resulted from association of photosynthetic and plasmid-associated thylakoids to form a compartment containing DNA, ribosomes and Calvin cycle enzymes. b, Mitochondria resulted from fusion of plasmid-associated respiratory thylakoids to form a compartment containing Krebs cycle and fatty acid metabolising enzymes. c, Cell at intermediate stage with three distinct compartments: mitochondria (M), plastids (P) and nucleocytoplasm, whose protonuclear envelope (N) with six linear chromosomes will eventually fuse (d) to form a nuclear envelope separating the cytoplasm with protein synthesising enzymes from the nucleus with DNA and RNA synthesising and processing enzymes.

Cell compartmentation and organelle origins

Increase in cell size and in diversity of cell components in response to the selection pressures described above would dilute each component and lower the efficiency of reactions. This could be prevented only by vastly increasing the amounts made and the total concentration of materials or by dividing the cell into compartments each specialising in different functions. Cells adopting the latter course would have a tremendous selective advantage. The evolution of cytosis not only provides the selective pressure but also the mechanism

Fig. 5 A possible pattern of eukaryote diversification following the formation of the first true eukaryote (red algal-like) "proto-alga"


for compartmentation.

The early ribosome-covered protolysosomes (Fig. 1) were already separate compartments (because of the need to secrete, and protect the cell from, their hydrolases) and could very simply have differentiated into rough and smooth endoplasmic reticulum, lysosomes, peroxisomes and Golgi apparatus as shown in Fig. 3; they and the original thylakoids could have formed the plastid, mitochondrial and nuclear envelopes by fusion as shown in Fig. 4.

Initially ribosomes, DNA, RNA and nucleic acid polymerases were divided into 3 compartments, Fig. 4c. The nucleoid in the cytoplasmic compartment was segregated by microtubules and its DNA became linear and fragmented as suggested above. Chloroplast and mitochondrial plasmids were present always in large enough numbers per cell not to require a special segregation mechanism, and so (generally) remained circular because with multiple copies the selection pressure for linearity was much less. In both plastids and mitochondria, DNA, messenger RNA and ribosomes are in the same compartment (as in bacteria) so would be expected to retain many prokaryotic properties. By contrast nuclear DNA and RNA became segregated from cytoplasmic RNA and ribosomes (Fig. 4d) so ribosomes could no longer start translating messenger while it was still being made and new mechanisms were required for the transport of messenger and nascent ribosomal subunits across the nuclear envelope. (Nuclear pores allowing free passage of small and medium sized molecules, but not larger ones and macromolecular complexes[32], probably arose in response to the need to regulate nucleocytoplasmic exchange.) Nucleocytoplasmic separation would have imposed new selective forces on DNA and RNA. Though it is premature to speculate on their nature I predict that they will go far to explain other differences between nucleocytoplasmic genetic systems on the one hand and prokaryote/mitochondrial/plastid ones on the other.

The origin of the unique features of cytoplasmic ribosomes and of nucleoli probably dates from the time when the pre-alga became completely compartmented to form the first true eukaryote—the proto-alga (Fig. 5). I suggest that originally the pre-algal plasmids and nucleoid had identical ribosomal DNA present in multiple tandem copies (many copies were needed because of the large cell size), and that this identity was maintained by recombination involving a ribosomal DNA episome (replicating as a rolling circle[33]). But, after complete compartmentation, DNA and ribosomes could no longer cross the membranes (but proteins could be secreted directly across them by membrane-bound ribosomes[34]), so plasmid and nuclear ribosomal DNA then evolved independently. This predicts that gene amplification and rolling circle replication of nucleolar DNA will be found universally in eukaryotes. The existence of a distinct nucleolus is connected with the need to transport both ribosomal and messenger RNA across the envelope.

Nucleocytoplasmic separation, the breakup of operon-like gene clusters and the production of large amounts of redundant DNA as suggested above, were probably enough to lead to completely novel systems of gene regulation in eukaryotes[36] which would subsequently make possible the evolution of highly differentiated multicellular organisms. In future research it will be important to determine, by careful comparison of primitive unicellular eukaryotes and differentiated multicellular ones, which features (for example, giant heterogeneous nuclear RNA[35], repetitious DNA[36], palindromes[37]) are universal features of eukaryote genetic systems and which are specifically associated with complex multicellular differentiation. ·

Comparison with symbiosis theories

My model is superior to symbiosis theories in three main ways. First, it explains how eukaryote nuclei evolved. In doing so it provides a plausible selective advantage for the evolution

of all major features of eukaryote nuclear structure and genetic systems (except the presence of histones). According to my theory the absence of sex in an entire major eukaryote group, for example euglenoids[38], is the result of secondary loss and not a primitive feature. The absence of histones in dinoflagellates[39] might also be a secondary feature perhaps resulting from the loss of sex. If so the primary function of histones could have been efficient packing of DNA to facilitate meiotic pairing and segregation.

Second, it gives plausible reasons for the differences between nucleocytoplasmic and prokaryote/plastid/mitochondrial genetic systems. This the symbiotic theories do not do; they ignore the fact that both kinds of genetic systems must have evolved from prokaryote systems, and so resemblances are not at all surprising[21]. The real problem is why the nucleus is different, which symbiosis does not explain.

Third, it is far simpler than any symbiotic theory. These postulate two to five separate symbiotic events[16]. Though the symbiotic origin of mitochondria and chloroplasts is a possibility (and one compatible with the origin of nuclei by the mechanism proposed here), the resemblances between them and prokaryotes are to be expected on either theory. The symbiotic origin of flagella and the mitotic apparatus[7,12], is untenable for many reasons[8,24]. The idea that the complexities of sex and meiosis evolved independently 27 times (Fig. 2–6 of ref. 7) in much the same way is incredible.

Eukaryote diversification

I regard the absence of flagella in red algae (possibly also in higher fungi if they evolved from them by plastid loss[40]) as primary[20,21,24]; they are probably the most primitive living eukaryotes. Though some amoebae without flagella could have evolved from primitive red algae by plastid loss, most eukaryotes must be derived from a red algal line which evolved 9+2 flagella from aggregates of microtubules. The selective advantage is obvious: they could colonise a completely empty niche as the first marine phytoplankton (or if, unlike today[25], there were then blue-green algae in the open sea, become their first predators) through their new ability to stay in suspension and migrate to the level most suitable for photosynthesis and (or) predation. By loss of phycobilins and the development of other pigments a great variety of brownish and green phytoflagellates were formed[39,41,42]. These were the ancestors of all plants and, by plastid loss, of non-photosynthetic protists and animals (Fig. 5). The generality of the circadian clock in eukaryotes (and possible absence in bacteria) is easiest to understand if it evolved in a photosynthetic common ancestor to maximise photosynthesis by day and division by night. Complex polysaccharide–protein cell walls or surface coats, often secreted by the Golgi apparatus, evolved in many lines. Adhesion between such extracellular layers led to multicellularity, in many separate lines[43,44].

Comparative studies clearly indicate that centrioles are derived from basal bodies[45] and probably became secondarily associated (perhaps on several independent occasions) with the spindle poles, and are not essential for mitosis[24,46]. Chromosome-to-pole spindle microtubules probably evolved long after the origin of mitosis, but only in some eukaryote groups[24]. Microtubules have also independently evolved into many other organelles of motility, such as axostyles[47], axopods[48], suctorian tentacles[49] and haptonemata[30] as well as numerous structural elements as in the cortex of protist cells[39,50], the phycoplast[51] or neurotubules[52].

My view that the origin of all eukaryotic organelles and genetic systems can be traced back to two fundamental innovations, (1) cytosis involving actomyosin and (2) microtubules, has many implications (too numerous to discuss properly here) which can be tested by observations on living organisms. Unfortunately evidence from the fossil record[42,53] will be very hard to come by because the ancestral eukaryotes had no cell walls and because the changes postulated could have occurred very rapidly indeed, possibly in a very restricted locality.

Palaeolithic remains at the Hadar in the Afar region

Gudrun Corvinus

Institut für Urgeschichte, University of Tübingen, Schloss, 74 Tübingen, Germany

Studies of Plio–Pleistocene deposits along the Awash River in the Hadar region of Ethiopia have revealed for the first time several Palaeolithic sites. In addition to a large number of artefacts which provide evidence of early to late Stone Age industries the deposits have also yielded a rich vertebrate fauna including what may be the earliest hominid remains yet discovered.

NEAR the confluence of the rivers Awash and Hadar, about 60 km ESE of Bati, the latter river has cut deeply into the gravel covered surface of the floor of the Ethiopian Rift (see Fig. 1) and has exposed 105 m of fluviatile, lacustrine and tuffacious sediments of Plio–Pleistocene age.

The flat surface of the rift floor consists of an extensive boulder gravel, 3–6 m thick, which lies unconformably on the Upper Pliocene and Lower Pleistocene sediments of the Hadar Series. This gravel extends from the foot of the Ethiopian Rift escarpment in the west, thinning slowly to beyond the Awash River in the east[1]. It seems to have been deposited as a series of large confluent fans derived from the escarpment, which form an extensive behada or peripediment. It is not cemented and consists of well rounded to subrounded boulders and pebbles 30–40 cm in size, set in a matrix of sandy, calcareous silt. The pebbles are neither sorted nor oriented into any stream direction. The gravel is probably of Middle Pleistocene age, as indicated by Early Stone Age (ESA) implements found *in situ*; no fauna has yet been found.

Beneath the boulder gravel the Hadar has exposed a 105-m section of the Hadar sediments—Upper Pliocene and Lower Pleistocene fossiliferous beds of sandstones, sands and clays, and occasional tuffs. A very rich vertebrate fauna indicates a relative age of more than 3 Myr for these beds[2].

Fossils of *Australopithecus*, at least 3 Myr old[3], were found for the first time during the survey of the Lower Hadar sediments by members of the 1973 International Afar Expedition. These included three fragments of femur and one fragment of tibia from a small hominid and a piece of cranium (mastoid) from a more robust *Australopithecus*.

In the Hadar area the terraces of the Awash River are not very pronounced. The Awash meanders in a flood plain about 1 km wide. In the inner parts of the meanders the silty and fine-sandy, modern alluvial plain is covered by a thick riverine forest comprising various species of acacia and tamarisk. The height of the plain is not more than 2 m above low water level.

A terrace 3–5 m high runs along the inner meanders beyond the riverine forest. It is covered by a thin, bouldery gravel within a sandy matrix. The same terrace also stretches along the Denen Dora tributary further west. There, a broad terrace covered by large boulders and pebbles extends between the Denen Dora and the Sidi Hakoma tributary, rising to 4 m above the bed of the Denen Dora.

Any pre-existing higher terraces of the Awash and the Hadar have been destroyed by erosion. Significantly, many—though not all—of the Badland Hills, 25–90 m in height along the Awash, have a covering of loose, well-rounded boulders in a sandy–silty matrix lying unconformably on earlier Hadar deposits.

All the boulders which cover the river terraces and erosional surfaces in the Hadar area have been derived from the erosion of the Middle Pleistocene boulder gravel. The pebbles of this
Fig. 1 Sketch map of the Hadar region. Stippled areas, Badland Hills; horizontal lines, rift floor more than 100 m above the Awash River; long straight lines, faults; ●, artefact localities.

boulder gravel consist of amygdaloidal basalt, trachyte, rhyolite and ignimbrite, derived from the Tertiary Trapps of the Ethiopian Plateau. They have a red-brown to dark-brown polish when they have been exposed for a long time. The boulders on the erosional surfaces and terraces are of the same type but they often have a deeper, sometimes black polish.

We may assume that the boulder cover of the Badland Hills represents a residue of boulder spreads which were redeposited on erosional surfaces during the downcutting of the area and which were originally derived from the boulder gravel of the Ethiopian Rift floor.

Artefact sites

Artefacts of all ages occur everywhere in the region (Fig. 1) both on the surface and in the river gravels. At some localities up to 45 specimens were found. They occurred mostly on the surface and were rarely *in situ*, except for a few Middle Acheulian bifaces found in recent, reworked river gravels. In most cases the artefact assemblages were mixed; that is, Middle Stone Age (MSA) flakes and cores have been found together with Late Stone Age (LSA) flakes, cores and waste. Choppers and bifaces also occur occasionally among them. The bifaces, choppers, modified pebbles, and the MSA flakes and cores, are all made from the local boulders of trachyte and basalt. The LSA people however, used siliceous material, such as jasper, chalcedony and, rarely, fine grained basalt. The subrecent specimens are of obsidian and quartz.

A few sites, however, contained assemblages of an homogeneous character. Sites Hdr 9 and Hdr 22 (Fig. 1) are Acheulian sites situated on the low terrace of the Denen Dora tributary. Bifaces were found at site Hdr 9 on the surface of the wide, flat, 4-m terrace of the Denen Dora near the confluence with the Awash. At site Hdr 22 the assemblage was found on the 1.50–3.00-m recent terrace in the middle part of the stream. The bifaces from that site do not, on the whole, have a dark-brown polish but have a grey to white, calcareous patination or no patination at all. They must therefore have been eroded out from the bouldery deposit of the terrace, rather than having been brought down from a higher level; most of the other pebbles on the surface and hill slopes are polished, having been exposed for a long time. The majority have been rolled down from the surrounding hills but no artefacts were found amongst them there. It is therefore necessary to ascertain from where the tools are derived. The Acheulian bifaces are all quite fresh

and show no evidence of river transport. But a few artefacts which are quite rolled and of a rather primitive appearance represent evidence of an older industry elsewhere.

I surveyed the whole of the Denen Dora river up to the source at the escarpment of the Ethiopian Rift floor and noticed that no artefacts could be found upstream of site Hdr 22. This suggests that the tools from site Hdr 22 were not brought down from the boulder gravel covered rift floor by the Denen Dora

Fig. 2 Bifacial choppers from site Hdr 10-III: *a*, from surface; *b*, found *in situ*.
Fig. 3 Unifacial protohandaxe from site Hdr 22; *a*, ventral face; *b*, dorsal face, which is of cortex, showing the typical black polish.

River, but must derive from nearby, the original site having been destroyed.

A few very rolled, primitive bifaces and a chopper, however, were found in a small stream bed, which joins the Denen Dora from the west and which descends directly from the rift floor at site Hdr 10 (Fig. 1).

There is, therefore, evidence that at least two different types of industry were developed along the Denen Dora river. The first dates from the Middle Acheulian with rather fresh, well-made bifaces. The second, apparently older industry produced protohandaxes, choppers and crude flakes of rolled appearance.

Site Hdr 10 is situated immediately to the west of the Denen Dora on a narrow remnant of the otherwise eroded rift floor, where the boulder gravel is 3–4 m thick above the Hadar Series. At site Hdr 10-III, within an area of about 50 by 70 m, I found 32 second type artefacts on the surface and one within the boulder gravel.

These artefacts, lying among a large number of boulders and pebbles with a light-brown to dark-brown polish, seem to have come originally from within the boulder gravel. Most of them have a dark-brown polish, some of them only a light polish, and the *in situ* chopper has no polish at all but a thin crust of white lime like that on the pebbles within the boulder gravel. The artefacts comprise choppers, polyhedral and modified pebbles, crude flakes and cortex flakes and primitive handaxes or protohandaxes.

The few second type artefacts in the Denen Dora must have been brought down from the boulder gravel of site Hdr 10-III. At sites Hdr 10-I and II, I also found a few crude artefacts, some *in situ* at the edge of the boulder gravel; I dug two trial trenches into the gravel, one at each site to verify the origin. I excavated nine artefacts from the small trenches and I found eight *in situ* in the gravel along the edges. Forty-four artefacts were found on the surface.

Artefacts

Artefacts found in the Hadar area can be placed in five categories. First, at sites Hdr 10-I, II, III, (and occasionally from sites Hdr 22, Hdr 24 and Hdr 25) there were choppers, polyhedral and modified pebbles, crude flakes and protohandaxes; second, mainly at sites Hdr 22, Hdr 23, and Hdr 9, were found bifaces and a few flakes of the Middle Acheulian type (this category includes occasional pieces from other localities); third, mainly at sites Hdr Camp 14, and Hdr 11 (with occasional pieces from other localities) there were flakes and cores of a Middle Stone Age industry, mostly without retouch, struck off from prepared cores with prepared, thinned talons; fourth, mainly at sites Hdr 1, Hdr Camp 14, Hdr 15, Hdr 18 (and a few other places), there were flakes, cores and waste of a Late Stone Age industry, made of jasper, chalcedony and various other siliceous material; fifth, mainly at sites Hdr 3, Hdr 4, and Hdr 19 (and other localities), flakes, cores and waste from subrecent to recent industries, made of obsidian and quartz.

At site Hdr 10 the choppers, modified pebbles and protohandaxes are all made of Trapp material. The choppers usually have a bifacial edge, formed by alternate flaking in two directions, though sometimes they are unifacial, formed by having a few flakes struck off in one direction only; the rest is cortex (Figs 2 and 3). Interestingly, a number of choppers seem to be transitional to bifaces or unifacial handaxes. These tools display unifacial or alternate bifacial flaking at one end of the pebble in such a way that a rounded or irregular point, or a point and part of a lateral edge is produced.

Some crudely worked pieces have been classified as modified pebbles. Polyhedrons and discoids are rare. Spheroids are absent.

The protohandaxes are a special group of artefacts showing much individual variation. Ten specimens were collected from sites Hdr 10, three from the tributaries of the Denen Dora and ten from sites Hdr 22 and Hdr 9 (Fig. 3). They show a few irregular flake scars. Much cortex remains not only at the butt end, but often over large parts of the tool. The edges are not regular; and often only one edge or part of one edge is produced with an asymmetrical, often blunt, point. In rare cases there are two edges, which are irregular, zig-zag, and with no secondary trimming. Some protohandaxes may have one face made entirely of cortex, so not all of these artefacts can be called protobifaces and the term protohandaxes is preferable. There are a few small triangular forms in which only the point has been worked bifacially.

The flakes have all been struck from unprepared, large cores (Fig. 4). The talons are plain with a large angle towards the flake surface, and the bulbs are pronounced. The dorsal face often consists partly of cortex, with only one or two former flake scars. There is no preferred shape. They may have been used, though the edges are usually irregular and often blunt.

The Acheulian artefacts from sites Hdr 22 and Hdr 9 were found mostly on the surface of the low terrace of the Denen Dora, though some were found *in situ*, redeposited in the terrace gravel.

On the whole, the bifaces are well-made, trimmed by large,

Fig. 4 Dorsal faces of flakes from site Hdr 10.

shallow flaking, with more or less biconvex sections and elongate-ovate shapes. The edges run around the whole of the circumference and are rather straight with secondary trimming in the finished specimens. Characteristically, almost all of them retain a small cortical part at the butt or, rarely, on the upper face. A few prepared cores (with basal preparation) and flakes from prepared cores also belong in this assemblage.

There are, however, a number of artefacts which are much cruder in appearance and which do not belong to the Middle Acheulian. These include crude flakes of the Hdr 10 type and a few protohandaxes. As they are all found on the surface it is possible that they originated at site Hdr 10 and were transported from there by the small, steep western tributary of the Denen Dora.

The Middle Stone Age flakes occur only on the surface in the Hadar area, not only on the lower terraces but at all levels of the eroded landscape around the Hadar River and on the floor of the Rift, too. It is, therefore, impossible to say anything about their stratigraphic context, or their age. Unlike the younger flakes, however, they are all made of basalt and trachyte and they may well be products of an Acheulian light-duty industry.

These flakes have been struck from prepared cores. The dorsal faces show primary flake scars and in many cases the talon has also been prepared. Evidence of retouch is extremely rare and any that does occur is possibly a result of chipping or battering by natural agencies during transport rather than intentional retouch. Many of the flakes are quite rolled. The shapes are mostly irregular, often with blunt edges so that a great part of them seems to be waste. But there are a few parallel-sided and pointed flakes. Cores are not abundant. There are rare tortoise-shaped cores, with a base formed by one or two flake scars; cores with a bifacial edge, with flakes removed alternately along the edge; cores with two platforms at right angles; and cores with two parallel platforms.

My thanks go to the Centre National de Recherche Scientifique, the National Science Foundation, and Mr Taieb, leader of the International Afar Expedition of 1973.

Integration of viral genomes

V. M. Zhdanov

The D. I. Ivanovsky Institute of Virology, Moscow, USSR

DNA transcripts of infectious RNA viruses were found to be integrated in the DNA of chronically-infected tissue cultures. DNA sequences homologous to RNA of measles virus were found in tissues affected with systemic lupus erythematosus. These data open up a new class of virus–cell interaction that may be a result of cooperation between infectious and oncogenic viruses.

Two types of interaction between the virus and the infected cell are characteristic of virus infections: autonomous replication of the virus in the cell and integration of the viral genome into the host cell chromosome.

Until now, integration has been found only with the temperate bacteriophages, oncogenic viruses and the related 'slow' viruses. We have shown, however, that nuclear DNA of avian, mammalian and human cells can integrate genomes of classic infectious viruses such as measles virus[1] and arbovirus[2], and that a similar process occurs in systemic lupus erythematosus, an autoimmune disease of man[3]. Here I present the results of a study of integration processes both in artificial tissue culture and in clinical samples.

To study the molecular mechanisms of the persistence of virus in chronically-infected tissue cultures three systems were used. Details of the systems, chick embryo fibroblasts infected with measles virus (CEF-MV), mouse L cells infected with Sindbis virus (ML-SV), and human Hep-2 cells infected with tick-borne encephalitis virus (Hep-2 – TBEV), are given elsewhere[4-12]. Briefly, the chronically-infected cell lines were obtained by inoculating the cultures with low doses of virus (0.01 TCD$_{50}$ per cell of measles virus and 0.01 plaque-forming units (PFU) per cell of the arboviruses) with subsequent reimplantation of the cultures every 4–6 d. The CEF-MV line has now undergone more than 120 passages; ML-SV, more than 80 passages; and Hep-2–TBEV more than 600 passages. All three cultures show no signs of cytopathic changes and the viruses are regularly detected in the cytoplasm by immunofluorescence tests with virus-

specific sera. Infectious titres of intracellular viruses are low (10^2–10^3 TCD$_{50}$ per ml for MV; 10^2–10^3 PFU ml^{-1} for SV; and 10^3–10^4 for TBEV) and those of extracellular viruses even lower (1–10 for MW; 0–1 for SV; and 10–10^2 for TBEV).

Biophysical studies showed that in all three systems subviral structures are predominant in contrast to acutely-infected cells which produce mature viruses (Fig. 1). The specificity of viral ribonucleoproteins was confirmed by titration of infectivity.

These data were obtained in experiments where actinomycin D was added for 3 h. When the antibiotic was added for 12 h, the synthesis of virus-specific structures was strongly inhibited in chronically-infected cells, in contrast to acutely-infected cells, where the synthesis of virus-specific structures was resistant to the action of the antibiotic (Fig. 2) Similar data were obtained in experiments with measles and Sindbis viruses.

As actinomycin D inhibits the transcription of cellular DNA into RNA, DNA sequences homologous to the viral RNAs were looked for in the chronically-infected cells. ^{3}H-labelled RNA was hybridised with excess DNA from chronically-infected and uninfected cells. DNA from chronically-infected cells was found to contain sequences homologous to RNA of the corresponding viruses whereas no such sequences could be found in non-infected cells (Fig 3). DNA preparations from chronically-infected cells were then used to treat appropriate sensitive cells to see whether virus could be isolated from these treated cells. TBEV was isolated from SPEV cells treated with DNA from Hep-2 – TBEV cells (Table 1), and SV from the brains of mice inoculated with DNA from ML-SV cells. In both cases DNase destroyed the infectivity of the DNA preparations whereas RNase had no effect.

As none of the three viruses under study possesses virion-associated or virus-induced reverse transcriptase, the transcription of virus RNA into double-stranded DNA must have been accomplished by latent oncornaviruses present in the cultures. The chickens used as a source of the CEF-MV
Fig. 1 Sedimentograms of virus-specific structures produced by the cultures chronically infected with measles (a), Sindbis (b) and tick-borne encephalitis (c) viruses. The cultures were treated with actinomycin D (2 μg ml⁻¹) at zero time, then ³H-uridine (20 μCi ml⁻¹) was added 1–3 h after treatment with the antibiotic. Thereafter the cells were disrupted in TNE buffer (Tris HCl 0.01 M pH 7.4, NaCl 0 1 M, EDTA 10⁻²) by a Dounce homogeniser, the nuclei and mitochondria were removed by centrifugation (15,000g, 20 min), the cytoplasmic extracts were layered on sucrose density gradients 15–40% (w/v) prepared in TNE buffer, centrifuged in a SW 27.1 rotor of a Spinco L 3-50 centrifuge at 122,500 r.p m. for 1 h 45 min (a) of 2 h (b, c), and acid-insoluble radioactivity of the gradient fractions was determined in a Packard-Tricarb liquid scincillation counter. In parallel experiments VERO cells were infected with measles virus, chick embryo fibroblasts with Sindbis virus, and SPEV (swine) cells with tick-borne encephalitis virus. The cultures were grown without actinomycin D, labelled with ³H-uridine (10 μCi ml⁻¹) overnight; the viruses were collected from the culture medium; the cell debris removed (15,000g, 20 min); the viruses were pelleted (120,000g, 2 h) and purified by equilibrium centrifugation (25,000 r.p.m. 16 h) in sucrose density gradients 20–60% (w/v) prepared in TNE buffer. The gradient fractions that corresponded to the density of viruses studied (1.22–1.24 g ml⁻¹) were collected and subjected to velocity centrifugation as indicated above. The arrows show sedimentation peaks of virions in the gradients parallel to a, b, and c.
Fig. 2 Sedimentograms of virus-specific structures produced in SPEV cells acutely infected (a, b) and in Hep-2 cells chronically infected (c, d) with tick-borne encephalitis virus. SPEV cells were infected with the virus (10 PFU per cell), treated with actinomycin D (0.5 μg ml⁻¹) at zero time and incubated for 3 h (a) and 12 h. (b) ³H-uridine (20 μCi ml⁻¹) was added 1 to 3 h after infection (a) and 10 to 12 h (b) after infection. Hep-2-TBEV cells were treated with actinomycin D (0.5 μg ml⁻¹) at zero time and ³H-uridine was added 1 to 3 h (c) and 10 to 12 h (d) after treatment with the antibiotic. Cytoplasmic extracts were obtained and studied by velocity centrifugation in sucrose density gradients in the same way as described in the legend to Fig. 1.

cell line usually contain endogenous C-type oncornaviruses[13], Hep-2 cells have been reported to contain a new oncornavirus[14], and L cells are known to produce an endogenous C-type oncornavirus[15]. We carried out experiments to reveal latent oncornaviruses using a test that reveals reverse transcriptase activity associated with high molecular weight (60–70S) RNA[16] Such reverse transcriptase activity was shown in all three chronically-infected tissue cultures, and also in uninfected L and Hep-2 cells but not in uninfected primary chick embryo fibroblasts.

These results suggest that during the prolonged persistence of infectious viruses in cells containing latent oncornaviruses, the two types of viruses interact, resulting in the transcription of the infectious virus RNA genomes into double-stranded DNA which is then integrated into the genomes of the chronically-infected cell. The main molecular mechanism of virus persistence in these cultures is
Fig. 3 Hybridisation of ³H-labelled RNAs of measles virus (a) with DNA from chronically infected (●) and uninfected (○) chick embryo fibroblasts; tick-borne encephalitis virus (b) with DNA from chronically infected (●) and uninfected (○) Hep-2 cells; Sindbis virus (c) with DNA from chronically infected (●) and uninfected (○) L cells The viruses were labelled with ³H-uridine, ³H–adenosine and ³H-guanosine (50 μCi ml⁻¹, 25 μCi ml⁻¹ and 25 μCi ml⁻¹, respectively) and purified as described in the legend to Fig 1 RNA was extracted with sodium dodecyl sulphate (0.5%) and phenol, precipitated with ethanol and stored at −20 °C Specific activity of the RNA preparations was 2 × 10⁵ to 6 × 10⁵ c p.m. μg⁻¹ and more than 80% of RNA sedimented in the region of 50S (measles) or 42–45S (Sindbis, tick-borne encephalitis). DNA from chronically-infected cells was extracted with phenol after treatment of the nuclear fraction of the cells with 0.2% SDS and Pronase (200 μg ml⁻¹) at 37 °C for 3 h. DNA was fragmented in an MSE ultrasonic disintegrator; RNA admixtures were hydrolysed by 0.5 M NaOH (37 °C, 16 h) with subsequent neutralisation; DNA was precipitated by ethanol and stored at −20 °C The hybridisation mixture contained in 0.1. ml: Tris HCl 0.02 M pH 7.4, NaCl 0.6 M, EDTA 10⁻³M, SDS 0.05%, RNA 2,000 c.p.m, DNA 1 5–2.5 mg ml⁻¹. The mixture (1 2 ml) was incubated at 68 °C; aliquots (0.1 ml) were taken at various intervals and stored at −20 °C to the end of the experiment. Then the samples were diluted with 3 ml of TN buffer (Tris HCl 0.01 M pH 7.4, NaCl 0 4 M), treated with pancreatic ribonuclease (50 μg ml⁻¹) at 37 °C for 1 h and acid-insoluble radioactivity was determined. RNA alone and RNA with calf thymus DNA incubated at the same temperature were taken as controls for self-annealing and nonspecific annealing. The corresponding radioactive counts (that were less than 100 c.p.m.) were subtracted and the % ribonuclease-resistant RNA–DNA hybrids were calculated and plotted against the corresponding C_0t values.

Table 1 Transfection of tick-borne encephalitis virus with DNA from Hep-2-TBEV cells

No. of experiments	Isolation of virus after treatment of SPEV cells with DNA from Hep-2-TBEV cells		
	Native DNA	DNA treated with RNase (300 μg ml⁻¹)	DNA treated with DNase (200 μg ml⁻¹)
1	10³ ⁵	10³ ¹	0
2	10³ ³	10³ ⁴	0
3	10³ ²	10³ ⁰	0

SPEV cells were treated with DEAE–Dextran (0 1%) for 10 min, then with DNA (200 μg) from Hep-2-TBEV cells, thereafter culture medium was added and the cultures were observed until cytopathic changes appeared. The figures indicate the titre of the virus (PFU ml⁻¹) in the culture medium. The specificity of the virus strains isolated was determined by plaque titration and neutralisation with immune serum and by intracerebral inoculation of mice.
Fig. 4 Kinetics of hybridisation of ^{3}H–labelled measles virus RNA with DNA from leukocytes ($\triangle$), lymphatic node ($\bullet$), and kidney ($\bigcirc$) of a patient and of a fatal case of systemic lupus erythematosus and with DNA from normal embryonic human spleen ($\times$). The methods of preparation of ^{3}H-labelled measles virus RNA and of DNA from tissues as well as techniques of hybridisation were the same as described in the legend to Fig. 3. Hybridisation was carried out in the volume of 1.2 ml; aliquots (0.1 ml) were taken at various intervals and the percentage RNA hybridised was plotted against the corresponding $C_0 t$ values.

therefore the production of subviral structures, whose production is inhibited by the prolonged addition of actinomycin, by the cell genome, rather than the autonomous replication of virus particles, which are produced shortly after addition of the antibiotic.

As these models may be considered artificially induced, similar natural pathological processes were looked for. Systemic lupus erythematosus (SLE) provides a suitable study system. The disease is characterised by high titres of measles antibodies which correlate with the pathological course of the disease[17], by the presence of measles antigens in leukocytes detected by immunofluorescence[18], and by tubular structures in the cytoplasm of SLE-affected tissues resembling nucleocapsids of paramyxoviruses[19]. ^{3}H-labelled measles virus RNA was hybridised to DNA from tissues and leukocytes from SLE patients and fatal cases. Sequences homologous with measles virus were detected in the DNA from these tissues (Fig 4). No such sequences were detected in DNA from normal human tissues and in

DNA from leukocytes of measles patients taken at an early stage in the disease and in convalescence.

Tissues affected with lupus erythematosus and leukocytes from patients with the generalised form of the disease were assayed for reverse transcriptase activity associated with high molecular weight RNA. This test is positive with cytoplasmic extracts from lupus erythematosus tissues. In parallel studies we revealed tubular structures in lupus-affected tissues (electron microscopy) and measles virus antigens in leukocytes (immunofluorescence). These results suggest the following molecular mechanism for the initial events in the development of SLE.

In comparatively rare cases of infection with measles or measles-like virus, the virus interacts with a latent oncornavirus, resulting in transcription of the RNA of the infectious virus into double-stranded DNA and integration of the latter into the cell genome. The integrated viral genome may be expressed in the synthesis of virus-specific envelope proteins that, in the case of paramyxoviruses (including measles virus) are incorporated into the cell membrane and modify its antigenic properties[20]. Such cells become targets for attack by immunocompetent T cells and this triggers the development of the autoimmune disease.

Among human diseases similar molecular mechanisms may underlie syndromes closely related to lupus erythematosus (dermatomyositis, sclerodermy, periarteriitis nodosa) and also some chronic degenerative diseases of the central nervous system (subacute sclerosing panencephalitis, disseminated sclerosis).

letters to nature

Definition of 'charge on an atom' and nature of the inductive effect

A PRECISE measure of the charge on an atom in a molecule is provided by calculating the number of electrons within a sphere of covalent radius using molecular wavefunctions. The results for alkyl substitution suggest that the simple qualitative ideas of the inductive effect may be less simple than is commonly supposed and that methyl groups are not intrinsic electron donors but rather attracters of charge.

Although the only precise 'charge on an atom' is its nuclear charge, chemists frequently use the expression for what is

more correctly the charge 'close to' an atom. Quantum mechanical calculations provide values of such quantities by using the so-called Mulliken Population Analysis[1]. This has the virtue of being easily programmed for a computer, but has the defect of assigning all the charge in a molecule to particular nuclei. Nonetheless it is the origin of most of the quoted 'charges on atoms' which appear in the literature, and its well known defects such as equal division of charge between bonded centres and occasional negative populations are usually ignored.

In principle, from a molecular wavefunction, ψ, it is possible to calculate the electronic charge in any restricted region of
Fig. 1 Relationship between calculated charge within one covalent radius of nitrogen atoms and X-ray photoelectron shifts $(1s_N)$ for: a, NH_3; b, CH_3CN; c, $^*NNO$, d, N_2; e, NO; f, NN^*O, g, NO_2; h, NF_3.

space by integrating the value of $\psi\psi^*$ over the defined region. This precise definition of charge in a specified region has rarely been used[2,3] because the computation of the integrals over restricted regions of space is very difficult.

As part of our interest in the charge 'on' the nitrogen atom in the ammonium group of biologically active amines, we have overcome these integration problems by taking the interesting atom (nitrogen) as the centre of our polar coordinate system. The charge, q, within a sphere of radius r centred on the nitrogen atom is then given by:

$$q = \int_0^{2\pi} \int_0^{\pi} \int_0^{r} \psi\psi^* r^2 \sin\theta \, dr \, d\theta \, d\varphi$$

In these calculations, the approximation has been made that the charge around an atom arises only from the integral of the following terms in the square of the LCAO expression:

$$\sum_i \sum_j (c^2_i\chi^2_i + 2c_ic_j\chi_i\chi_j + c^2_j\chi^2_j)$$

where the is are atomic orbitals of the central atom, and the js are centred on atoms bonded to this central atom. This is an excellent approximation: terms from non-bonded atoms are very small.

Table 1 Calculated charges in substituted ammonium ions

Molecule	Charge on nitrogen atom
NH_4^+	5.054
$CH_3 \cdot NH_3^+$	4.774
$C_2H_5 \cdot NH_3^+$	4.786
$(CH_3)_3NH_4^+$	4.492
$CH_3 \cdot NH^+_2 \cdot C_2H_5$	4.501
$CH_3 \cdot NH_2 \cdot i\text{-}C_3H_7$	4.508
$CH_3 \cdot NH_2 \cdot n\text{-}C_3H_7$	4.503

For each molecule we have considered, good *ab initio* molecular wavefunctions have been calculated using the Gaussian '70 molecular orbital program[4] which takes account of all the electrons in the molecule, and overlap integrals have been calculated using the method of Barnett and Coulson[5]. The charge 'on' the nitrogen atom is defined as the electronic charge—the number of electrons—within one covalent radius (0.7 Å).

Charges were first calculated for small nitrogen-containing molecules for which X-ray photoelectron spectra (ESCA)

shifts are available[6]. The energy shifts for 1s-electron ionisation are thought[7] to depend in a reasonably direct way on the charge 'on' the atom, and thus provide a means of testing the physical significance of our calculated charges. Figure 1 shows that the correlation between charge and shift is good. The Mulliken charges, in spite of the simple basis on which they are computed, give a correlation with shift which is only slightly less good.

As model compounds of particular interest to us we considered substituted ammonium ions. The calculated charges are shown in Table 1. The fact that the charge on the nitrogen atom decreases with increasing substitution of hydrogen atoms by alkyl groups is particularly significant and is in direct opposition to the traditional view that alkyl groups have a $+I$ effect—that they donate electrons, relative to hydrogen.

Much of the evidence from which the $+I$ effect of alkyl groups is inferred pertains to reactions and equilibria in solution: the present calculations refer to molecules in the gas phase, and so comparisons with solution data must be made with caution. But some gas-phase data are available; the most directly relevant concern dipole moments.

Laurie *et al.*[8] have performed a series of microwave measurements of dipole moments. They have shown that the dipole moment of propane is $0.085D$ with the electron drift in the direction shown:.
This very strongly suggests that methyl groups are in fact 'electron-withdrawing' relative to hydrogen atoms.

The dipole moments of a series of chloroalkanes are shown in Table 2. Assuming that the dipole acts in the direction $R \rightarrow Cl$, the electron-withdrawing power of the different alkyl groups, R, may be inferred to be:

$$CH_3 > C_2H_5 > n\text{-}C_3H_7 > i\text{-}C_3H_7$$
This is also the order inferred from the calculated charges in ammonium ions.

Spectroscopic measurements suggest that in certain circumstances alkyl groups may act as electron acceptors rather than as electron donors[9]. The principle electronic transition in phenol, anisole, aniline and dimethylaniline in the gas phase may be presented crudely as·
Solvent effects confirm that the electron migration in these transitions is indeed away from the functional group Z and towards the *para* substituent R. Now when R is an alkyl group, the energy of the transition is lower than when R is a hydrogen atom· thus the alkyl group seems to act as an electron acceptor.

Table 2 Dipole moments of chloroalkanes[10]

Molecule	Dipole moment (D)
$CH_3 \cdot Cl$	1.83
C_2H_5Cl	2.00
$i\text{-}C_3H_7Cl$	2.15
$n\text{-}C_3H_7Cl$	2.04

Ingold[10] and Braumann[11,12] have suggested a reason why alkyl groups should seem to donate electrons in many experimental situations. The gas-phase basicities of ammonium derivatives increase in the order:

$$NH_2 < CH_3 \cdot NH_2 < (CH_3)_2NH$$

This is often quoted as evidence for the $+I$ effect of methyl groups. But Braumann et al.[11,12] have measured the gas-phase acidities of the same compounds, and have found that these increase in the same order. The $+I$ effect cannot explain both these sets of observations. Alkyl groups can, however, be polarised much more than hydrogen atoms, they are thus more able to stabilise both anions and cations, and therefore enhance both acidity and basicity.

Work by Hudson et al.[13] has placed this polarisability effect on a somewhat more quantitative basis by use of a perturbation model of alkyl substitution. The influence of the alkyl group is considered to be split into two parts, one a repulsion which is greater in the neutral molecule than in the ion, and one an attraction which acts only in the ion. This treatment predicts that alkyl groups in alcohols or amines may act as either apparent donors or acceptors, depending on the conditions.

Perhaps the area in which the idea of alkyl groups as electron donors has been most widely used is in the explanation of the activating, ortho–para directing effect of one or more alkyl groups introduced into benzene. Preliminary calculations suggest that, although the p-toluene tetrahedral intermediate involved in electrophilic substitution is indeed lower in energy than the meta-substituted intermediate, the charge distribution is unlike that predicted by simple resonance bonding theory. But the situation is far from simple and it is possible that solvation effects are very important.

A low velocity zone underlying a fast-spreading rise crest

We present the results of an unreversed seismic refraction profile on the East Pacific Rise near the Siqueiros Fracture Zone recorded using a digital ocean bottom seismograph (OBS)[1]. An analysis of P wave arrival times and amplitudes indicates a velocity gradient in the top 2 km, with the velocity reaching 6.7 km s^{-1}. This is underlain by a low velocity channel some 1.4 km thick in which the velocity decreases to around 4.8 km s^{-1}. Below this low velocity region there is a velocity gradient from 6.2 to 6.8 km s^{-1} and mantle velocities of 7.7 km s^{-1} are reached at a depth of 6 km below the sea bed.

Many surveys have been made of the structure in the neighbourhood of slow spreading ridges, particularly the Mid-Atlantic Ridge, but very little work has been done on fast spreading ridges. Two surveys[2,3] on the East Pacific Rise near the area of this work show mantle velocities below 8 km s^{-1}.

During the course of a gravity and seismic refraction survey in the neighbourhood of the Siqueiros Fracture Zone (Fig. 1)
Fig. 1 Position of OBS refraction profile along the crest of the East Pacific Rise Contours are in uncorrected fathoms.

made with the Hawaii Institute of Geophysics, a refraction profile was carried out along the crest of the East Pacific Rise, all shots being recorded on a single OBS. The local spreading half rate is high, about 60 mm yr^{-1}, and the portion of the rise crest studied consists of a horsted block about 10 km across.

A record section of this ridge crest profile is shown in Fig. 2. A reduction velocity of 8 km s^{-1} has been applied to the section and, to facilitate amplitude studies, the traces have been normalised to a shot size of 109 kg (ref. 4). Since all shots were recorded with the same instrument, there is no problem with variability in instrumental response. The records have been passed through an aliasing filter in the OBS before digitising at 128 samples s^{-1} and subsequently bandpassed with a zero phase 1–9 Hz filter. Timing corrections have been made for the depth of the shot and bottom topography near the shot points.

The travel times (T) for both first arrivals and prominent second arrivals were measured for each distance (X). The graphical construction technique of Bessonova et al.[5] was then used to determine the delay time τ ($= T - pX$) for the values of the ray parameter p ($= dT/dX$) present in the records. A smoothed spline was also fitted to the (T,X) data and estimates of the slope p made from this, τ values were then found by direct construction. The values of $\tau(p)$ obtained from the two methods were in good agreement. The ray parameter, or inverse phase velocity, p corresponds to the local slope of a travel time curve and the delay time $\tau(p)$ to the time intercept at zero distance made by a tangent to the travel time curve with this slope.

The advantages of working with the $\tau(p)$ relation are that the delay time τ is a monotonically decreasing function of the ray parameter, and that for a model containing a low velocity zone

it exhibits a discontinuity for p equal to the reciprocal of the velocity at the lid of the zone. In the present case the τ/p curve we have determined has two distinct branches separated by a jump of 0.4 s between the values for phase velocities of 6.70 km s^{-1} and 7.00 km s^{-1}, which suggests the probable existence of a low velocity zone with a lid velocity of 6.7 km s^{-1}. Analysis of sonobuoy records at short range taken on the same profile give independent evidence for a velocity of 6.7 km s^{-1}.

From our delay time results we estimated upper and lower bounds on $\tau(p)$ and then inverted these to give extremal velocity profiles using the method of Bessonova et al.[5]. With the adoption of an assumed lower bound on the velocity in any low velocity zone, we are able to prescribe upper and lower bounds on the depth at which a velocity can occur, outside of a low velocity zone. Travel times for models which satisfied these bounds were tested against the travel time observations, and successful models were used in the amplitude calculations. Synthetic seismogram sections were calculated for these velocity profiles using a modification of the reflectivity algorithm[6,7] which enables the attenuation structure to be included. Although a large number of models could be found to fit the travel times, the relative amplitude of arrivals along the records proved an effective discriminant.
Fig. 2 Seismic profile and interpretation. Top figure shows the data with travel time curve corresponding to model at right. Bottom figure shows synthetics corresponding to model.

The model presented in Fig. 2, together with the corresponding synthetic seismogram section, was the best fit to both the travel time and amplitude criteria. Several attempts to model the observed records without a low velocity zone proved singularly unsuccessful with regard to the amplitude criteria. Models without low velocity zones also yielded crustal thicknesses significantly greater than any measured in ocean basins. We have assumed that all attenuation arises in shear[8] and adopted a shear wave Q of 175 in each of the layers, except in the low velocity channel where it was dropped to 100, since this improved the fit to observations. Unfortunately, we have no independent evidence to determine attenuation values. It should be noted that the amplitude of the first arrival between 30 and 50 km decreases too slowly for the transition to a 7.7 km s^{-1} layer to be a discontinuity, but the behaviour can be modelled quite well with a gradient. Even our best model does not fit the amplitude data exactly. Factors contributing to this difficulty in fitting the data include the inexactness of the normalisation and the likelihood of lateral variations along the profile.

The low velocity, lower Q zone beneath the ridge crest is hypothesised to be a zone of partial melt or a magma chamber as predicted by Cann[9,10]. This low velocity material is underlain by high velocity crust, and there is evidence of a low velocity 7.7 km s^{-1} mantle. Our observation of a mantle arrival requires any intrusion zone to be narrower than about half a wave length (0.7 km) wide at the mantle interface. This low velocity mantle is in agreement with most previous work at spreading centres[11-13].

For profiles conducted on the flanks of the rise crest during the same survey, mantle velocities in excess of 8 km s^{-1} were only detected when the crustal age exceeded 5 Myr.

The work was supported in part by the NSF; B.K thanks the Lindemann Trust for a fellowship.

Mercury contamination in a 54-m core from lake Huleh

THERE has been some discussion[1] concerning the suggestion of Aston et al.[2] that recent technological growth has resulted in a progressive increase in mercury in the sediments of Lake Windermere, UK. Here I report some data from another lake to substantiate their suggestion.

A 54-m core[3] was taken in the deepest portion of the now drained Lake Huleh located in the upper part of the Jordan Valley. The sediments are indicative of a swamp which underwent small periodic changes in level and was converted to a lake, presumably by the damming of the Jordan River by the late Pleistocene Yarda Basalt some 30,000 yr b.p. Before the great rise in water level reflected in the upper lacustrine series, there are two small lacustrine episodes when the water must have been transitorily too deep to deposit peat. Figure 1 shows the gross stratigraphy of the core.

The concentration of Hg in the Huleh sediments is highest in the surface mud of the modern lake (Fig. 1 and Table 1), whereas that in the second and first lacustrine periods is lower. Forty duplicate samples of each level ($n = 746$) were analysed for Hg by optical emission spectroscopy[4,5]. These results were confirmed by another laboratory using flameless atomic absorption spectroscopy. Mercury concentrations in the Huleh mud ranged from 2.36 to 0.11 p.p.m. with a mean of 0.36. The percentage relative s.d. for high values was 0.62 and that for low ones was 3.1 (ref. 4).

In the first 137 cm of the core, the Hg distribution follows that of Fe (ref. 6) (Fig. 1 and Table 2). The concentration of Hg begins to decline about 122 cm. From 142 cm to the beginning of the peat (4,572 cm) the distribution of Hg follows that of organic matter, here measured as percentage loss of weight on ignition[3]. There is a significant relationship between Hg and organic matter in the peat zones but the Hg concentration is more variable in this type of material. Although plant fragments prevalent in the more recent sediments may contribute to the Hg content[7], it would be presumed that this would also be the case in the peat zones, yet the latter contain sections where there is less Hg than in the standard lake mud.
Fig. 1 Distribution of Hg and percentage loss of weight on ignition[3] in a 54-m core taken from Lake Huleh. Radiocarbon dates (organic C)[3] and the stratigraphy[3] of the core are included. *a*, Shallow water sediments with shell and some plant remains; *b*, grey stiff lake sediment with occasional shell; *c*, grey stiff lake sediment with shell largely absent; *d*, grey stiff lake sediment with decomposed clam shells; *e*, darker grey and more organic-looking material; *f*, beginning of main lacustrine episode, material less organic; *g*, peat with shell layers; *h*, second lacustrine period, dark grey sediment; *i*, peat; *j*, less peaty; *k*, peat with shell layers; *l*, first lacustrine period, very wet grey mud; *m*, peat with shell layers.

This would suggest that the plant fragments do not contribute significantly to the Hg content of the sediments.

It would seem on the basis of the linear correlation coefficients that Hg is initially associated with Fe and detrital clay particles. This has been noted in Lago Maggiore, Italy[8]. In Lake Huleh, for the whole core[9], quartz is associated significantly with halloysite ($r = 0.922$) and with generalised clay peak at 4.48 Å ($r = 0.884$) so that a correction for the diluting effect of quartz was not made[10]. The relationship between the mineralogical components of the core and Hg is significant only in the upper portion of the mud (Table 2).

Table 1 also shows the mean concentration of a few other elements that may reflect the effect of technological development. Both Ag and Cd are, in the absolute sense, more concentrated in the upper, more recently deposited mud than in the grey lake sediment beneath, although the mean rise in Ag is hardly significant. With Pb, however, the concentration at the surface is low because there is little automobile traffic in the vicinity of Lake Huleh. Presumably the oscillations in Pb reflect the natural erosion processes in the basin.

It has been suggested by some[1] and rejected by others[2,10] that upward postdepositional migration of Hg by organisms, or through interstitial waters by ionic or molecular diffusion, or compaction of the sediment, could produce a rise in Hg concentration in the upper portions of the more recently deposited sediment. As the surface muds of the earlier lacustrine periods do not show the increase in concentration so noticeable in the recent modern surface, such upward mobility does not seem to have been significant in the Huleh core.

On the basis of radiocarbon dates[3], the rise in Hg in the Lake Huleh sediments begins about 1200 AD. The first recorded mention of Hg was by Aristotle in the fourth century BC when it was used in religious ceremonies[11]. Until the sixteenth century[12], consumption was small and chiefly for medicinal and cosmetic purposes. Before 1850 (ref. 12), two great mines dominated European production. The Almaden mine in Spain began production in 400 BC and the Idria mine in Yugoslavia was first used about 1470. Besides such activity, heavy industry, the burning of fossil fuels and sewage disposal have all contributed to the global Hg distribution which eventually finds

Table 1 Mean concentration (p.p.m.) of some elements in various portions of the Lake Huleh core

Depth (cm)	Hg	Cd	Pb	Ag	Number of samples	Stratigraphy
0–77	1 07	1.66	94 9	0.069	15	Modern Lake mud surface
82–792	0.36	0.58	97 2	0.055	91	Grey Lake mud
4,245–4,425	0.48	0.78	113.5	0.054	25	Second lacustrine period
4,890–4,941	0.65	2.49	111.5	0 11	11	First lacustrine period

Table 2 Pertinent linear correlation coefficients between Hg and other substances[7,9] in the Lake Huleh core

Depth (cm)	Montmoril-lonite	Halloysite	4.48 Å peak	Quartz	Calcite	Fe	% Loss of weight on ignition
0–77	0.640*	0.918	0.922	0.910	−0.852	—	—
0–137	—	—	—	—	—	0.939	−0 221

Peat						−0.129†	0.956
0–5,400							0.194
Without peat							0.562
Without peat and 0–137 cm							0.982

*Not significant, †, 2% level.
Unless otherwise noted all are significant beyond the 0 1% level.

its way to the atmosphere. Such information and the data obtained from the analyses of the Lake Huleh mud certainly suggest that the increase in Hg concentration in recently deposited lake muds reflects man's global activities.

I thank the National Science Foundation for support and Dr F. Breck of the Jarrell–Ash Company, Waltham, Massachusetts for Hg analyses.

A resonant point absorber of ocean-wave power

Various large scale systems have been proposed for absorbing and utilising the energy carried by ocean waves[1-4]. In principle, such a system consists of a damped oscillator which interacts with the wave. The net result is that energy is transferred from the wave to a load. Here we call a system a 'point absorber' when its horizontal extent is much smaller than one wavelength, and a 'linear absorber' when the system is made as a straight construction, at least a few wavelengths long[1].

A progressive wave on deep water transports an energy of

$$K = (\rho g^2/2\omega)\ \langle \eta^2 \rangle$$

per unit time and per unit length of the frontage of the wave. Here, ρ is the density of water, g is the acceleration of gravity, η is the surface elevation and ω is the angular frequency of the wave. $\langle \ \rangle$ Represent average over a time which is typically 20 min.

For the region west of the Hebrides Salter[1] reports that K has an annual average of 77 kW m^{-1}. Although the power incident on the coast may be somewhat smaller, ocean waves represent a very interesting energy resource for the coastal countries if the energy can be converted at a reasonable cost.

We report here on a proposed point absorber which is optimised for efficient energy conversion[3]. The resonant frequency of such an absorber is at all times tuned to the characteristic frequency of the wave. This may be realised by incorporating into the oscillating system a flywheel with adjustable moment of inertia. The importance of this tuning facility is that at resonance, the movement of the oscillator is in phase with the dynamic pressure of the incoming wave, resulting in a substantial transfer of energy from the wave to the oscillator. At resonance the motion of the oscillator is magnified with respect to the motion of the incoming wave. So the oscillator is able to produce the oscillating fluid displacement which is required for an effective interaction between the wave and the point absorber. Thereby, in a very efficient way, a secondary, ring-shaped, outgoing wave is generated, which interferes with the incoming wave in such a way that the resulting transmitted wave carries with it less energy than the incoming wave does.

Another condition which must be satisfied to obtain optimum performance concerns the energy delivery from the resonant oscillator. If the waves are sinusoidal, the condition for optimum

power output is that equal amounts of energy are delivered to the load and to the generated outgoing waves. This means that the mechanical load resistance should at all times be adjusted equal to the radiation resistance. But for wind-generated waves, which are not purely sinusoidal, the load resistance should be somewhat larger than the radiation resistance[3] to obtain maximum power output.

Resonant point absorbers having horizontal oscillating movement can be constructed, as can absorbers with vertical movement. As an example, consider the cylindrical, vertically oscillating tank of diameter $2a$ shown in Fig. 1. When the
Fig. 1 An example of a single unit of a point absorber. The tank a is kept in a semi-submerged equilibrium position by means of the wire s which is stretched by the buoyancy of the auxilliary tank b. The wire s also drives a flywheel f so that it rotates in one direction when the tank a moves downwards and in the opposite direction when the tank moves upwards. The resonance frequency of the point absorber is tuned to the characteristic frequency of the wave by adjusting the inertia moment of the flywheel f which is placed in a housing d on the bottom of the sea.

resonant frequency is tuned to the frequency of the wave and the damping is optimised, then the maximum available useful power in small amplitude sinusoidal waves is[3]

$$P_{opt} = [(\rho g \pi a^2)^2/4R_r]\ \langle \eta^2 \rangle$$

Here R_r is the radiation resistance, and $\langle \eta^2 \rangle = \eta_0^2/2$ where η_0 is the amplitude of the wave.

We define an absorption length d_a by

$$P_{opt} = Kd_a$$

Here d_a expresses the width of a wave front across which passes an average amount of power equal to that converted by the point absorber. For the shallow tank in Fig. 1 we find that in sinusoidal waves of period of the order of 10 s the absorption length exceeds 50 m even though the diameter of the tank is only 16 m. But because of the power limit of the mechanical absorber and the corresponding electric generator, and because of the fact that wind-generated waves are not purely sinusoidal, the effective absorption length is smaller. With a reasonable power limit and a wave power spectrum with relative half-value width of 0.2, we obtain[3] an effective absorption length of

approximately 20 m as an annual average for waves typical of the North Atlantic.

The functioning of a point absorber is analogous to the operation of the antenna of a radio receiver. Such an antenna absorbs much more power from the wave, to which frequency it is tuned, than is incident on to its physical cross section. Correspondingly, the tuned oscillating tank has an absorption length larger than its diameter.

In contrast, a linear absorber has an absorption length which is, obviously, smaller than its physical extent. Reports on the linear absorber proposed by Salter indicate[5] an absorption length which exceeds 50% of the length of the construction.

Since the wave energy is available in a relatively narrow spectral frequency band, the resonant point absorber is a very effective energy converter. Its physical dimensions are not prohibitively large for mooring the device. The mooring provides a steady reference against which the oscillator can act with very good efficiency.

A practical construction of a resonant point absorber will probably be different from that shown in Fig. 1. It is possible to design a system where the flywheel and the other machinery are placed inside the heaving tank. Except for a mooring wire and anchor, no installation is then necessary on the bottom of the sea. The resonant point absorber is preferably placed in an exposed location just off the coast. This condition requires that the depth is, perhaps, 50 m at the installation site.

The absorbed energy may be converted to electrical energy by a generator connected to the flywheel, and which then acts as the adjustable load resistance. Since the construction is moored, the electrical energy produced could be brought ashore by cables.

As indicated previously it is necessary that any wave energy absorber generates secondary, outgoing waves. It should be noted that practically all the volume of the heaving tank is used to displace fluid and thus to generate outgoing waves. In contrast, other proposed wave absorbing systems have a considerable amount of dead volume which does not participate in generating secondary waves.

The technological problems, including mooring, force transmission, and energy conversion seem to be manageable. A technological and economic study is, however, necessary before designing a real resonant point absorber.

If the aim is to optimise the ratio between the absorbed, converted energy and the energy in the waves incident on a coastline, the linear absorber proposed by Salter[1] is probably a better solution than an array of point absorbers. But if the aim is to convert a given amount of energy as cheaply as possible, we believe that a line of resonant point absorbers may be superior to a linear absorber. The previously mentioned, movement magnification in the resonant oscillator is probably an additional advantage when the technological details of the power converting system are being considered.

A large scale power station must consist of many, say 100, resonant point absorbers. If they are placed on a line with a distance of 100 m between neighbouring units, they will cover a coast line of 10 km. The individual units (each of 16 m diameter) will then operate practically independently of each other and absorb at least 20% of the wave power which is incident on the 10 km coastline.

Climatic reversal in northern North Atlantic

OVER the European arctic and subarctic seas the atmospheric circulation has recently tended towards northerly airflow, with an accompanying climatic deterioration. Since the 1950s direct northerly outbreaks have swept the Norwegian–Greenland Sea with increasing frequency, adding almost every year, particularly in the 1960s, to the severity of the climate in areas as far south as the British Isles. This change has been associated with the establishment over Greenland in the early 1950s of a persistent ridge of pressure anomaly and with its subsequent maintenance and intensification (on average) throughout the late 1950s and 1960s. Compared with the 'normal' climatic period of 1900–39 this cell represented an increase of over 3 mbar in the mean annual pressure at sea level in Greenland over the period 1956–65, but was very much more pronounced during the cold season (November–March). During the winter quarter (December–February), the increase in the mean pressure at sea level in Greenland amounted to over 7 mbar between 1900–39 and 1956–65 (Fig. 1a) and the pressure rise continued during the late 1960s. (Throughout, listed dates refer to the second year of the winter in question; thus, "winter 1956" refers to the period December 1955–February 1956.) A further increase of over 5 mbar occurred in Greenland between the winters of 1956–65 and 1966–70 (Fig. 1b). Coupled with a slight decrease of pressure over the eastern Norwegian and Barents Seas this change has resulted in ". . . a remarkable difference of pressure between Greenland and the eastern Norwegian Sea; this has increased since 1950 in every month of the year . . ."[1].

The resulting increase in the occurrence of northerlies over the Norwegian–Greenland Sea, and the physical repercussions, have been reviewed by Dickson and Lamb[2] and by Rodewald[3]. First, the great boosting of northerlies during the winter months resulted in a steep decline in the mean winter air temperature throughout this sector, especially in those areas lying to the north and west of the atmospheric and oceanic polar fronts. South from the high arctic, towards the British Isles, the winter cooling becomes rapidly less marked but there is evidence that since the early 1960s the resulting decline in sea temperature on the European shelf during the critical spring months (March–May) has been sufficient to affect (favourably) the survival of North Sea cod, which in those latitudes are approaching the equatorward limits of their range[4].

Apart from those effects, the strengthening of the northerly airstream has been responsible for a progressive southward extension of sea ice across the Greenland Sea, reaching a maximum extent in the spring of 1968. Icelandic observations[5] suggest that this change took place in two stages. First, as the northerlies increased in strength, the hydrographic character of the cold east Greenland and east Icelandic currents was altered so that they became cooler and less saline as the proportion of polar water increased. The east Icelandic current, which had been an ice-free arctic current during 1948–63, became a polar current in 1964–71, transporting and preserving drift ice.

Ancillary biological changes have been attributed to this climatic deterioration. They include an economically important alteration of the annual feeding migration of the Atlanto–Scandian herring stock to Iceland[2,6] and a delay in the spring production of phytoplankton in the southern Norwegian Sea (ref. 2, and G. A. Robinson, unpublished); a two-week reduction in the length of the growing season in England has also been reported during this period of cooling[7].

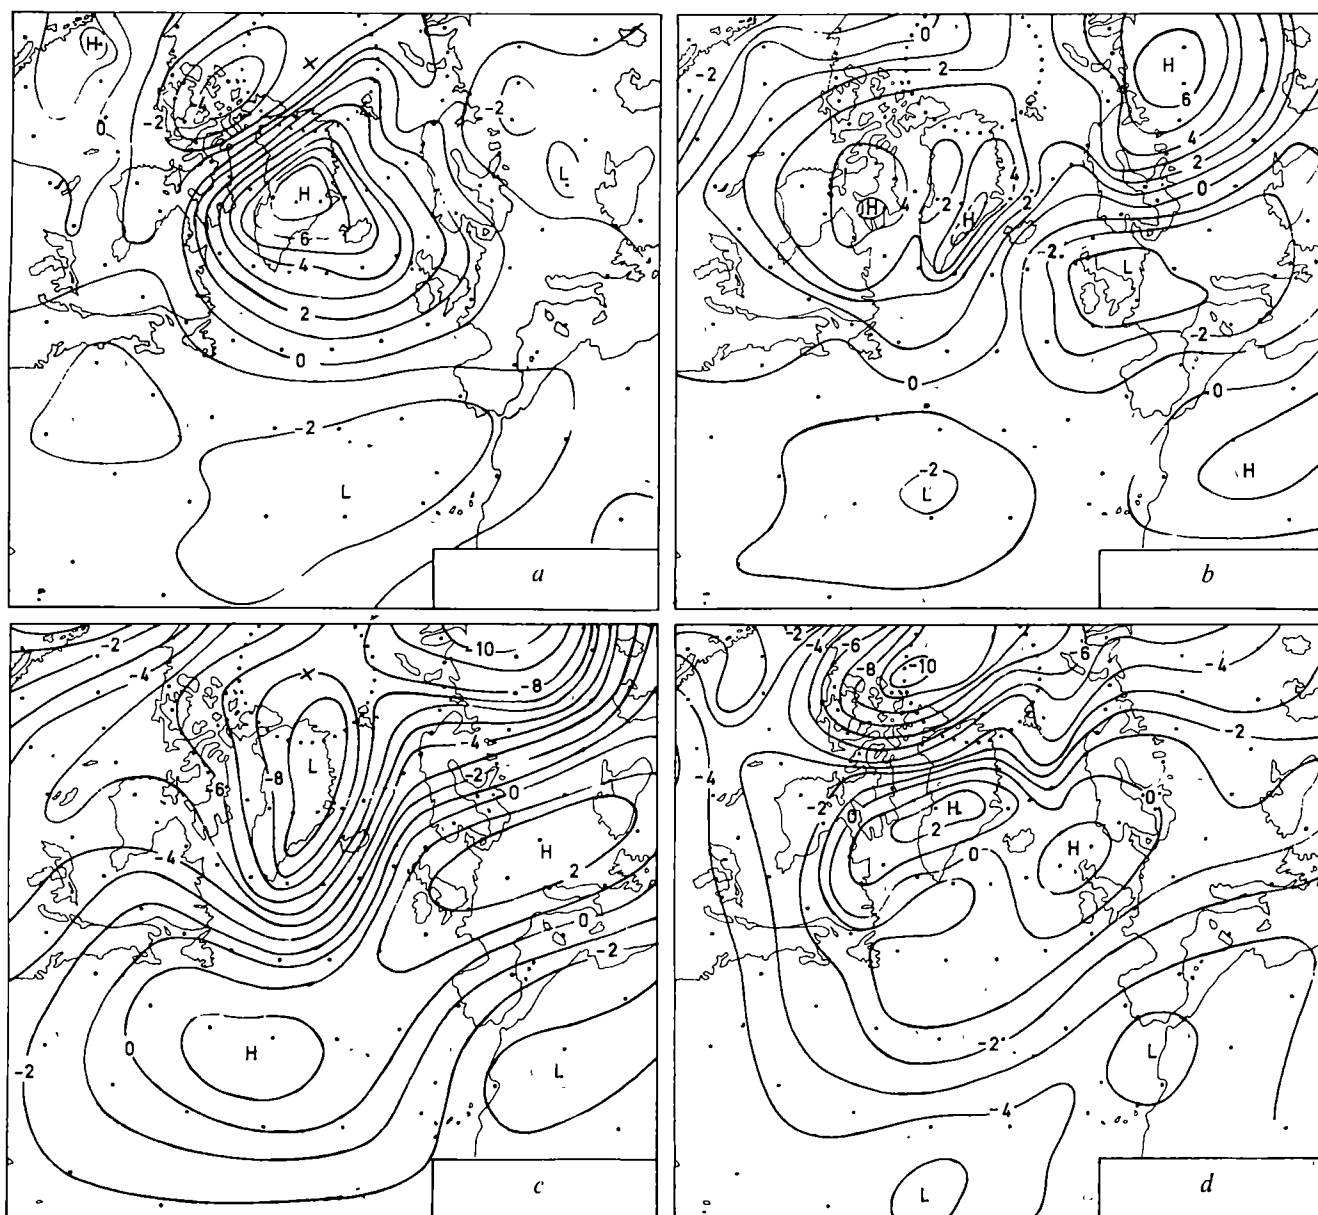
In the winter of 1970–71, the striking climatic trends evident over the Norwegian–Greenland Seas came to an abrupt halt. The high-pressure anomaly cell over Greenland, which had for so long dominated the patterns of climatic behaviour in


Fig. 1 Change of mean winter sealevel pressure (mbar) between the periods: *a*, 1900–39 and 1956–65; *b*, 1956–65 and 1966–70; *c*, 1966–70 and 1971–74; *d*, 1900–39 and 1971–74.

this sector, collapsed almost totally, and the mean pressure at sea level during winter fell by 9.6 mbar over Greenland between 1966–70 and 1971–74 (Fig. 1*c*). This ridge has not yet been totally eradicated, since in the earlier of the two periods the Greenland ridge had attained a peak intensity of over 12 mbar above the long term 'normal' (1900–39). Nevertheless, even though there is still a residual, high-pressure anomaly of some 2.8 mbar over Greenland (Fig. 1*d*) it is clear that the northerlies have been drastically weakened in the European arctic and subarctic since the winter of 1970.

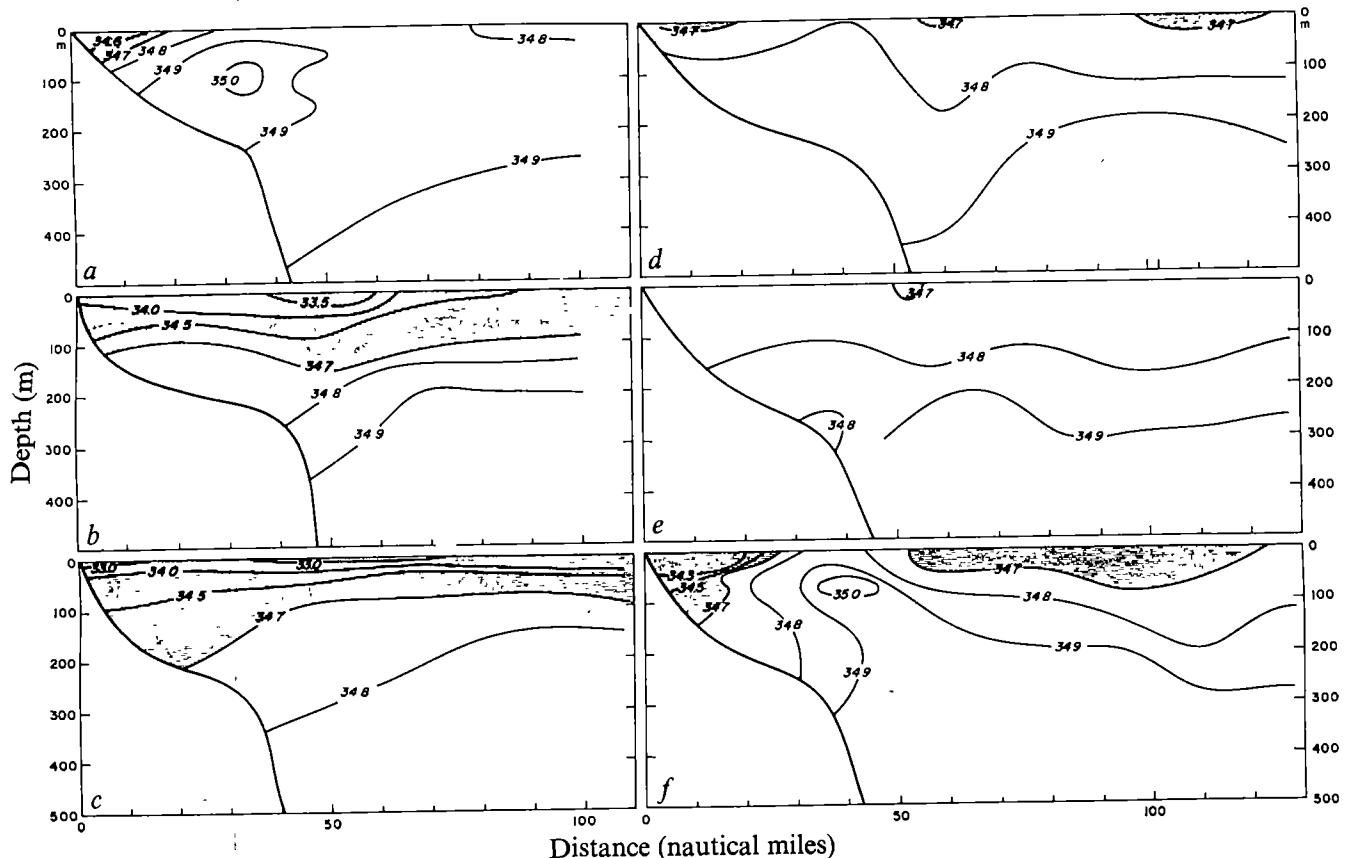
The reason why such a persistent feature as the Greenland ridge should become weakened so drastically remains obscure, though the effect of the weakening is readily apparent in the succession of mild winters experienced over most of Europe since 1970. It is now also evident that this change has already brought about some amelioration in the marine climate off North Iceland. Fig. 2 illustrates the deviations of temperature and salinity from the 1950–58 mean, using observations made in June. Though conditions have not reverted to those of the mild 'arctic current' period (1948–63), both the temperature and salinity of the near-surface layer have risen since 1971 compared with the values obtaining during the 'polar current'
Fig. 2 Anomaly of temperature (*a*) and salinity (*b*) in June at a depth of 25 m in a study area between Iceland and Jan Mayen Island (67–69°N, 11–15°W; the averages for the normal period 1950–58 are shown).


Fig. 3 Salinity distribution (°/oo) along a standard section worked north-eastwards from Langanes (north-eastern Iceland) in the month of June: 1957 (*a*), 1965 (*b*), 1968 (*c*), 1972 (*d*), 1973 (*e*) and 1974 (*f*).

period between 1964 and 1971. The increase in surface salinity is of especial importance in this area since, at salinities of more than 34.7‰, before the freezing point is reached, the surface layers will attain a sufficiently high density to over-turn and mix with the slightly warmer and more saline water at intermediate depths. At salinities of less than 34.7‰ the surface layers will not reach a sufficiently high density, even at the freezing point, to mix with these underlying layers and, instead, ice will tend to form.

Fig. 3 illustrates the recent weakening of polar influence off northern Iceland. The salinity section for June 1957 (Fig. 3*a*) is representative of a normal year during the relatively warm arctic period; 1965 (Fig. 3*b*) and 1968 (Fig. 3*c*) reflect conditions during the cold polar period (which reached its most extreme development in 1968) and the profiles for 1972–74 (Fig. 3*d–f*) represent conditions during the relatively mild period of the most recent years. As shown, polar water with a salinity of less than 34.7‰ was almost completely absent from the section in June 1972 and 1973, and though some renewed increase of polar water was observed in June 1974 its distribution was more restricted than in the 'polar current' period, 1964–71. Signifi-cantly, sea ice has posed no problem to navigation in northern Icelandic coastal waters since 1971 (H. Sigtryggson, personal communication).

In general, it may be concluded[8] that during the spring months of 1972–74 the Atlantic influx into northern Icelandic waters was stronger than in any year during the period 1965–71 (though remaining slightly weaker than the earlier 1950–60 normal[9]). The polar water component to the north and north-east of Iceland was weaker in the spring of 1972–74 than in any year since 1963 and only slightly stronger than in the warm period of earlier years. Thus the 'little ice age' observed in northern Icelandic waters in recent years seems to have ended with an amelioration of the marine climate during 1972–74. (It should be stressed, however, that this conclusion is diagnostic rather than prognostic.)

Although these physical and economic repercussions were most conspicuous close to the oceanic polar front at northern Iceland, similar trends of hydrographic change were also observed throughout the Norwegian–Greenland Sea during this period[10]. On 14 standard hydrographic sections worked in June across the entire ice-free area of the Norwegian–Greenland Sea from the latitude of Spitsbergen to that of south-western Norway (~60°–80°N), a general cooling has been observed between the mid 1950s and the late 1960s, with a rapid reversion to positive temperature anomalies occurring in the early 1970s. These broad scale changes in ocean temperature are in parallel with the strengthening and weakening tendencies of the northerlies in this sector, and presumably reflect changes both in the heat loss from the sea to the atmosphere, and changes in the poleward transport of warm water by the principal Atlantic current branches.

Americium 242m in nuclear test debris

DIAMOND et al.[1] discussed the production, in a thermonuclear explosion, of isobars of mass numbers 239 and greater by neutron reactions on uranium, followed by β decay; much the same arguments seem to apply to phenomena in plutonium devices. Both cases, viewed in this way, suggest that mass number 241 will be represented by both ^{241}Pu and ^{241}Am, mass number 242 only by ^{242}Pu, and mass number 243 only by ^{243}Am. Such considerations neglect, however, the fact that weapons-grade plutonium is always more or less contaminated by ^{241}Am, and that this nuclide has an appreciable cross section (100 barn for thermal neutrons and slightly larger for epithermal neutrons) for neutron capture leading to ^{242}Am; about 10% of such captures yield ^{242m}Am, the others going to the ground state. It seems, then, that one should expect to find in the debris from nuclear explosions not just two, but all three, of the long lived americium nuclides: ^{241}Am, ^{242m}Am and ^{243}Am.

extremely low levels, it should be practicable to measure ^{242m}Am in a variety of other samples, by searching for ^{242}Cm that is supported by a longer lived precursor. Actually we have remeasured one sample contaminated by fuel-reprocessing waste, and found that about 3% of the ^{242}Cm it contained was supported in this way.

The conclusion that ^{242m}Am has been produced, measurably, in nuclear tests, has some interesting consequences:

The ^{242}Cm daughter supported by decay of ^{242m}Am, in addition to being readily measurable in most areas of high fallout, should have, as a consequence of its generation by two rapidly successive radioactive decays (^{242m}Am decays, with a half life of 152 yr to ^{242g}Am, which decays with a half life of 16 h to ^{242}Cm), unusual environmental mobility, separating from other fallout transuranics much as ^{234}U has been found to separate from ^{238}U and ^{235}U.

Since ^{242}Cm decays to ^{238}Pu, its presence represents not merely an unevaluated additional source of this transuranic, but of a moiety of ^{238}Pu that would be expected to be more mobile than the fraction of that nuclide produced in the original event.

In plutonium the content of ^{241}Pu is greater in proportion to the fraction of Pu that has come as byproduct from electric power generation[4,5]; ^{241}Pu will, however, be a less important constituent of breeder reactor plutonium[6]. These considerations suggest that americium 242m will be a significant component of the debris from future nuclear tests, or peaceful

Table 1 Concentrations in disintegrations per minute per 100 kg

	^{239,240}Pu	^{241}Am	^{242}Cm	^{244}Cm	^{242}Cm/^{241}Am
Sample A	216±11	37.8±0.7	0.21 ±0.02	0.01±0.004	0.54%
Sample B	18± 3	2.67±0.06	0.013±0.004	ND	0.49%

ND, Not detectable.

We have been led to this consideration by our finding of a small but readily measurable amount of ^{242}Cm in samples of seawater that had been contaminated by close-in fallout from an isolated, low yield nuclear test in 1962. The 60-1 samples had been sealed in polyethylene containers from collection until being opened for radiochemical analysis in 1974. Americium 241 was separated from other nuclides, and prepared for α spectrometry, by radiochemical procedures[2,3]; in this scheme curium isotopes accompany americium almost quantitatively. The americium plates from the samples in question were counted in a low-level α spectrometer for 8,000 min, in a special effort to detect any ^{244}Cm remaining from that produced in the test. Because the two samples represented different water depths, and thus different dilutions of the test debris, the concentrations of transuranic nuclides were very different, but the ratios among them were similar (Table 1).

α-Emissions of energy corresponding to those of possible naturally occurring contaminants were absent, confirming the cleanness of the radiochemical separation.

The ^{242}Cm cannot, after more than 25 half lives, represent curium originally in the samples; we believe there is little likelihood it represents laboratory contamination. Great care was taken in the radiochemistry, and we have never before seen ^{242}Cm in americium plates, except in samples expected to have this nuclide from waste disposal; also the uniformity of ^{242}Cm/^{241}Am ratio in two samples of different activity level argues against accidental contamination.

It seems to us necessary to conclude that the ^{242}Cm observed is the daughter of ^{242m}Am produced in the original nuclear event, probably by neutron capture of ^{241}Am. Direct observation of ^{242m}Am, at the concentrations indicated, would be quite impossible: detector backgrounds are too high for measurement either of its own X-ray emission, or of the β particles from its daughter ^{242}Am. Because detector backgrounds can be maintained, for solid state α spectrometry, at

nuclear explosions, although diminishing in proportion to the increasing use of breeder reactor plutonium.

We urge our colleagues in environmental radiochemistry to make a careful search for ^{242m}Am, both to establish baseline data describing its present distribution in nature, and to set limits on the influence of this nuclide on the environmental behaviour of its descendants, ^{242}Cm and ^{238}Pu.

Tree remains in southern Pennine peats

RECENT work in Ireland[1-3], Wales[4], and south-west England[5] has demonstrated the coincidence in time of the onset of blanket peat accumulation with increased levels of prehistoric human activity in the vicinity; since many upland blanket bog areas in the British Isles have remains of trees embedded within the basal peat layers, it has been suggested that these tree remains represent a former forest cover, the deliberate clearance of which led directly to blanket peat formation. That is to say, the tree remains are assumed to immediately predate the oldest blanket peat layers.
Fig. 1 Stratigraphy and selected pollen values for the basal peat layers at site 1, Lady Clough Moor, Yorkshire (at the blanket peat margin). The pollen values are expressed as percentage total land pollen. The broken line marks the position of the Elm Decline

Table 1 Records of tree remains in southern Pennine blanket peats

Species	No. of sites	Altitudinal range (m)
Birch (*Betula* spp.)	16	320–595
Pine (*Pinus sylvestris*)	15	350–500
Oak (*Quercus* spp.)	10	320–470
Alder (*Alnus glutinosa*)*	5	290–400
Willow (*Salix* spp.)†	4	400–490
Hawthorn (*Crataegus* spp.)	1	about 350
Hazel (*Corylus avellana*)	1	about 320

* Includes 4 records of 'alder/birch wood' by Hicks[11].
† Includes one tentative record by Conway[9].

In the southern Pennines tree remains (in the form of twigs, charcoal, larger branches, procumbent trunks up to 2 m in length, or trunk bases and roots) occur widely within or below the basal blanket peat layers at altitudes from 290–595 m. Table 1 summarises the data currently available for 36 known sites, in terms of tree species recorded and the numbers of sites and altitudinal ranges at which they occur. The data are derived partly from records in the literature[6-11], partly from personal records, and particularly from extensive field surveys carried out by D. W. Yalden. The sites vary considerably in extent, ranging from those comprising the isolated tree stump in a moorland area of several hectares to those with locally dense concentrations of stumps and wood fragments. The majority of the sites are close to the margins of the blanket peat, but this distribution may merely reflect the relative scarcity of situations elsewhere where deep peat faces are exposed down to the underlying bedrock (and thus where

basal tree remains can be observed). Tree remains are rarely recorded from altitudes above 500 m. Some sort of altitudinal zonation can be detected from the data in Table 1 for the four commonest species, with birch and pine remains predominant in the peat at the higher altitudes, and alder restricted to altitudes below 400 m. The widespread distribution of pine remains in the peat has not hitherto been recognised for the southern Pennines, and, indeed, pine remains have hitherto only been widely reported from Scottish blanket peats.

Several studies have shown that much of the blanket peat in the southern Pennines started to form in early Atlantic times, around 5000 BC; and accordingly it seems likely at first that these widespread pine remains represent relics of the pre-peat forests of Boreal times (as in Scotland[12]). But at the three sites so far investigated in detail, both pine and birch remains occur not at the soil–peat interface but actually within the basal peat layers. Although roots may extend downwards into the underlying mineral soil, the smaller twigs in particular are situated at distances of 5–20 cm upwards into the peat. Pollen diagrams from one of these sites (Lady Clough Moor, grid reference SK 105926, altitude 500 m) are shown in abbreviated form in Figs 1 and 2. At the peat margin on Lady Clough Moor, with peat depths of less than 1 m on slopes of up to 25°, pine remains are abundant in the peat, and coincide in position with a temporary peak of *Pinus* values in the pollen diagram (Fig. 1); farther back from the margin, on slopes of less than 10° and with deeper peat, birch remains are predominant, but the *Pinus* pollen peak is still present (Fig. 2). Clearly this *Pinus* peak can be referred to the Sub-Boreal period (pollen zone VIIb, about 3000–500 BC), since it occurs a short distance above the initial decline of *Ulmus* pollen values (the Elm Decline, shown
Fig. 2 Stratigraphy, selected pollen values, and estimates of carbon content for the basal peat layers at site 2, [Lady Clough Moor, Yorkshire (30 m in from the blanket peat margin). The pollen values are expressed as percentage total land pollen. The broken line marks the position of the Elm Decline

by a broken horizontal line in Figs 1 and 2) and the first appearance of occasional pollen grains of *Plantago*. Although more precise dating of the pine and birch remains is not yet available, it is possible that they could be as late as the uppermost alder/birch layers at Leash Fen[11], which have been radiocarbon dated at 1500–1790 BC. Without further extensive field surveys, pollen analyses, and radiocarbon datings it is clearly impossible to say whether this Lady Clough Moor site is typical, or whether some of the tree remains in the southern Pennines do indeed predate the inception of the peat blanket. There is no reason, however, to suppose that the site is not typical, and accordingly some mechanism has to be postulated whereby secondary colonisation of shallow blanket peat by trees became possible for a relatively short time during the Sub-Boreal period.

In the basal layers of all marginal peats so far investigated in the southern Pennines there is widespread evidence of burning —either in the form of microscopic carbon particles (similar to contemporary 'soot'), small charred plant fragments, or larger lumps of charcoal. Figure 2 shows some preliminary attempts to quantify this evidence of burning. The two right-hand columns show the abundance of soot-like particles and of charred plant fragments in the microscope slides prepared for pollen analysis, assessed subjectively on a five-point scale of frequency. The third column shows the weight of insoluble residue left after digestion of the peat with 20% potassium hydroxide and concentrated nitric acid (expressed as a percentage of the oven-dry weight of the peat). Under the microscope the majority of this insoluble residue seems to be carbonaceous. Carbonisation of the peat occurs in all samples examined, although there are clear differences in levels of carbon in different samples. Evidence of burning is least in the samples with high *Pinus* values, whereas high soot levels in the peat occur immediately above and below this *Pinus* pollen peak, and also immediately below the Elm Decline. Patterns of change in *Calluna*, *Corylus*, and Gramineae pollen values to some extent follow the evidence from burning patterns.

Probably the whole southern Pennine area is within the potential altitudinal range of tree growth, so that it is possible that before, and in the early stages of peat formation, colonisation by trees was prevented by recurrent fires. These recurrent fires could have been a natural phenomenon, but it is equally plausible that they were anthropogenic in origin. Numerous Mesolithic chipping sites, where flint or chert brought in from outside was worked into the characteristic artefacts, have been recorded from the southern Pennine uplands (see ref. 13 and references therein), and the area seems to have been a favoured seasonal hunting ground for Mesolithic populations for several millennia[13]. Most of these Mesolithic sites are clustered around the present-day blanket peat margins, at altitudes of 360–480 m. At two of these sites pollen analyses have shown considerable local disturbances in the vegetation at the level of Mesolithic occupation[13]. But the widespread carbonaceous remains in the basal peat layers indicate more than just local disturbance of the vegetation. There is evidence from contemporary hunter–gatherer communities of the widespread use of fire to increase the stocking capacity of hunting grounds and to control herd movements[14], so that it is possible that sporadic burning was also carried out in the southern Pennine uplands before 3000 BC by Mesolithic hunters. Evidence of burning in the peats, however, continues upwards into the Sub-Boreal period, when Mesolithic populations had almost certainly been replaced by Neolithic cultures. Since at several sites in the southern Pennines there is apparent continuity of occupation from Mesolithic to Neolithic times[15], it is possible that the uplands continued to be used primarily as seasonal hunting grounds for many centuries after the first advent of Neolithic peoples (at the time of the Elm Decline). With the gradual development of more intensive agriculture, anthropogenic pressure on the uplands may ultimately have diminished, and with reduced frequencies of

burning, trees were able to colonise the drier shallower peats. The subsequent disappearance of these trees could have been the result of natural death from waterlogging consequent on peat accumulation, but since most tree remains in the peat are of relatively young trees it is more probable that deliberate woodland clearance was involved. Contrary to recent hypotheses[4] peat formation was already well advanced by this time.

Regularities in duration of regional desert locust plagues

DURING a plague of desert locusts, *Schistocerca gregaria* (Forskal), extensive areas are infested by successive generations of gregarious populations, and for working purposes a plague can be considered to be in progress as long as the progeny of swarms remain in swarms. In the periods between plagues, or recessions, the species exists mainly in low density populations, and such small swarms as occasionally occur seldom persist beyond one generation.

The total area invaded by desert locust swarms during plagues extends from West and North Africa eastwards to Assam, and from the Middle East to Tanzania, and can be divided into four major regions—western, eastern, north-central and south-central[1] Each region contains complementary seasonal breeding areas connected by migration circuits which are characteristic, but not always closed. From records assembled at the Anti-Locust Research Centre (now Centre for Overseas Pest Research) it was possible to reconstruct the incidence of regional plagues back to 1900 in the north-central and south-central regions, and to 1860 in the western and eastern regions. The data obtained were examined to see if there was evidence of plague regularities or of periodicities such as have been suggested for the eastern[2] and western[3] regions. The main conclusions are summarised below; the full data and their discussion, and all the details of statistical analyses, are presented in refs 1 and 4.

Table 1 Frequency distribution of intervals between onsets of successive regional plagues

Interval (yr)	≤4	5–7	8–10	11–13	14–16	17–19
Frequency of occurrence	5	9	7	5	8	2

Parameters available for analyses were the lengths of regional plagues and recessions, and of the intervals between onsets of successive regional plagues. To have sufficient data for statistical tests, combined values from all regions were used in each analysis. This is not strictly valid, as swarms may move between regions, which are therefore not entirely independent. As the continuation of regional plagues seems to be independent of such move-

ments, however, we decided to pool the data and regard conclusions as tentative.

Table 1 shows that the intervals between onsets of successive plagues in the same region were very variable. The evidence of any regularity was not increased when plagues were considered in sequence, for in all the regions the serial correlation of successive intervals was not significant. As in three regions the correlations were negative, the intervals between onsets of one and the next but one plague were calculated, such double intervals were found, however, to vary from 9–28 yr. Thus the intervals provided no evidence of periodicity.

The frequency distributions of the durations of regional recessions and plagues (Fig. 1a and b) were considered separately Both were tested by examining their goodness of fit to the frequency distributions which could be expected on the following hypothesis : once started, a plague or a recession continues independently of how long it has lasted, until a chance occurrence of conditions which bring it to an end. The respective χ^2 tests showed that the actual distribution of recession lengths was consistent with this hypothesis, whereas the distribution of the plague lengths was not, so that for them the hypothesis could be reasonably discarded.

It follows that the termination of a plague may depend on how long it has already lasted. When estimates of the probabilities of a plague finishing in a particular year were calculated from the frequency distribution of plague lengths they suggested (Table 2) that the probability of a plague lasting only 1 yr was quite high, but that of it

Fig. 1 Frequency distribution of durations of regional desert locust recessions (a; $n = 36$) and plagues (b; $n = 40$).

finishing after 2 yr was very small, thereafter the longer the plague lasted, the more likely it was to end, with the probability of it lasting more than 8 yr being very small indeed. In effect, only one regional plague lasted more than 8 yr and in 55% of cases they lasted 6–8 yr (Fig. 1b).

The overall lack of periodicity in the onsets of regional plagues arises from a combination of the lengths of the plagues, which show some regularities, with those of recessions, which do not. The large proportion of brief regional recessions (Fig. 1a) may partly be caused by their termination by swarm invasions from outside. But some of them came to an end as a result of local plague upsurges, suggesting residual populations capable of a rapid rise to plague level.

Table 2 Estimated probabilities of a plague finishing in a particular year when it existed at the beginning of that year

Plague existing in year:	1	2	3	4	5	6	7	8
Probability of it finishing	0.18	0 00	0.06	0.10	0 18	0.36	0 47	0 88

From the frequency distribution of regional plague lengths it seems that plagues may be of two types—longer ones, which seem to carry the seeds of their own destruction, and short ones The termination of some recent plagues, both short and long[5], may have been contributed to by control measures. It is certain, however, that such measures used in earlier times could not have had any significant effect on swarming populations. It is also known that the ending of some of the plagues was associated with droughts[1,6]. It seems doubtful, however, that climatic factors, acting either directly or by differing from those to which locusts may have been preconditioned by the photoperiodic regimes of their progenitors[7], could have accounted for the termination of most of the longer plagues, which ended at comparatively regular intervals after their irregularly occurring onsets. A cumulative effect of parasites and predators could be consistent with such regular intervals, but a review of available data on effects of all biotic factors on this highly mobile species indicated that they probably did not materially affect large swarming populations[8].

The tendency of the longer plagues to last a comparatively regular and seldom exceeded period suggests that their declines may be brought about by some deterioration in populations persisting in a crowded state for a long succession of generations. Deleterious changes in high density insect populations are known[9-11] and in locusts the reproductive capacity becomes reduced on crowding[12]. This suggestion could be tested, in the event of another desert locust plague, by comparing in standard optimum conditions the survival and reproductive potentials of members of swarming field populations differing by known numbers of gregarious generations from the initial swarms.

Development of a desert locust plague

THE role of phase change in the development of plagues of the desert locust, *Schistocerca gregaria* (Forskal), has been debated for many years[1-5]. Much confusion has arisen because changes in behaviour, form and colour, which have all been used as indicators of phase status, do not proceed at the same rates It is generally agreed, however, that behavioural changes are crucial in phase transformation. The subject at issue in the population dynamics of the desert locust is whether plagues, periods when extensive areas are infested by successive generations of gregarious populations, originate from an upsurge in numbers and associated transformation from the solitary-living to the gregarious state, or from successful breeding by gregarious populations postulated to survive continuously throughout the interplague recession periods[3]. Fundamental questions about the strategy of plague prevention depend on determining which of these hypotheses is correct[1,3,4,6].

An analysis of events preceding and during the 1968 desert locust plague has demonstrated the importance of phase transformation in plague development[6]. The upsurge of this plague, which began in mid-1967, was the result of an increase in numbers and densities of initially solitary-living locusts in successive generations. Each generation bred successfully following periods of rainfall over large parts of the normally arid recession area. It has been tentatively concluded from analysis of 36 occurrences of successful breeding that 25 mm is the threshold rainfall requirement for multiplication from mature parents to filial fledglings. This is slightly more than the 20 mm previously shown to be necessary for successful oviposition and incubation[7]. The timing of these falls of rain was such that a very short period usually elapsed between fledging and maturation, and this may be critical in upsurges.
Fig. 1 A sequence of breeding by desert locusts. The first generation (F_0) bred in early 1967, and the F_8 generation in late 1968. There is no evidence of breeding by F_7 adults. Arrows indicate direction of displacement between generations. Breeding areas are not drawn to scale.

Small and usually transient swarming populations are intermittently reported during recessions[4,5]. Careful examination of all reports of desert locusts in 1966 and 1967 (ref. 6) suggests that the last two authentic swarms, before the buildup in mid-1967, were found in January 1966—one in Ethiopia and the other in Somalia. Neither produced gregariously-behaving adults in the next generation.

From mid-1967 to mid-1968 increasingly large numbers of locusts were reported from a number of places within the 14 million km² desert recession area stretching from West Africa to India. In each generation in each sequence of breeding there were progressive changes in the character of the populations, and the sizes of the infested areas. This can be illustrated by examining one such sequence, traced

over eight generations (Fig. 1). Detailed analysis has shown that the preliminary assessment of events outlined by Pedgley and Symmons[8] was substantially correct. It is almost certain that the first generation bred in the south-western interior of the Arabian peninsula in April–May 1967 (F_0). The second probably bred partly in that area and partly on the coastal plain of Yemen and Saudi Arabia in July 1967 (F_1). There is no evidence of gregarious behaviour in either of these generations, that is to say no bands of hoppers or swarms of adults were reported. One sequence that developed from this source involved a further generation breeding on the coastal plain after rain in November 1967, and two more on the coastal plain and in the interior of Saudi Arabia after rain in February and April 1968.
Fig. 2 The approximate numbers of locusts in each generation (×) and the gross areas infested by different types of population during the sequence of breeding shown in Fig. 1. Open bars show areas infested by locusts that were not fully gregariously-behaving; black, by swarms; striped, by bands. Gross infested area is the area needing treatment to reduce the population to an insignificant size.

In these three generations (F_2, F_3 and F_4) an increasingly large number of locusts were found in an expanding area (Fig. 2) and an increasingly large proportion of the population showed some gregarious behaviour. The F_5 generation, however, was the first in which almost all the locusts were in bands and swarms. From May–August swarms of this generation emigrated from Saudi Arabia. About half migrated south-west across the Red Sea to Egypt and Sudan, where they started to breed in June 1968. Once gregarisation had occurred the gross infested area was reduced by about an order of magnitude between generations F_4 and F_5 in this sequence, although the number of locusts continued to increase (Fig 2). Approximately half of the F_6 swarms emigrated from Sudan to Morocco, where low winter temperatures delayed maturation and almost all the swarms were killed before they could breed. Other swarms from Sudan migrated towards the Red Sea coastal plains; some were controlled and the remainder oviposited between September and November. There, the F_7 generation was much reduced by control, and the survivors died without producing gregarious locusts in the next generation. The progressive reduction in infested areas from F_5 to F_7 and in numbers from F_6 to F_7 (Fig. 2) resulted from control

Values of means of first canonical
variates of samples
Fig. 3 Values of means of first canonical variates of samples from successive generations in two upsurge sequences. *a*, West Africa: F_2 Niger, September, 1967; F_3 Mali and Algeria, November 1967–March 1968; F_4 Mali, July 1968; F_5 Mali and Niger, September–November 1968. *b*, Sequence shown in Figs 1 and 2

measures and natural mortality, and cannot be taken to represent typical development during a plague.

Morphometrics are available for several samples from generations F_2 to F_7 in the above sequence The largest representative samples are shown in Fig. 3, which shows that the steady increase in gregarious behaviour was paralleled by a shift from the solitariform to the gregariform in the means of the first canonical variates[9]. The F_7 sample came from the Red Sea coast population that was the progeny of the most solitariform of the populations from which the F_6 samples were derived, so the shift towards gregariform continued in this generation The two more gregariform F_6 samples were derived from the swarms which moved westwards from Sudan towards Morocco. Similar shifts can be seen in other sequences of breeding that contributed to the plague, the most complete of which is also shown in Fig. 3

Phase transformation was progressive, and an integral part of the development of the most recent desert locust plague. One aspect of phase transformation is that during swarm formation (Fig. 2), the gross area requiring treatment contracts. The same area dosage rates are required for effective control of locusts whatever their density, so it is clearly more economical to concentrate control on the initial gregarious populations than to attempt to control the much larger areas infested at earlier stages in an upsurge, or the subsequent swarming generations which may be larger. A fuller account of this work will be published elsewhere.

Seed-borne microorganisms
stimulate seedcorn maggot egg laying

LARVAE of the seedcorn maggot, *Hylemya platura* (Meigen) may damage or kill young plants of many crop species by feeding on the cotyledons and plumules (Fig. 1). Damage may

be caused by larvae already present in the soil before the seeds are planted[1] or by larvae that hatch from eggs laid near germinating seeds[2,3]. It has been assumed that the stimulus for oviposition is provided by the germinating seeds themselves but we suspected that seed-borne microorganisms growing on seed exudates could produce metabolites that promote oviposition. Many metabolic processes begin at the onset of seed germination, and concurrently organic substances are leached from the seeds which provide substrates for microorganisms. We now report that microorganisms growing on substrates from seeds produce metabolites which stimulate egg laying in *H. platura*, and that germinating microorganism-free seeds are not stimulatory. This is an excellent example of a complex ecological interaction between an insect pest, the host plant and organisms of the microenvironment.
Fig. 1 *a*, Flies, eggs, puparium and larva of *H. platura*. *b*, Examples of varying degrees of injury on squash seedlings caused by earlier maggot feeding.

Squash (*Cucurbita pepo L.*) seeds, which elicit profuse oviposition[3] were planted in a system designed to prevent microbial contamination and to provide a suitable ovipositional substrate. Seeds or their microorganisms were incubated for 24 h for complete seed imbibition and/or microbial growth to occur. Flies that had been reared using a modified Harris technique[4] were then given access to beakers containing either the seeds or microorganisms for 24 h, immediately after which the eggs were counted[5]. All experiments were repeated five times.

We compared microorganism-infested seeds with seeds free from infestation. Earlier work demonstrated that Butternut squash seeds were preferred by the flies[3] but we could not eliminate seed-borne microflora from this variety without killing the seeds. We therefore included Table Queen seeds whose microflora could be eliminated without imparing germination[6]. With both varieties, most egg laying occurred in beakers containing seeds infested with microorganisms,

Table 1 Oviposition by *H. platura* in beakers containing squash seeds incubated on water agar and covered by a layer of sterile acid-washed quartz sand

Seed	% Total eggs oviposited
Infested Butternut	47
Infested Table Queen	27
No seeds	17
Microorganism-free Table Queen	8

The results are all significantly different at the 5% level as determined by Duncan's multiple range test on arcsin transformations.

significantly fewer eggs were found in containers with no seeds, and very few with microbe-free seeds (Table 1). These results show that microorganisms on squash seeds stimulate *H. platura* oviposition. In addition, germinating squash seeds in the absence of microorganisms may deter oviposition (Table 1). Two additional tests not reported here gave similar results.

Before attempting to identify some of the microorganisms involved we had to develop a system enabling us to isolate them in pure culture. Since either germinating seeds or soil may provide the substrates for growth of the stimulatory microorganisms, we developed a system using squash seed exudate

Table 2 *H. platura* oviposition in beakers containing various media and microorganisms from squash seeds

Medium	% Total eggs oviposited*
SSEA†+microbes	49.8 (a)
SEA‡+microbes	18.5 (b)
SEA	14.5 (b)
SSEA	8.9 (b)
Water agar	8.4 (b)

The microorganism inoculum was a mixture of microorganisms obtained from the Butternut seeds. The substrate was in polypropylene reservoirs surrounded by water agar and covered by a sterile glass-fibre filter and a layer of sterile acid-washed quartz sand.

*Percentages followed by different letters are significantly different at the 5% level as determined by Duncan's multiple range test on arcsin transformations.

†Squash seed exudate agar (SSEA) was prepared from a mixture of 100 g of Butternut squash seeds in 1 l of distilled water that had been shaken for 16 h. The seeds were removed by filtering through cheesecloth, the liquid portion clarified by centrifuging at 10,000g for 10 min followed by filtration through a Reeve-Angel 934 H glass filter. The resulting liquid was heated with sufficient agar to make a 2% solution and sterilised by heating at 120 °C for 20 min.

‡Soil extract was prepared by heating a mixture of 100 g of greenhouse soil with 1 l of tapwater at 100 °C for 30 min, then adding about 1 g of $CaCO_3$, filtering, and finally sterilising in the autoclave for 20 min at 120 °C. The complete soil extract agar (SEA) was prepared by mixing 100 g of soil extract, 0.5 g K_2HPO_4, 1 g of glucose, 20 g of Bactoagar and 1 l of water. This mixture was heated until the agar was in solution and then sterilised at 120 °C for 20 min. The pH of SSEA was 4.9–5.1, that of SEA was adjusted to 8.4.

agar (SSEA) or soil extract agar (SEA) (Fig. 3). The media were inoculated with 200 µl of a mixture of microorganisms obtained by shaking 10 g of the highly stimulatory Butternut seeds for 16 h in 100 ml of distilled water at 23–25 °C; dilution plates of the mixture yielded 10^{10}–10^{12} microorganisms ml^{-1} with Bacto-Nutrient Agar. When inoculated, heavy microbial growth occurred on both SSEA and SEA but the former was preferred for oviposition (Table 2). These results indicate that squash seed exudates provide substrates for microorganisms which produce stimulatory metabolites and provide a system for routine assay.

Table 3 Oviposition by *H. platura* in beakers containing various microorganisms grown on SSEA

Microorganism	% Total eggs oviposited*
Pseudomonas+Torulopsis aeria	47 (a)
Pseudomonas sp	26 (b)
Torulopsis aeria	22 (b)
None	6 (c)

The substrate was in a polypropylene reservoir surrounded by water agar and covered by a sterile glass-fibre filter and a layer of sterile acid-washed quartz sand.

*Percentages followed by different letters are significantly different at the 5% level as determined by Duncan's multiple range test on arcsin transformations.

Among the pure cultures obtained from Butternut seeds, a bacterium, a *Pseudomonas* sp. (Migula)[7] and a yeast, *Torulopsis aeria* (Saito) Lodder[8], were the most effective elicitors of oviposition. Isolates of these organisms have been deposited in the USDA Northern Marketing Research Division Collection, Peoria, Illinois, and have been designated NRRL B-4287 and NRRL Y-7845, respectively. Mixed cultures of these two organisms stimulated oviposition to a greater extent (Table 3).

This work provides a model system for metabolite identification. Syntheses of ovipositional stimulants may improve population monitoring of *H. platura* in the field as is the case with pest monitoring and modelling using synthetic insect sex pheromones[9].

We thank Glenda Nash and Helen Van Buskirk for technical assistance.

Defensive stoning by baboons

REPORTS of the use of tools in offence or defence by wild animals is limited to accounts of chimpanzees throwing branches at conspecifics, potential predators and at human observers[1]. Anecdotal accounts of stone throwing by baboons[2] have been dismissed on the basis of the unreliability of correspondents and the improbability of oriented throwing by a quadruped anatomically incapable of overhand throwing[3]. In spite of several years of field study elsewhere in Africa, often in rocky terrain, there are no reports by professional field observers of deliberate stone throwing by baboons[4–7].

Nevertheless, in the course of a one-year study of three chacma baboon (*Papio ursinus*) troops living on the desert floor of the Kuiseb Canyon in South West Africa we observed numerous instances of stone release directed towards us.

Stoning by these baboons is done from the rocky walls of the canyon where they sleep and retreat when they are threatened by real or imagined predators. Stones are lifted with one hand and dropped over the side. The stone tumbles down the side of the cliff or falls directly to the canyon floor. We recorded the details of 23 such incidents involving the voluntary release of 124 stones towards us. All age and sex classes larger than 2-yr-olds participated at least occasionally in stoning (Table 1). But the most frequent participants are 4-yr-old and older males. The unhabituated nature of the troop members and the early stage of the study made individual identification impossible.

These stoning activities were accompanied by escape movements and typical "wahoo" alarm and barking calls, further identifying the context of the event as a predator–prey interaction. Such vocalisations are given typically in the presence of other predators such as leopards and sometimes hyaenas. The only animals preying on baboons in the Kuiseb Canyon today are the spotted hyaena (*Crocuta crocuta*), the brown hyaena (*Hyaena brunnea*) and man. Leopards lived in the canyon until recently but are now absent. Baboons have probably not been hunted by man in this canyon in recent years.

Stoning is aimed in the sense that the stone is released in such a way that it falls towards the observer, the stoning individual having moved to a position on the cliff directly above or opposite the observer. A stone is picked up, sometimes by prying it loose from the substrate, and released with an underhanded shovelling motion, or is simply dropped over the edge. This frequently resulted in stones whizzing over our heads. Usually we could dodge; but occasionally two or more individuals release stones at approximately the same time, complicating evasion. Stoning persisted when we were far enough out from the walls to preclude any possibility we might be struck. On one occasion we saw a stone released in the typical manner when we were above the releasing individual.

Stoning was never observed in the context of intraspecific

encounters, either in intratroop combat or in intertroop encounters. Baboons remove stones from sleeping ledges when these sites are occupied at dusk. The material removed at such times is copious and gives the opportunity to evaluate the selectivity of defensive stoning. Of 200 randomly selected stones picked up from below a sleeping cliff following occupation of that cliff by one troop the mean size was 9 cm × 5 cm and weighed 88 g. The mean size of 22 stones released towards us from that cliff was 165 cm × 104 cm and weighed 583 g. Evidently baboons select relatively large stones to release towards intruders.

A special set of conditions is required to elicit this stoning behaviour. The initial response by baboons to our presence in the Kuiseb Canyon was to flee up the rocky slopes of the canyon wall. No stones are released in such circumstances, although occasionally one may be kicked free and tumble down the cliff. Late in the year of our study the troops became more accustomed to us and, although they retreated from our close approach, they dropped no stones. Stoning occurred only when a troop was partially habituated to our presence. This occurred in the middle months of our study and when we returned following a 2-month absence.

Table 1 Age/sex distribution of stoning individuals in three troops

Age/sex (No. of individuals, 3 troops)	No. of incidents	Expected incidents
I (11)	0	2.6
J1, J2 (10)	0	2.4
J3 (11)	5	2.6
J4M (2)	2	0.5
AF (21)	2	5.0
SAM (7)	3	1.7
AM (17)	7	4.1
Unknown	4	—

Expected values are derived from the age/sex distribution of the 79 individuals comprising the three troops observed.
I, Infant; J, juvenile; AF, adult female; SAM, subadult female; AM adult female.

For stoning to take place there must be associated cliffs with free or loose rocky material. Individuals initiating stoning generally persist with several stones. If loose material is exhausted the thrower may work vigorously, attempting to free loose rocky material from the canyon walls.

Stones were never seized when the relevant conditions prevailed and the troop was on a talus slope rather than on a steep cliff. The threat must come from beneath the cliff to elicit stoning. During some of our later observations of this behaviour we deliberately elicited stoning either to gain additional data or to demonstrate it to other observers. By carefully gauging the movement of the troop we were able to approach them when they were near a suitable cliff. Our presence moved them up on to it. By remaining beneath their cliff but out of range we were regularly able to elicit stoning behaviour. The need for troops to be partially habituated to begin stoning may explain the confusion concerning the reality of aimed stone throwing by baboons elsewhere in Africa. If stoning does occur elsewhere in Africa it could easily be missed. Animals habituated away from cliffs may not throw stones when observations are made in an otherwise appropriate environment.

Eccentricity-specific dissociation of visual functions in patients with lesions of the central visual pathways

THE human retina projects not only to the lateral geniculate bodies and from there to the visual cortices, but in a parallel fashion to several other subcortical centres as well. One such centre is the superior colliculus, and it has been suggested that a rudimentary discrimination capacity of the locus of visual stimuli may be mediated by this structure[1]. Results of anatomical studies with subhuman primates indicate that the macular region does not project to the superior colliculus[2,3] (or that it is represented by a different population of retinal fibres which have not yet been identified by anatomical techniques[4]). The macular region seems to project only to the lateral geniculate bodies and from there to visual cortices, whereas the retinal periphery projects to several subcortical centres. This raises the question of whether a similar dissociation of projection between the central and peripheral retina also can be found in the human visual system. We present data obtained from patients with lesions of the central visual pathways which indeed suggest such a dissociation.

Besides kinetic and static perimetry[5], the measurement of the critical flicker fusion (CFF) has proved to be a fruitful technique in the evaluation of visual dysfunctions in patients. A cortical lesion seems to result almost always in a diminution of the CFF in the contralateral visual field[6,7], also affecting the intact regions of the visual field and even the ipsilateral half field[8]; it has been suggested that the diminution of CFF in cases of brain injury is associated with changes in other visual functions such as the increment threshold[9], by which retinal sensitivity is measured, although this claim does not seem fully supported by the published material.

Table 1 Effect of stimulus eccentricity on CFF (Hz)

Patient	Contralateral to				Δ5°	Δ20°
	Lesion side		Intact side			
	20°	5°	5°	20°		
E A.	23.7	19.5	30.6	25.3	—11.1	—1.6
F.H.	31.0	26.0	33.3	29.0	—7.3	+2.0
G.J	30.4	30.5	31.6	30.3	*—1.1	+0.1
	Left side		Right side			
Control subjects (n=9)	30 8 (23 5–39.1)	32.1 (25 5–36.9)	32.0 (27.6–36.9)	30.9 (23.0–40.8)	0.1	0.1

$*P \leqslant 0.01$

We measured the CFF in three patients with injuries of the central visual pathways and in nine control subjects. Two patients (see Table 1, E. A. and F. H.) had homonymous upper quadrant defects, whereas one patient (G. J.) had no obvious visual field defects, but had received a penetrating brain injury by a gunshot that ended in the lateral and caudal thalamic nuclei presumably injuring fibres of the geniculo-cortical pathway. The CFF in the patients and control subjects was measured at 5° and 20° eccentricity along the 225° (left lower quadrant) and 315° (right lower quadrant) meridians. These eccentricities were chosen because the anatomical evidence from primates suggests that the borderline of dissociation of central pro-

jection is beyond 5° but below 20° eccentricity[3]. For stimulus presentation the Tubinger perimeter[5] was used. The CFF was measured binocularly after a careful monocular perimetry had been carried out. The diameter of the stimulus was 116 arc min visual angle, its luminance and the background luminance were 10 apostilb (3,183 cd m^{-2}). The red fixation point had a diameter of 30 arc min visual angle. The fixation was observed by the experimenter throughout the CFF measurements. For determination of the CFF, the ascending method of limits was used, starting at a frequency well below the fusion threshold. With the exception of one patient (G.J.) seven measurements were taken at each eccentricity. The means of these measurements are shown in Table 1 for the patients E.A. and F.H. and in averaged form for the nine control subjects (the range is given in parentheses). The measurements on patient G.J. were much more extensive. On 7 different days 15 CFF values for 5° and 10 CFF values for 20° eccentricity were determined, each value being the average of 5 single measurements. The mean values of these 10 and 15 values are also shown in Table 1.
Fig. 1 Peephole visual field of a patient (H. H.) with a vascular lesion of both occipital lobes. S, Visual stimulus used to measure the visual field (116 arc min visual angle, 1,000 apostilb), BG, light intensity of the homogeneous background (10 apostilb); FP, fixation point (60 arc min visual angle, 1,000 apostilb); FD fixation distance.

The results (Table 1) show no difference of CFF for the control subjects if the measurements of 5° and 20° on both sides of the visual field are compared. As would be expected for these conditions, CFF is slightly lower towards the periphery[10]. For the patients E.A. and F.H. we observe a striking diminution of CFF contralateral to the lesion side for 5° eccentricity; CFF is 11.1 and 7.3 Hz less than contralateral to the intact side. Such a diminution of CFF is not seen for 20° eccentricity. For patient G.J. we observe no difference of CFF, if the measurements at 20° eccentricity on both sides of the visual field are compared (Wilcoxon test: $T=12$, $P \geqslant 0.05$). Although there is only a 1.1 Hz difference in CFF if the measurements at 5° eccentricity are compared, this difference turns out to be highly significant (Wilcoxon test: $T=1$, $P \ll 0.01$).

Our observations can be summarised as follows : a lesion of the central visual pathways results selectively in a diminution of CFF in the perifoveal area leaving CFF in the periphery of the visual field apparently unaltered. The diminution of CFF is observed in the intact part of the

visual field, and it may even be observed if no obvious visual field defect is present (patient G.J.) stressing the sensitivity of CFF for diagnostic purposes.

We suggest that the selective influence of a lesion of the central visual pathways on CFF in the perifoveal area but not in the periphery of the visual field is a consequence of a dissociation of retinal projection as it has been observed in lower primates. This is supported by a further observation in one patient (G.J.). Latencies of saccadic eye movements are much longer for targets at 5° eccentricity when they lie contralateral to the lesion side, but such a difference was not seen for targets with 20° eccentricity. An eccentricity-specific dissociation was not seen for increment threshold, however, which was higher at all eccentricities between 5° and 25° contralateral to the lesion side. The observation of a dissociation seems to be dependent on the selection of the test. Furthermore, the diminution of CFF at 5°, but not at 20°, suggests that the retino-collicular and cortico-collicular pathways are somehow involved in the perception of flicker. In experiments on programming of saccadic eye movements[11] it has been observed that targets within 10° of the visual axis are reached by one eye movement, whereas targets beyond 10° elicit at first an orienting response bringing the line of sight closer to the target, and then in a second step the target is reached by a corrective saccadic eye movement. These observations and the facts presented here favour the hypothesis that visual information is analysed in a qualitatively different manner by the nervous system according to its distance from the visual axis. The anatomical observations in subhuman primates would suggest that this differential analysis is dependent on a dissociation of the retinal projection in the human visual system.

Evidence for visual function mediated by anomalous projection in goldfish

IN goldfish, there is a complete decussation of the optic nerves and only contralateral projection to the optic tectum is present. If one tectum is removed surgically, a few months later, the contralateral eye projects to the remaining ipsilateral tectum, superimposes the normal projection in a mirror-image fashion and retains its normal polarity[1]. The method of mapping visuo-tectal projection involved presynaptic recordings of the optic fibre terminals in the tectum. It is not known, however, whether or not the anomalous projection is able to mediate visual behaviour. To determine whether the regenerated optic nerve fibres have formed functional connections in the tectum, post-synaptic recordings and (or) behavioural tests are required. We report here a preliminary finding that the anomalous ipsilateral

visuotectal projection, after removal of the contralateral tectum, may mediate the detection of a visual stimulus, with a threshold not significantly different from the normal projection. Sharma[1] has observed that in animals with complete removal of the right tectum "after removal of the right eye in these animals, the behaviour mediated by the left eye was apparently normal", and here we supplement those observations with psychophysical data.

Three adult fish were prepared as described previously[1]; the entire left optic tectum was removed by cutting and suction, and the skull flap replaced; both eyes were left intact. Psychophysical testing began 125 d after tectal removal, at which time an organised ipsilateral projection is present. The fish was restrained in a transparent plastic envelope, and respiration recorded by suspending a thermistor, operated in its heating mode, in front of the fish's mouth. Breathing produced a temperature change in the thermistor; the resistance changes were recorded on a polygraph and were also converted to digital form with a saturating amplifier and sensitive relay. Details of the method are described elsewhere[2]. The fish was suspended in an experimental tank with one eye facing a stimulus field (4×6 cm) at a distance of 45 cm. The field was illuminated constantly at a luminance of 3.3 cd m^{-2}. The stimulus consisted of five vertical bright bars, 15 mm across, which were moved back and forth twice each second at a rate of 11 cm s^{-1}.

Carbon rod electrodes were suspended on either side of the fish, through which an AC shock could be delivered; shock intensity was adjusted to the minimum level which would reliably produce a deceleration of respiration. Visual conditioned responses were established by the following procedure: (1) there was a 10 s period in which the number of breaths was counted and a stimulus was not presented; (2) this was followed by a 20-s delay; (3) a stimulus was turned on for 10 s and the number of breaths counted; (4) a shock of 250 ms duration was delivered on every trial when the stimulus was turned off. The criterion for conditioning (and detection of the stimulus) was as follows: total number of breaths during the 10-s stimulus was two less than during a similar period without a stimulus, and(or) there was at least one inter-breath interval greater than 1 s during the stimulus. To check for false-positive responses, a series of trials was run without a stimulus being presented during the second 10-s period but with electric shock being delivered as on stimulus trials; the incidence of response by the criterion of two-fewer breaths was less than 2%, and an inter-breath interval of more than 1 s was never recorded. Trials were presented randomly in time with an average interval of 3 min, to prevent temporal conditioning.

The number of breaths per 10-s interval varied between subjects and from day to day within a single subject, in the range 13–22. As an example of consistency of response, the mean breath rate for 1 d was 16.75 per 10 s (s.e. 0.38).

After reliable conditioned responses were established (which usually required only 8–10 trials), thresholds were determined by a staircase method: if a conditioned response was obtained to a given stimulus, the next stimulus was reduced in luminance by 0.3 log unit; if a response was not obtained, the next stimulus was increased by 0.3 log unit. This procedure continued until the reversals in the staircase reliably occurred in a small range of luminances.

All three fish produced vigorous conditioned responses with either eye facing the stimulus field. There was no reliable difference between the thresholds obtained with the two eyes. All measurements were made at least four times. The fact that thresholds were nearly identical with the two eyes argues against the possibility that responses with the right eye facing the stimulus were mediated by scattered and reflected light in the tank, which stimulated the left eye. This possibility was completely eliminated by removing the left eye, under anaesthesia, of one fish: there was no measurable change in threshold with the right eye facing the stimulus.

The visuotectal projection was mapped 148 d after tectal removal, and 4 d after the left eye was removed. The remaining (right) eye projected on to the remaining ipsilateral (right) tectum in normal retinotopic order, as described previously[1]. The anomalous ipsilateral visuotectal projection in goldfish is then able to mediate visual behaviour with sensitivity as great as the normal projection. The conditioned responses cannot be mediated by the remaining normal retinothalamic projection, as tectal lesions result in absolute scotomas[3], although opto-kinetic nystagmus is still present[4]. Experiments are in progress to investigate visual acuity, summation area and visual direction in the reinnervated tectum.

Thymus rudiment of the athymic nude mouse

IT is accepted that the polycystic organ, composed of branching ducts and differentiating during the first month of postnatal life into a system of interconnected cysts and acinar arrangements of serous and mucoid cells and containing almost no lymphoid cells, represents the dysgenetic thymus of the nude homozygote mouse[1,2]. No epithelial cystic cells and no cells with specific inclusions which may be the cellular source of the thymic factors affecting pathways for differentiation of T lymphocytes, were found in the polycystic organ[3,4]. The nude mouse has, however, not only the prethymic cells capable of differentiating into T cells in a thymic graft from an euthymic donor[5], but also surprising numbers of θ-positive cells in the spleen[6]. It is suggested that these T cells may leak across the placenta from the euthymic mother into the nude foetus, may differentiate under the influence of the maternal thymic hormone, or may acquire their T-cell properties by some kind of non-thymic induction[7].

Fig. 1 The lymphoepithelial rudiment of a nu/nu (BALB/c) male aged 122 d. H & E, ×160.
Fig. 2 Sensitivity of cells from euthymic mouse thymus and *nu/nu* lymphoepithelial rudiment (thymus?), spleen and lymph nodes to anti-θ antibodies. Solid columns, anti-θ-C3H+ complement; hatched columns, C only.

We have made histological serial sections of the entire area from the thyroid cartillage caudally to the bifurcation of the trachea in 42 *nu/nu* mice obtained from cross–intercross breeding of CBA mice with *nu/nu* mice, in 8 *nu/nu* mice from the eighth backcross to BALB/c mice (donated by Dr C. W. Friis) and in 3 *nu/nu* mice from the third backcross to C3H mice. All animals (both sexes, aged 30–122 d) were from *nu/nu* male × hybrid female matings. Between five hundred and two thousand haematoxylin–eosin stained sections of each mouse have been studied.

A paired ovoid structure (transversal sections usually not exceeding 400×200 μm in diameter), composed of condensed lymphatic tissue and situated ventrally to the trachea and laterally to the polycystic organ was found in all *nu/nu* mice (Fig. 1). The structure was surrounded by a thin fibrous capsule and a poorly demarcated sinusoidal space underneath the capsule. On the medial aspect it was bordered with mature fat tissue. Typical small lymph nodes were found in the same sections laterally or dorsally to the trachea. In one *nu/nu* (CBA) male aged 4 months a single ovoid thymus-like organ with a dense cortical and loose medullary component and more pronounced subcapsular sinus was found in the same location as the lymphatic tissue described above.

Fig. 3 The lymphoepithelial rudiment of a *nu/nu* (C3H) female aged 88 d. Lymphocytes in the cortical part surrounding epithelial cells (arrow). Toluidine blue, ×1,520.
This lymphatic rudiment was isolated from 12 *nu/nu* mice of all three genetic backgrounds and processed for electron microscopy (glutaraldehyde fixation, Vestopal embedding, semi-thin sections stained with toluidine blue, ultrathin sections contrasted with uranyl acetate and lead citrate observed in a Tesla BS 242 D electron microscope). Lymphoid cells teased from the rudiment of five *nu/nu* (BALB/c) mice were assayed with anti-θ C3H antibodies[8]. These were obtained from the ascitic fluid of AKR mice immunised repeatedly with C3H thymocytes and injected with S37 cells 14 d before killing. The *nu/nu* lymphoid cells were incubated with anti-θ C3H in Eagle's MEM for 30 min at 0 °C and subsequently with guinea pig complement (1:10) for 45 min at 37 °C. $2 \times 10^5 - 4 \times 10^5$ cells from the rudiment were used and compared in the anti-θ assay with *nu/nu* spleen and lymph node cells and with BALB/c thymic cells. Control samples were incubated only in MEM and complement (30 min and 45 min). Each suspension was counted in a Burker chamber and in the Trypan-blue exclusion test before and after incubation and the results expressed as a percentage of viable cells from the initial count.
Fig. 4 The lymphoepithelial rudiment of a *nu/nu* (C3H) female aged 88 d. Lymphocytes and epithelial cells (arrow) in the central portion A high endothelium venule (v) with lymphocytes in passage through the wall. Toluidine blue, ×1,400.

Whereas few *nu/nu* spleen cells and even fewer lymph node cells were killed by anti-θ antibody and complement, the proportion killed of lymphoid cells from the *nu/nu* lymphatic rudiment and of BALB/c thymocytes was comparably high (80–90%), (Fig. 2). Absorption studies would be needed, however, before quantitative statements could be made about the average amount of θ antigen on the different cells examined.

In electron microscope and semi-thin sections the rudiment contained typical thymic lymphocytes (mostly of the dark variety) in nests and layers; among them mesenchymal reticulum cells, occasional macrophages, groups of epithelial cells with electron-dense granules, clear vesicles, lipid-containing vesicles and accumulated cysts were observed. The epithelial cystic cells resembled the thymic epithelial cystic cells. A few plasma cells and mast cells were also seen. The entire tissue was transversed with numerous blood capillaries and (in the deeper or central part) postcapillary venules with very high endothelium containing many lymphocytes in the passage from or into the lumen (Figs 3–5).

These observations indicate that *nu/nu* mice of different genetic background have a lymphatic rudiment containing θ-positive lymphocytes and secretory epithelial cells in the thymic region. It may be the organ responsible for the generation of T cells established in the *nu/nu* spleen. This organ

Fig. 5 Electron microscope appearance of the lymphoepithelial organ of a *nu/nu* (CBA) male aged 55 d. Lymphocytes surrounding a cystic epithelial cell (CEp). ×5,540.

does not have all the histological attributes of a well-developed mammalian thymus; in its organisation it is more like the thymus of lower vertebrates. Ontogenetically, it may be a true derivative of the branchial pouch III entoderm, whereas the polycystic organ may represent the aberrant development of thymus IV only[5], or of the ectodermal component (ductus ectobranchialis). The polycystic structures can be found also in *nu/+* hybrids with normal thymus development[2], and inside or outside the thymus of normal euthymic inbred mice (M.H., Vanecek, and P.R., unpublished).

Striated muscle fibres differentiate in monolayer cultures of adult thymus reticulum

THE thymus[1] is credited with a central role in the generation of clonal diversity of lymphocytes[2], and it may perform a critical function in the generation and(or) prevention of autoimmune disorders[3]. Less attention has been paid to other, non-immunological thymus functions, such as control of haemo-poiesis[4], development of certain leukaemias[5], and regulatory roles in the organism's hormonal balance[6].

We have described a tissue culture method that allows growth *in vitro* of thymus reticulum monolayers derived from

adult normal rats or mice[7]. These cultures at early stages consist of two main cell types, reticular and epithelial. In this communication we report the clonal differentiation of a third cell type, namely fully differentiated, striated muscle fibres in thymus reticulum cultures. This cell system, besides offering an approach to the analysis of muscle differentiation from adult mammalian precursors, has interesting biological and clinical implications.

The preparation of the cultures has been described in detail elsewhere[7]. Thymuses from young adult inbred Lewis rats (4–6 months) or C3Heb mice (4–6 weeks) were excised and carefully trimmed free of adjacent connective tissue as well as of the surface capsule. They were then minced with scissors, rinsed with phosphate-buffered saline (PBS), and subjected to differential trypsinisation to increase the concentration of the reticulum cells. The dissociated cells were suspended in Waymouth's medium enriched with 5% postnatal calf serum and plated into plastic Petri dishes (Fa. Greiner, Nürtingen), at a concentration of 30×10^6 cells ml^{-1}. In later experiments, we used gelatin-coated dishes[8]. After 2–3 d, most of the lymphoid cells were eliminated because of the relatively poor initial culture medium. The supernatant liquid containing the cellular debris was discarded and the cultures were replenished with Eagle's medium containing 15% horse serum. The medium was changed every 4 d.

During the first days of culture, single adhering thymus reticulum cells begin to divide and form confluent monolayers by day 7. In more than 95% of the cultures (about 150 independent platings) we found small spindle-shaped cells forming clones and fusing to contracting muscle fibres from day 8–10 (Fig. 1). These clones closely resemble those seen in myoblast cultures derived from chicken and rat embryos[8,9]. To demonstrate myosin biosynthesis, duplicate cultures of varying ages were labelled with 3.75 μCi ^{14}C-leucine (342 μCi $mmol^{-1}$) per dish for 2 h in leucine-free minimal essential medium. Myosin was extracted and assayed as described elsewhere[10]. Table 1 demonstrates that concomitantly with muscle fibre fusion, myosin synthesis is initiated.

Table 1 Myosin biosynthesis by thymus muscle clones

	Days *in vitro*	Myosin ^{14}C (c.p.m per 100-mm dish)
a	7	1,175 (background)
	7	1,476 (background)
b	12	25,457
	12	27,482

a, No fibre colonies present in the cultures; *b*, fibre colonies present in the cultures.

The origin of the thymus-derived striated muscles remains an open question. Trivially, these muscle cells could have developed from myoblasts in the connective tissue 'contaminating' the thymus reticulum cultures. To test this possibility, we removed not only the thymus capsules but also the adjacent cortical tissue and established parallel cultures from this material as well as from the rest of the thymus gland. The majority of the muscle clones arose from the latter starting material. Since the cortical fraction contains a higher proportion of connective tissue cells than the medullar fraction, it is probable that the muscle cells are derived from a genuine thymus component. This is corroborated by our failure to establish muscle cultures from non-thymic organs such as spleen, bone marrow, liver and kidney (H. W., unpublished).

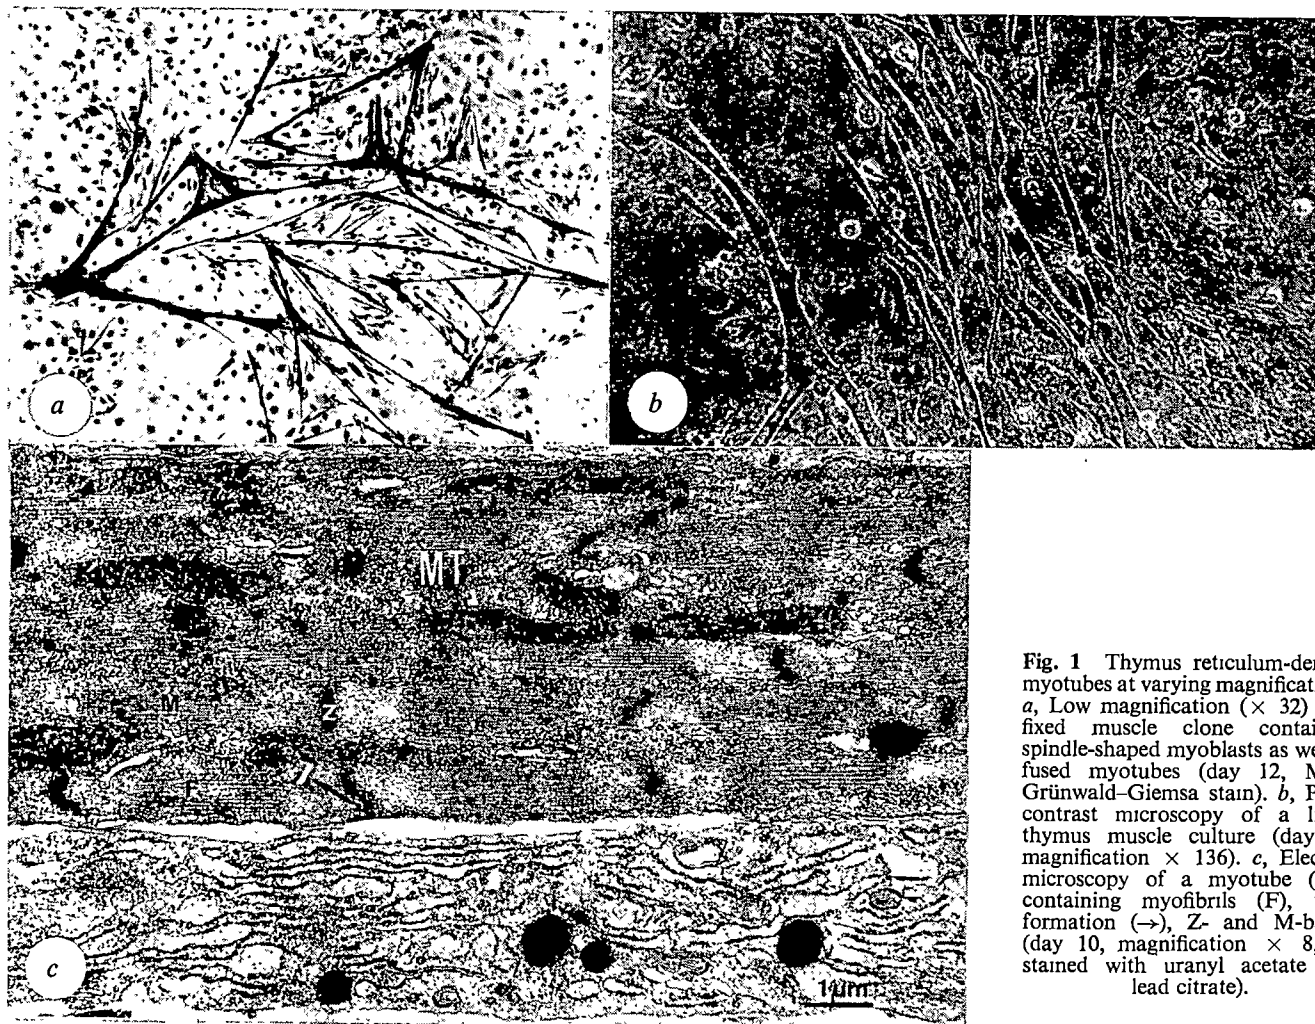
Mammalian thymuses could contain committed myoblasts as physiological components. Indeed, myoid cells have been described in very early studies[11]. Striated muscle was observed in reptile and avian thymus[12,13]. The fact that there are but very few claims that myoid cells exist in normal adult mam-


Fig. 1 Thymus reticulum-derived myotubes at varying magnifications. *a*, Low magnification ($\times$ 32) of a fixed muscle clone containing spindle-shaped myoblasts as well as fused myotubes (day 12, May–Grünwald–Giemsa stain). *b*, Phase contrast microscopy of a living thymus muscle culture (day 10, magnification $\times$ 136). *c*, Electron microscopy of a myotube (MT) containing myofibrils (F), triad formation ($\rightarrow$), Z- and M-bands (day 10, magnification $\times$ 8,925, stained with uranyl acetate and lead citrate).

malian organs[14] might argue against the possibility that thymus muscle clones are derived from pre-existing committed precursor cells.

Thus, we are left with the third possibility, namely, differentiation of thymus muscle clones from pluripotential stem cells. Several arguments seem to favour this possibility. It has been shown that, apart from muscle, tissues as different as osteocytes[15] and chondrocytes (D. Yaffe, personal communication) can differentiate from thymus cells in particular conditions *in vitro*. In our cultures, the relatively long latency period of 8 d preceding muscle cell fusion could be due to differentiation processes of originally pluripotential stem cells. This is well in line with the strikingly similar behaviour of mouse teratoma cells. Undifferentiated OTT 6050 embryoid body cells differentiate into muscle tubes when they are cultured in very similar conditions to our thymus cells[16].

The relationship of thymic cells and neoplastic pluripotential stem cells may be more than coincidental. It should be noted that the anterior mediastinal space shows the highest rate of teratomas, next to the gonads, and that these teratomas are thought to originate from thymic tissue[17]. It is tempting to speculate that mediastinal teratomas arise from neoplastic transformation of pluripotential stem cells in the thymus. Such stem cells, accumulated in this organ, may have a physiological role in the regeneration of the body's tissues. Experimental studies of congenital aplasias, for example in nude mice, should yield further information.

A final, very obvious implication could concern the correlation of thymic lesions and muscle autoimmune diseases like myasthenia gravis in particular. As we demonstrated before, thymocytes can be *in vitro* sensitised against autochthonous thymus reticulum cells[3]. It seems possible, therefore, that, following a defect of control, thymus lymphocytes could be

autosensitised against a thymus component bearing muscle antigens, and that such autosensitised lymphocytes cause the pathological lesions leading to myasthenia. Whether or not this is the case, our culture system provides the means to approach this problem experimentally.

Continuous cultures of fused cells secreting antibody of predefined specificity

THE manufacture of predefined specific antibodies by means of permanent tissue culture cell lines is of general interest. There are at present a considerable number of permanent cultures of myeloma cells[1,2] and screening procedures have been used to reveal antibody activity in some of them. This, however, is not a satisfactory source of monoclonal antibodies of predefined specificity. We describe here the derivation of a number of tissue culture cell lines which secrete anti-sheep red blood cell (SRBC) antibodies. The cell lines are made by fusion of a mouse myeloma and mouse spleen cells from an immunised donor. To understand the expression and interactions of the Ig chains from the parental lines, fusion experiments between two known mouse myeloma lines were carried out.

Each immunoglobulin chain results from the integrated expression of one of several V and C genes coding respectively for its variable and constant sections. Each cell expresses only one of the two possible alleles (allelic exclusion; reviewed in ref. 3). When two antibody-producing cells are fused, the products of both parental lines are expressed[4,5], and although the light and heavy chains of both parental lines are randomly joined, no evidence of scrambling of V and C sections is observed[4]. These results, obtained in an heterologous system involving cells of rat and mouse origin, have now been confirmed by fusing two myeloma cells of the same mouse strain,

The protein secreted (MOPC 21) is an IgG1 (κ) which has been fully sequenced[7,8]. Equal numbers of cells from each parental line were fused using inactivated Sendai virus[9] and samples contining 2×10^5 cells were grown in selective medium in separate dishes. Four out of ten dishes showed growth in selective medium and these were taken as independent hybrid lines, probably derived from single fusion events. The karyotype of the hybrid cells after 5 months in culture was just under the sum of the two parental lines (Table 1). Figure 1 shows the isoelectric focusing[10] (IEF) pattern of the secreted products of different lines. The hybrid cells (samples c–h in Fig. 1) give a much more complex pattern than either parent (a and b) or a mixture of the parental lines (m). The important feature of the new pattern is the presence of extra bands (Fig. 1, arrows). These new bands, however, do not seem to be the result of differences in primary structure; this is indicated by the IEF pattern of the products after reduction to separate the heavy and light chains (Fig. 1B). The IEF pattern of chains of the hybrid clones (Fig. 1B, g) is equivalent to the sum of the IEF pattern (a and b) of chains of the parental clones with no evidence of extra products. We conclude that, as previously shown with interspecies hybrids[4,5], new Ig molecules are produced as a result of mixed association between heavy and light chains from the two parents. This process is intracellular as a mixed cell population does not give rise to such hybrid molecules (compare m and g, Fig. 1A). The individual cells must therefore be able to express both isotypes. This result shows that in hybrid cells the expression of one isotype and idiotype does not exclude the expression of another: both heavy chain
Fig. 1 Autoradiograph of labelled components secreted by the parental and hybrid cell lines analysed by IEF before (A) and after reduction (B). Cells were incubated in the presence of ^{14}C-lysine[14] and the supernatant applied on polyacrylamide slabs. A, pH range 6.0 (bottom) to 8.0 (top) in 4 M urea. B, pH range 5.0 (bottom) to 9.0 (top) in 6 M urea; the supernatant was incubated for 20 min at 37 °C in the presence of 8 M urea, 1.5 M mercaptoethanol and 0.1 M potassium phosphate pH 8.0 before being applied to the right slab. Supernatants from parental cell lines in: a, P1Bu1; b, P3-X67Ag8; and m, mixture of equal number of P1Bul and P3-X67Ag8 cells. Supernatants from two independently derived hybrid lines are shown: c–f, four subclones from Hy-3; g and h, two subclones from Hy-B. Fusion was carried out[4,9] using 10^6 cells of each parental line and 4,000 haemagglutination units inactivated Sendai virus (Searle). Cells were divided into ten equal samples and grown separately in selective medium (HAT medium, ref. 6). Medium was changed every 3 d. Successful hybrid lines were obtained in four of the cultures, and all gave similar IEF patterns. Hy-B and Hy-3 were further cloned in soft agar[14]. L, Light; H, heavy.

and provide the background for the derivation and understanding of antibody-secreting hybrid lines in which one of the parental cells is an antibody-producing spleen cell.

Two myeloma cell lines of BALB/c origin were used. P1Bul is resistant to 5-bromo-2'-deoxyuridine[4], does not grow in selective medium (HAT, ref. 6) and secretes a myeloma protein, Adj PC5, which is an IgG2A (κ), (ref. 1). Synthesis is not balanced and free light chains are also secreted. The second cell line, P3-X63Ag8, prepared from P3 cells[2], is resistant to 20 μg ml^{-1} 8-azaguanine and does not grow in HAT medium.

·sotypes (γ1 and γ2a) and both V_H and both V_L regions (idiotypes) are expressed. There are no allotypic markers for the C_κ region to provide direct proof for the expression of both parental C_κ regions. But this is indicated by the phenotypic link between the V and C regions.

Figure 1A shows that clones derived from different hybridisation experiments and from subclones of one line are indistinguishable. This has also been observed in other experiments (data not shown). Variants were, however, found in a survey of 100 subclones. The difference is often associated with changes
Fig. 2 Isolation of an anti-SRBC antibody-secreting cell clone. Activity was revealed by a halo of haemolysed SRBC. Direct plaques given by: *a*, 6,000 hybrid cells Sp-1; *b*, clones grown in soft agar from an inoculum of 2,000 Sp-1 cells; *c*, recloning of one of the positive clones Sp-1/7; *d*, higher magnification of a positive clone. Myeloma cells (10⁷ P3-X67A g8) were fused to 10⁸ spleen cells from an immunised BALB/c mouse. Mice were immunised by intraperitoneal injection of 0.2 ml packed SRBC diluted 1:10, boosted after 1 month and the spleens collected 4 d later. After fusion, cells (Sp-1) were grown for 8 d in HAT medium, changed at 1–3 d intervals. Cells were then grown in Dulbecco modified Eagle's medium, supplemented for 2 weeks with hypoxanthine and thymidine. Forty days after fusion the presence of anti-SRBC activity was revealed as shown in *a*. The ratio of plaque forming cells/total number of hybrid cells was 1/30. This hybrid cell population was cloned in soft agar (50% cloning efficiency). A modified plaque assay was used to reveal positive clones shown in *b–d* as follows. When cell clones had reached a suitable size, they were overlaid in sterile conditions with 2 ml 0 6% agarose in phosphate-buffered saline containing 25 µl packed SRBC and 0.2 ml fresh guinea pig serum (absorbed with SRBC) as source of complement. *b*, Taken after overnight incubation at 37 °C. The ratio of positive/total number of clones was 1/33. A suitable positive clone was picked out and grown in suspension. This clone was called Sp-1/7, and was recloned as shown in *c*; over 90% of the clones gave positive lysis. A second experiment in which 10⁶ P3-X67Ag8 cells were fused with 10⁸ spleen cells was the source of a clone giving rise to indirect plaques (clone Sp-2/3-3). Indirect plaques were produced by the addition of 1:20 sheep anti-MOPC 21 antibody to the agarose overlay.

in the ratios of the different chains and occasionally with the total disappearance of one or other of the chains. Such events are best visualised on IEF analysis of the separated chains (for example, Fig. 1*h*, in which the heavy chain of P3 is no longer observed). The important point that no new chains are detected by IEF complements a previous study[4] of a rat–mouse hybrid line in which scrambling of *V* and *C* regions from the light chains of rat and mouse was not observed. In this study, both light chains have identical C_κ regions and therefore scrambled V_L–C_L molecules would be undetected. On the other hand, the heavy chains are of different subclasses and we expect scrambled V_H–C_H to be detectable by IEF. They were not observed in the clones studied and if they occur must do so at a lower frequency. We conclude that in syngeneic cell hybrids (as well as in interspecies cell hybrids) *V*–*C* integration is not the result of cytoplasmic events. Integration as a result of DNA translocation or rearrangement during transcription is also suggested by the presence of integrated mRNA molecules[11] and by the existence of defective heavy chains in which a deletion of *V* and *C* sections seems to take place in already committed cells[12].

The cell line P3-X63Ag8 described above dies when exposed to HAT medium. Spleen cells from an immunised mouse also die in growth medium. When both cells are fused by Sendai virus and the resulting mixture is grown in HAT medium, surviving clones can be observed to grow and become established after a few weeks. We have used SRBC as immunogen, which enabled us, after culturing the fused lines, to determine the presence of specific antibody-producing cells by a plaque assay technique[13] (Fig. 2*a*). The hybrid cells were cloned in soft agar[14] and clones producing antibody were easily detected by an overlay of SRBC and complement (Fig. 2*b*). Individual clones were isolated and shown to retain their phenotype as almost all the clones of the derived purified line are capable of lysing SRBC (Fig. 2*c*). The clones were visible to the naked eye (for example, Fig. 2*d*). Both direct and indirect plaque

assays[13] have been used to detect specific clones and representative clones of both types have been characterised and studied.

The derived lines (Sp hybrids) are hybrid cell lines for the following reasons. They grow in selective medium. Their karyotype after 4 months in culture (Table 1) is a little smaller than the sum of the two parental lines but more than twice the chromosome number of normal BALB/c cells, indicating that the lines are not the result of fusion between spleen cells. In addition the lines contain a metacentric chromosome also present in the parental P3-X67Ag8. Finally, the secreted immunoglobulins contain MOPC 21 protein in addition to new, unknown components. The latter presumably represent the chains derived from the specific anti-SRBC antibody. Figure 3*A* shows the IEF pattern of the material secreted by two such Sp hybrid clones. The IEF bands derived from the parental P3 line are visible in the pattern of the hybrid cells, although obscured by the presence of a number of new bands. The pattern is very complex, but the complexity of hybrids of this type is likely to result from the random recombination of chains (see above, Fig. 1). Indeed, IEF patterns of the reduced material secreted by the spleen–P3 hybrid clones gave a simpler pattern of Ig chains. The heavy and light chains of the P3 parental line became prominent, and new bands were apparent.

The hybrid Sp-1 gave direct plaques and this suggested that it produces an IgM antibody. This is confirmed in Fig. 4 which shows the inhibition of SRBC lysis by a specific anti-IgM

Table 1 Number of chromosomes in parental and hybrid cell lines

Cell line	Number of chromosomes per cell	Mean
P3-X67Ag8	66,65,65,65,65	65
P1 Bu1	Ref. 4	55
Mouse spleen cells	—	40
Hy-B (P1–P3)	112,110,104,104,102	106
Sp-1/7-2	93,90,89,89,87	90
Sp-2/3-3	97,98,96,96,94,88	95

antibody. IEF techniques usually do not reveal 19S IgM molecules. IgM is therefore unlikely to be present in the unreduced sample *a* (Fig. 3*B*) but μ chains should contribute to the pattern obtained after reduction (sample *a*, Fig. 3*A*).

The above results show that cell fusion techniques are a powerful tool to produce specific antibody directed against a predetermined antigen. It further shows that it is possible to isolate hybrid lines producing different antibodies directed against the same antigen and carrying different effector functions (direct and indirect plaque).

The uncloned population of P3–spleen hybrid cells seems quite heterogeneous. Using suitable detection procedures it should be possible to isolate tissue culture cell lines making different classes of antibody. To facilitate our studies we have used a myeloma parental line which itself produced an Ig. Variants in which one of the parental chains is no longer expressed seem fairly common in the case of P1–P3 hybrids (Fig. 1*h*). Therefore selection of lines in which only the specific antibody chains are expressed seems reasonably simple. Alternatively, non-producing variants of myeloma lines could be used for fusion.

We used SRBC as antigen. Three different fusion experiments were successful in producing a large number of antibody-producing cells. Three weeks after the initial fusion, 33/1,086

Fig. 3 Autoradiograph of labelled components secreted by anti-SRBC specific hybrid lines Fractionation before (*B*) and after (*A*) reduction was by IEF *p*H gradient was 5 0 (bottom) to 9 0 (top) in the presence of 6 M urea. Other conditions as in Fig. 1. Supernatants from: *a*, hybrid clone Sp-1/7-2; *b*, hybrid clone Sp-2/3-3; *c*, myeloma line P3-X67Ag8.

Fig. 4 Inhibition of haemolysis by antibody secreted by hybrid clone Sp-1/7-2. The reaction was in a 9-cm Petri dish with a layer of 5 ml 0.6% agarose in phosphate-buffered saline containing 1/80 (v/v) SRBC Centre well contains 2.5 μl 20 times concentrated culture medium of clone Sp-1/7-2 and 2.5 μl mouse serum *a*, Sheep specific anti-mouse macroglobulin (MOPC 104E, Dr Feinstein); *b*, sheep anti-MOPC 21 (P3) IgG1 absorbed with Adj PC-5; *c*, sheep anti-Adj PC-5 (IgG2a) absorbed with MOPC 21. After overnight incubation at room temperature the plate was developed with guinea pig serum diluted 1:10 in Dulbecco's medium without serum.

clones (3%) were positive by the direct plaque assay. The cloning efficiency in the experiment was 50%. In another experiment, however, the proportion of positive clones was considerably lower (about 0.2%). In a third experiment the hybrid population was studied by limiting dilution analysis. From 157 independent hybrids, as many as 15 had anti-SRBC activity. The proportion of positive over negative clones is remarkably high. It is possible that spleen cells which have been triggered during immunisation are particularly successful in giving rise to viable hybrids. It remains to be seen whether similar results can be obtained using other antigenes.

The cells used in this study are all of BALB/c origin and the hybrid clones can be injected into BALB/c mice to produce solid tumours and serum having anti-SRBC activity. It is possible to hybridise antibody-producing cells from different origins[4,5]. Such cells can be grown *in vitro* in massive cultures to provide specific antibody. Such cultures could be valuable for medical and industrial use.

Naturally occurring cytotoxic tumour reactive antibodies directed against type C viral envelope antigens

TYPE C RNA viruses are frequently present in murine tumours, but the nature of the association between these viruses and malignancy is uncertain. The oncogene theory[1,2] contends that type C viruses possess oncogenic information and that malignancy is the result of activation of this genetic information. Alternatively, the expression of type C viruses in a tumour may be a consequence, rather than a cause, of the neoplastic change and may be beneficial to the host by providing for potential immunological detection and eradication of neoplastic cells[3]. If type C viral antigens are targets for an immune surveillance mechanism, then normal animals would be expected to show evidence of immune sensitisation against viral antigens expressed on the surface of tumour cells. Here, we present evidence that naturally occurring antibodies (NOA) cytotoxic for a type C virus releasing teratoma-derived cell line are directed against viral antigens.

TerA is one of several cell lines derived from a spontaneous ovarian teratoma of a C3H/HeIcrf mouse. NB1 is a cell line derived from a neuroblastoma adrenal metastasis which was present in the mouse bearing the primary ovarian teratoma. Wheras electron microscopic examination of TerA cells revealed abundant budding type C virus particles, no budding type C viruses were observed in electron micrographs of NB1 cells. Supernatant fluid from
Fig. 1 Cytotoxic activity of normal serum of C3Hf/He mice unabsorbed (●) or absorbed with purified virus from TerA cells (○) and tested on either TerA (a) or NB1 cells (b). Virus was pelleted by ultracentrifugation and banded in a sucrose gradient using routine procedures. Briefly, supernatant fluid was collected 24 h after the cells were fed, was clarified by Millipore filtration (0.45 μm Millipore filter) and, after the addition of glycerin (6% final concentration), ultracentrifuged. Virus pellet was banded in a 20–60% linear sucrose gradient. It banded in a fraction with a density of 1.153 g ml⁻¹. This fraction was diluted with BSS and the virus reconcentrated by Amicon filtration (XM100 filter). Negative-staining electron microscopy revealed intact viruses with no discernible cellular debris. A 100 μl of volume of BSS containing an estimated 10¹⁰ sucrose-gradient-banded viruses from TerA cells was added to an equal volume of undiluted mouse serum. The mixture was incubated at 37 °C for 60 min and at 25 °C for 60 min. The tubes were centrifuged at 8,000g for 5 min and the supernatant serum tested for residual cytotoxic activity. Control sera were incubated with BSS. Cytotoxic activity was determined by a two-step RC′-dependent cytotoxicity assay as described previously[6–8]. Normal mouse serum in the absence of RC′ and RC′ in the absence of normal mouse serum were not cytotoxic for either TerA or NB1 cells. The specific antibody-mediated lysis (%) was calculated by the formula:

$$\frac{(\% \text{ Cytotoxicity mouse serum}+\text{RC}')-(\text{RC}'\text{ control})}{\text{Maximum release}-\text{RC}'\text{ control}} \times 100$$

In all experiments TerA-derived virus specifically removed more than 80% of the cytotoxic activity of normal serum for TerA cells.
Fig. 2 Cytotoxic activity of normal mouse serum of C3Hf/He mice unabsorbed (●) or absorbed with either uninfected (○) or TerA virus-infected (△) SC1 cells, tested against TerA (a) or NB1 cells (b). Supernatants from TerA cell cultures were added to subconfluent cultures of SC1 cells. Cultures were treated as described in Table 1 and supernatants were assayed for reverse transcriptase as described previously[4]. Supernatant fluid from the infected SC1 cell lines was positive for reverse transcriptase activity (15 pmol ml⁻¹), whereas supernatant fluid from uninfected SC1 cell lines contained no reverse transcriptase activity. Undiluted normal mouse serum was absorbed for 40 min at 4 °C with a one-third volume of SC1 cells, either uninfected or infected 9 d previously with TerA-derived virus, and was tested for residual cytotoxicity against TerA and NB1 cells. Similar results have been obtained in two other experiments

TerA and NB1 cell cultures was assayed for RNA-dependent DNA polymerase (reverse transcriptase) activity and DNA-dependent DNA polymerase activity using the conditions described by Ross *et al.*[4]. The pelletable RNA-dependent DNA polymerase activity (pmol ³H-thymidine monophosphate incorporated per ml supernatant fluid) in supernatant fluid from TerA cell cultures was 20.83. The reverse transcriptase activity in supernatant fluid from NB1 cell cultures was −0.02. Supernatants from these cell lines did not contain significant levels of DNA-dependent DNA polymerase activity. Host range studies on TerA-derived virus indicated that the virus grew readily on the mouse indicator cell line SC1 but not on the rabbit cell line SIRC. In addition, the virus showed a 100-fold preference for replication in embryo-derived cultures from NIH Swiss mice compared with similar cultures derived from BALB/c mice in the XC cell assay[5]. The virus can, therefore, be classified as an N-tropic endogenous virus[5].

Normal sera of C3Hf/He mice were tested in neutralisation and in radioimmune precipitation assays for NOA reactive with the TerA-derived type C virus. A 1 : 10

Table 1 Neutralisation of infectivity of TerA-derived virus for SC1 by normal mouse serum

Dilution of supernatant containing TerA virus	Dilution of normal mouse serum	RNA-dependent DNA polymerase activity (pmol)
1 : 1	Nil	25.58 ± 0.42
1 : 10	Nil	21.24 ± 0.12
1 : 100	Nil	7.74 ± 0.91
1 : 1	1 : 10	1.44 ± 0.09
1 : 1	1 : 100	16 24 ± 1.08

Supernatant fluid from TerA cultures was filtered through a 0.45 μm Millipore filter. To aliquots of filtered medium was added normal mouse serum to final concentrations of 1 : 10 and 1 : 100. The medium was incubated at 37 °C for 1 h and refiltered through a 0.45 μm Millipore filter. Aliquots (2 ml) of untreated and mouse serum-treated undiluted TerA virus containing supernatants were added to subconfluent cultures of SC1 cells (2 × 10⁵ cells in 30 ml Falcon T flasks). In addition 2-ml aliquots of 1 : 10 and 1 : 100 dilution of TerA supernatant was added to SC1 cells, and the medium changed on day 3. Cells were subcultured on day 5 and the medium changed on day 8. Supernatant fluid was collected on day 9 and assayed for reverse transcriptase activity (pmol ³H-thymidine monophosphate incorporated per ml supernatant fluid) as described previously[4].

dilution of normal mouse serum markedly reduced the infectivity of the virus for SC1 cells. Significant neutralisation was also observed at a 1 : 100 dilution of mouse serum (Table 1). A radioimmune precipitation assay, using goat anti-mouse immunoglobulin antisera to precipitate ^{3}H-uridine-labelled virus bound to mouse immunoglobulin, confirmed that normal mouse sera contained NOA reactive with the type C virus (Table 2).

TerA and NB1 cells can be readily lysed in the presence of rabbit complement (RC') by NOA present in sera of C3Hf/He mice[6,7]. The antigens recognised by NOA on TerA and NB1 cells are, however, distinct. To determine whether NOA reactive with TerA cells were reactive with the type C virus produced by TerA cells, normal serum of C3Hf/He mice was preincubated with sucrose gradient banded TerA-derived virus before testing for residual cytotoxicity against TerA and NB1 cells. As shown in Fig. 1, absorption with purified virus greatly reduced the cytotoxicity of normal mouse serum against TerA cells but

---

Table 2 Radioimmune precipitation of ^{3}H-uridine labelled TerA-derived virus by normal mouse serum

Dilution of mouse serum	Radioactivity (%) bound by serum immunoglobulin
1 : 1	83.3 ± 3 4
1 : 5	62.6 ± 4.4
1 : 25	42.0 ± 5.0
1 : 125	2.1 ± 1.7

TerA-derived virus was labelled with ^{3}H-uridine (New England Nuclear) by incubating TerA cells with 10 μCi ml^{-1} isotope for 24 h. Supernatant fluid (10 ml) was collected and filtered through a 0.45 μm Millipore filter The virus was pelleted by ultracentrifugation and resuspended to a 100 μl volume, containing approximately 10^{10} viral particles A 10 μl volume of either undiluted or diluted mouse serum or of balanced salt solution (BSS) was added to 10 μl virus suspension and the mixture was incubated at 37 °C for 1 h and at 25 °C for 1 h. A volume (30 μl) of goat anti-mouse immunoglobulin antiserum (Dr R. Asofsky. NIH) was added to the tubes. A 10 μl volume of BSS was added to the tubes containing undiluted mouse serum and virus and 10 μl normal mouse serum was added to tubes originally containing either BSS or diluted mouse serum. A precipitate developed in each tube. After 2 h incubation at 25 °C the tubes were centrifuged at 1,000g for 10 min. A 20 μl aliquot from each tube was mixed with cold 10% TCA. Precipitates were collected on Millipore filters and assayed for radioactivity. Duplicate determinations were carried out on each serum dilution. Results are mean ± s. e. of values obtained in three separate experiments, and are expressed as a percentage reduction in supernatant radioactivity in tubes initially containing virus plus mouse serum compared with tubes initially containing virus plus BSS.

---

caused no significant reduction of anti-NB1 cytotoxicity. In some experiments, absorption of normal mouse serum with purified TerA-derived type C virus completely removed cytotoxicity against TerA cells. In addition, when normal mouse sera were absorbed with either uninfected SC1 cells or SC1 cells infected with TerA-derived virus and tested for residual cytotoxicity against TerA and NB1 cells, virus-infected SC1 cells specifically absorbed anti-TerA cytotoxicity (Fig. 2).

Our data indicate that NOA capable of binding intact type C virus released from TerA cells, and therefore presumably directed against viral envelope antigens (VEA), is cytotoxic, in the presence of RC', for TerA cells This finding contrasts with a report in which cytotoxicity was not demonstrated with NOA, shown by radioimmune precipitation assay to bind VEA of the Gross virus released from a cell line of AKR mice[9]. These authors used a single step cytotoxicity assay, rather than the more sensitive two-step assay used here In an immunoelectron microscopic study NOA were shown to react with both the cell surface of myeloma cells and with VEA of the type C virus released from the cells[10]. It could not be concluded, however, whether the cell surface antigen and the VEA recognised

by NOA were identical or whether the normal serum contained two populations of NOA recognising distinct antigens on the cell surface and on the viral envelope Sera of a variety of mouse strains are known to possess NOA capable of neutralising the xenotropic virus released from chemically treated cells of BALB/c mice[11]. These sera were not tested for reactivity with cell-surface antigens. Normal mouse. sera contain NOA reactive with a wide variety of tumour cell lines[6-8,12,13]. As partial expression of type C viral genetic information may occur, it cannot be excluded that NOA reactive with tumour cell lines which do not express type C viruses may not also be directed against a virally coded cell surface antigen. Although all tumour reactive NOA may not be directed against type C viral antigens, the findings reported in this paper are at least consistent with the notion that the selective expression of type C viral antigens by a tumour may assist in the immunological recognition of the tumour.

Antigen formation in metal contact sensitivity

THERE have been reports of experimental induction of contact sensitivity to dinitrochlorobenzene (DNCB) and dinitrofluorobenzene by injection of dinitrophenol (DNP) conjugated to lymphoid cells[1-3]. The DNP group is known to be capable of acting as a hapten but it is difficult to apply the term 'hapten' to the case of inorganic metals which act as contact sensitisers since antibodies with specificity for the metal ions have not been demonstrated. This is hardly surprising in view of the small size of some of the metals implicated as sensitisers, yet metal salts have been shown to produce stimulation of lymphocytes from individuals with metal contact sensitivity[4-6]. The following experiments were designed to determine whether lymph node cells pulsed with beryllium were capable of inducing beryllium contact sensitivity.

Guinea pig lymph node cells or peripheral blood erythrocytes were incubated with 1 ml 500 μM beryllium sulphosalicylate (BeSSA, trace labelled with ^{7}Be) in saline for 1 h at 37 °C (ref. 6). Lymph node cell and erythrocyte concentrations were 2×10^7 and 10×10^7 cells ml^{-1}, respectively. Radioactivity was counted before and after washing three times with culture medium without added serum. This number of washes was chosen arbitrarily as radioactivity continued to be released from

the cells even after eight washes. The amount of BeSSA remaining with the cell suspension after three washes was found to vary with individual experiments from 3 to 30% of the original BeSSA added.

Beryllium-treated lymph node cells (4.0×10^7) in 4 ml medium were injected intraperitoneally into normal recipient guinea pigs. Erythrocytes (16.6 or 13.3×10^7) in 4 ml medium were used for injection.

Recipient guinea pigs were tested for contact sensitivity to beryllium 14 d later by painting the shaved back with 100 μl 1% beryllium fluoride (BeF$_2$) in methyl cellosolve–water–Tween 80 (45:45:10). Reactions were recorded at 24 and 48 h on an arbitrary scale 0–3 (ref. 7). Animals were classified as contact sensitive when skin test readings were at least 0.5 at both 24 and 48 h and when at least one of these readings had a value of 1 or more.

It was then necessary to determine what proportion of guinea pigs which had been used as recipients were capable of being sensitised to BeF$_2$ since only a proportion of outbred animals are potential responders[8]. Recipient guinea pigs were therefore painted on the left ear on 3 successive days with 15% BeF$_2$ in Triton X-100[6] and skin tested 14 d later with 1% BeF$_2$.

Table 1 Induction of contact sensitivity to BeF$_2$ by intraperitoneal injection of lymphocytes pulsed with BeSSA

Dose of BeSSA injected	Carrier	Skin test reactivity to 1% BeF$_2$	Sensitisation by painting with 15% BeF$_2$
0.22–0.33 μmol	4×10^7 lymphocytes (60–80% viable)	9/11	ND
0.32 μmol	13.3×10^7 16.7×10^7 erythrocytes	0/8	6/8
0.30 μmol	—	0/6	2/4 (2d)
0.03 μmol	—	0/4	4/4
—	4×10^7 lymphocytes	0/3	3/3

Outbred Dunkin–Hartley guinea pigs were used as both donors and recipients. ND, Not determined.

Table 1 shows that allogeneic lymph node cells pulsed with BeSSA were capable of inducing contact sensitivity to BeF$_2$ in normal recipient guinea pigs. Animals injected with an erythrocyte suspension containing a similar amount of beryllium did not develop contact sensitivity although 6 out of 8 recipients were shown subsequently to be capable of being sensitised. Similarly, guinea pigs injected with 0.03 or 0.3 μmol BeSSA in culture medium alone gave no reaction, suggesting that free BeSSA leaking from lymph node cells is unlikely to account for their efficacy in inducing sensitisation.

An attempt was made to induce beryllium contact sensitivity by injection of lymph node cells treated with BeSSA and killed by incubation with 1% sodium azide for 45 min at 37 °C. Cell viability after washing was less than 10%. Five allogeneic Dunkin–Hartley guinea pigs received 4×10^7 lymph node cells intraperitoneally but none became sensitised to BeF$_2$.

Table 2 Induction of contact sensitivity to BeF$_2$ in Dunkin–Harley guinea pigs by intraperitoneal injection of strain XIII lymphocytes pulsed with BeSSA

Recipients	Lymphocyte donors	Dose of BeSSA injected	Skin test reactivity to 1% BeF$_2$	Sensitisation by painting with 15% BeF$_2$
Dunkin–Hartley	Strain XIII	0.03–0.25 μmol	4/11	7/11
Strain XIII	Dunkin–Hartley	0.04–0 31 μmol	0/12	ND

ND, Not determined.

Table 2 shows results of experiments in which strain XIII guinea pigs, genetically unresponsive to beryllium by painting skin with BeF$_2$ (ref. 8), were used as donors or recipients for beryllium-treated cells. Strain XIII lymph node cells, pulsed with BeSSA, were found to be capable of inducing beryllium contact sensitivity in Dunkin–Hartley recipients. Strain XIII guinea pigs which had received Dunkin–Hartley lymph node cells showed no evidence of skin reactivity to BeF$_2$.

It is of considerable interest that lymph node cells treated with the chelated beryllium complex, BeSSA, induced beryllium contact sensitivity since beryllium in a highly chelated form has been shown to be ineffective in eliciting a skin reaction[9]. The fact that allogeneic cells were capable of inducing sensitisation would argue that in this system the injected cells were contributing to the formation of immunogenic conjugates rather than becoming actively allergised *in vitro* as suggested by Polak and Macher[3] using DNCB. The finding that strain XIII lymph node cells were also effective in inducing sensitivity would further support the contention that immunogen was being transferred. Negative results following injection of killed cells could be explained by an alteration of the antigen following azide treatment.

We interpret these experiments as demonstrating that antigen capable of inducing contact sensitivity to beryllium is formed when lymph node cells are pulsed *in vitro* with BeSSA. At present there is no information on whether this antigen is attached to the cells or is released from them as a complex. It is unlikely that BeSSA combining *in vivo* with tissues of the recipient will account for these results, since free BeSSA injected intraperitoneally failed to sensitise

Induced thermal resistance in HeLa cells

IN mammalian cells, hyperthermia causes temperature-dependent changes in cell growth parameters[1], reduces DNA and protein synthesis rates[2] and cell metabolism[3], and leads to a loss of proliferative capacity[4,5]. Harris[6] has shown that temperature-resistant pig kidney cells can be obtained after multiple exposures to very high thermal doses (colony-forming ability reduced to 10^{-5}–10^{-6} of controls). The purpose of our experiments was to determine whether a single hyperthermic treatment (44 °C for 1 h) could induce a state of thermotolerance in cells, and if so, what was the mode of origin of the thermal resistant cells.

HeLa cells (Flow Labs; Rockville, Maryland) were maintained in exponential growth at 37 °C in medium 199 supplemented with 10% foetal calf serum (both from Gibco). Their doubling time in these conditions was 23–24 h. Proliferative capacity, as measured by colony-forming ability *in vitro*, was used as a measure of survival. Thermal doses were administered to these exponentially growing cells by immersion of culture flasks in a temperature controlled water bath (temperature constant to ±0.1 °C) As it was known that nutritional factors are important in determining cellular response to hyperthermia[7], a standard treatment protocol was used with cells being treated in full medium 20 h after inoculation in the treatment flasks

After thermal treatments, cells were removed from the flasks by trypsinisation, combined with any floating cells, diluted and plated for colony formation in 5 ml fresh medium.

Figure 1 shows the survival response of exponentially growing HeLa cells treated at 44 °C for increasing times up to 3.5 h. Survival decreases exponentially as a function of time at 44 °C. This result is similar to that already reported[4,5,7], except that no (or a very small) shoulder region is apparent on the single dose–survival curve. Figure 1 also shows that the survival response is exponential even when survival is reduced to less than 0.1%. Whereas previous authors[4,5] have shown cell cycle-dependent fluctuations in thermal inactivation, this observation suggests that subpopulations have similar inactivation rates, as a resistant tail is not apparent as cell killing increases. Note that Westra and Dewey[4] have shown that the difference in thermal response for CHO cells comparing sensitive mitotic and S-phase cells and resistant G_1 cells was primarily the result of a decrease in the shoulder of the survival curves, whereas the slopes of the exponential portion of the curves did not change. Thus, whereas the heterogeneous cultures reported here could contain subpopulations, some or all of which might have shoulders, a composite survival curve would also have a shoulder. This lack of a shoulder on the single dose–survival curve shown in Fig. 1 implies that these HeLa cells do not accumulate sublethal hyperthermic damage.

When two-dose experiments were used to test for the recovery of our HeLa cells from sublethal hyperthermic damage (Fig. 2a), cell survival increased with increasing incubation at 37 °C between two thermal treatments of 44 °C for 1 h. This result is similar to that previously reported for HeLa S-3 cells by Palzer and Heidelberger[5] who interpreted their data to be recovery

Fig. 1 Response of HeLa cells to two-dose fractionated hyperthermic treatments (each dose 44 °C for 1 h). *a*, Cellular survival when incubated at 37 °C for various times between the two (44 °C for 1 h) thermal doses. *b*, Response of cells to fractionated thermal treatments with incubation first at 0 °C and then 37 °C between doses. In these experiments, cells were treated at 44 °C for 1 h. Immediately after this treatment, the cells were transferred to 0 °C. After 1 and 2 h at 0 °C, some treatment flasks were immediately returned to 44 °C for 1. After 2 h at 0 °C, the other treatment flasks were transferred to 37 °C and after various times at 37 °C, were reexposed to 44 °C for 1 h. After the second 44 °C treatment, cells were collected and plated for colony formation. Control experiments showed that the immediate transition of cells from 44 °C to 0 °C did not have a lethal effect on cells. Standard errors of survival determinations are as shown.

Fig. 1 Thermal survival response of exponentially growing HeLa cells. ●, Survival response of cells treated with single exposures of 44 °C for increasing time; ○, response of cells treated at 44 °C for 1 h, returned to the 37 °C incubator for 2 h and given second graded doses of 44 °C for increasing times. Standard errors of survival determinations are as shown

from sublethal damage. That the increase in survival in HeLa cells (Fig. 2a) is not recovery from sublethal damage, however, is supported by two factors. First, the absence of a shoulder on the single dose–survival curve implies no capacity for sublethal damage accumulation. Second, the results shown in Fig. 1 demonstrate that when HeLa cells are challenged with 44 °C for 1 h, incubated for 2 h at 37 °C and then given graded second thermal doses, again no shoulder is evident during 4 additional hours of treatment, whereas the sensitivity of the survival response, as measured by the slope, is appreciably changed.

A comparison of the slopes of thermal survival curves with D_0 being a measure of the time for survival to be reduced to $1/e$ on the exponential portion of the curve at a given temperature supports this observation. Thermal treatment at 44 °C for 1 h followed by 2 h incubation at 37 °C reduces the thermal sensitivity at 44 °C of our HeLa cells by a factor of three, with the D_0 for previously unheated cells being 0.5 h and the D_0 for previously heated cells being 1.5 h. Thus, these data show that the increase in survival seen in the two-dose experiments of Fig. 2a is actually the result of a decrease in the sensitivity of cells to the second dose.

The possibility existed that the reduced sensitivity (Fig. 1) could be the result of cell progression from a sensitive cell cycle phase to a less sensitive phase, as S-phase cells are more sensitive to thermal inactivation than G_1 cells[4,5]. Data to be published elsewhere, however, demonstrate that the thermal doses used in these survival studies inhibit cell progression of both G_1 and S-phase cells for longer periods than those described in Figs 1 and 2 This implies only minimal reassortment of cells

into different cell cycle phases during these experiments and argues against a major accumulation of cells into a resistant cell cycle phase.

The reduced thermal sensitivity of these HeLa cells, after an initial thermal dose, has two characteristics. First, the process(es) leading to the changed sensitivity does not become active at 44 °C, as the single dose–survival curve of Fig. 1 does not show a resistant tail when cells are maintained at 44 °C for 3.5 h. Second, the changed sensitivity becomes apparent only when the cells are returned to 37 °C for a time before subsequent heating. To test this latter point, additional two-dose experiments were carried out. All cells were treated at 44 °C for 1 h, after which cultures were immediately transferred to an ice bath at 0 °C for up to 2 h and then transferred to a 37 °C incubator, with the second 44 °C (1 h) thermal dose being delivered at the end of hourly intervals for up to 5 h total incubation between doses. Incubation at 0 °C (Fig. 2b), which inhibits cellular metabolic activity, inhibits the increase in survival (Fig. 2a) when cells are immediately returned to 37 °C between the two hyperthermic treatments. When cells are returned to 37 °C after 2 h at 0 °C between doses, survival increases rapidly and reaches the same survival level 2 h later as cells incubated at 37 °C immediately after the initial thermal dose.

These results suggest that the thermal resistance seen in Fig. 1 is induced by the first thermal dose, is dependent on cell metabolism and in these HeLa cells, the maximum change in sensitivity occurs by 2 h after the end of the first hyperthermic dose. Results to be published elsewhere demonstrate that the level of induced thermotolerance is dependent on both the temperature and the time at the elevated temperature of the first thermal dose and that it persists for about one cell cycle but is not passed on to subsequent generations. Figures 1 and 2 argue that our HeLa cells are not able to accumulate or recover from sublethal hyperthermic damage. Rather, a single hyperthermic treatment can induce a transient state of thermotolerance, but cannot produce heritable hyperthermic resistance.

Regional turnover and synthesis of catecholamines in rat hypothalamus

THE occurrence of catecholaminergic systems in the hypophysiotropic area of the hypothalamus has led to numerous studies of the role of catecholamines in the control of pituitary function[1-4]. The lack of biochemical methods of sufficient sensitivity to estimate catecholamine concentrations and metabolism in small brain parts has, however, hampered progress in this field. It has been claimed on the basis of histochemical fluorescence studies, that predominantly dopamine is present in the median eminence of the rat (see ref. 3). Other reports, dealing with the fluorometric determination of catecholamine concentrations, have claimed that rat median eminence dopamine levels are low relative to the noradrenaline concentrations (see ref. 3). Using sensitive radiochemical catecholamine assays, both claims were disproved[5,6]. The considerable regional differences

in catecholamine concentrations in hypothalamic nuclei observed by Palkovits *et al.*[6] stress that great care should be taken to properly dissect the hypothalamus, a conclusion also indicated by Kavanagh and Weisz[7].

We present here data on regional hypothalamic noradrenaline and dopamine metabolism obtained with two methods, one involving measurement of the rate of catecholamine loss following synthesis inhibition using a sensitive radiochemical assay, and the other involving estimation of the rate of accumulation of ^3H-catecholamines from L-^3H-tyrosine *in vitro*.

Male Wistar rats (130–140 g) were used. The hypothalamus was dissected into median eminence, the area including the part of the arcuate nucleus dorsal to the median eminence, and the residual hypothalamus[5,7,8]. The average weights of the dissected regions were 0.51, 1.92 and 32.6 mg, respectively.

In the first series of experiments rats were given α-methyl-p-tyrosine methyl ester HCl (α-MPT; 300 mg kg^{-1}, intraperitoneally) 4, 2 or 1 h before decapitation. Noradrenaline, dopamine and, for steady state levels only, adrenaline, were assayed in the hypothalamus parts of untreated and α-MPT-treated rats, using a radiochemical method derived from that described previously (ref. 9 and details in J.G., H.L.J.M. Wijnen and D.H.G.V., unpublished).

Table 1 summarises the concentrations of noradrenaline, dopamine and adrenaline in the three regions investigated, the rate constants of noradrenaline and dopamine loss after α-MPT and the turnover rates calculated from these[10]. The plots of the logarithms of catecholamine concentrations against time were linear for both amines in all three regions. The steady state levels are close to those already reported[5-7]. Although the rate constant of dopamine loss in the median eminence was somewhat lower than in the arcuate nucleus area and the residual hypothalamus, the rate of dopamine turnover in the median eminence was extremely high relative to that in the other regions. Both the rate constant of noradrenaline loss and the noradrenaline turnover rate were markedly lower in the median eminence than in the other regions. A possible explanation for this phenomenon is the occurrence of a significant amount of median eminence noradrenaline in an extraneuronal pool[11]. The turnover of noradrenaline in the median eminence was considerably slower than that of dopamine. This is in agreement with the findings of Löfström *et al.*[12], who used fluorescence histochemistry in combination with microfluorometry to measure catecholamine depletion in the median eminence after synthesis inhibition, and observed a much lower catecholamine turnover in the subependymal layer, supposedly containing mainly noradrenaline terminals, than in the external layer, which is presumed to contain predominantly dopamine terminals.

In the second series of experiments hypothalamus parts were incubated for 45 min in Krebs–Henseleit bicarbonate medium in the presence of L-3,5-^3H-tyrosine to estimate the accumulation of tritiated catecholamines from the tritiated precursor amino acid as described previously for larger brain parts[13].

As can be seen from Table 2, a gradient was observed in the *in vitro* accumulation of ^3H-dopamine from median eminence to deeper hypothalamic structures, similar to that for the dopamine turnover rates. ^3H-noradrenaline accumulation, however, was of the same order of magnitude in all three regions. This latter observation is at variance with the data obtained from the α-MPT experiments, which suggested a slower turnover of noradrenaline in the median eminence than in the arcuate nucleus area and the residual hypothalamus. This may indicate that noradrenaline synthesis in the neuronal pool in the median eminence is relatively high, and suggests one of the disadvantages of the α-MPT method, that is, that it does not allow discrimination between various amine pools in the same brain region with different turnovers. Apart from this feature the results obtained with the two methods are similar. Both methods enable discrimination to be made between noradrenaline and dopamine metabolism in very small areas of brain and can be helpful in

Table 1 Steady state level, turnover and turnover rate of noradrenaline and dopamine in rat median eminence (ME), arcuate nucleus area (ANA) and residual hypothalamus (RH)

	Tissue weight (mg)	Noradrenaline			Dopamine			Adrenaline
		0 h level (μg g^{-1})	Turnover (k) (h^{-1})	Turnover rate (μg g^{-1} h^{-1})	0 h level (μg g^{-1})	Turnover (k) (h^{-1})	Turnover rate (μg g^{-1} h^{-1})	0 h level (μg g^{-1})
ME	0.50$\pm$0.01	3.57$\pm$0.24 (6)	0.051$\pm$0.006	0.185	7.64$\pm$0.67 (5)	0.310$\pm$0.009	2.194	NM (6)
ANA	1.93$\pm$0.04	3.03$\pm$0.17 (6)	0.210$\pm$0.009	0.549	0.50$\pm$0.06 (5)	0.470$\pm$0.012	0.212	0.121$\pm$0.004 (5)
RH	32.7$\pm$0.4	2.54$\pm$0.12 (6)	0.159$\pm$0.007	0.398	0.32$\pm$0.01 (5)	0 445$\pm$0.009	0.118	0.046$\pm$0.006 (6)

Hypothalamus parts of untreated rats and of rats which had been treated with α-MPT (H44/68, AB Biotec, Stockholm; 300 mg kg^{-1} intraperitoneally) 4, 2 or 1 h before decapitation were homogenised in 50–200 volumes 0.1 N $HClO_4$. Noradrenaline, dopamine and, for steady state levels only, adrenaline were assayed in 20-μl samples of the supernatants using a radiochemical method involving the paper chromatographic separation of the ^{3}H-methoxy derivatives of the catecholamines obtained by incubation of the samples with a rat liver catechol-O-methyltransferase preparation and S-adenosyl-L-methyl-^{3}H-methionine (Radiochemical Centre, Amersham; 5–9 Ci mmol^{-1}), (J.G., H. L. J. M. Wijnen and D.H.G.V. unpublished) Blanks, tissue blanks and internal as well as external standards were run parallel with the samples. Sensitivity of the assay for all three catecholamines was approximately 15 pg. Values have been corrected for cross interference, which amounted to less than 2%. The rate constants of amine loss (k) and turnover rates of the catecholamines were calculated according to Brodie et al.[10]. Results are expressed as mean values$\pm$s.e.m.; number of observations for levels was as indicated in brackets; number of observations for tissue weights, ks and turnover rates was 22–24.

NM, Not measurable because of interference from high dopamine levels.

Table 2 In vitro accumulation of ^{3}H-noradrenaline and ^{3}H-dopamine from L-^{3}H-tyrosine in rat median eminence (ME), arcuate nucleus area (ANA) and residual hypothalamus (RH)

	Tissue weight (mg)	^{3}H-tyrosine (μCi mg^{-1})	$\dfrac{^3\text{H-noradrenaline}}{^3\text{H-tyrosine}}$	$\dfrac{^3\text{H-dopamine}}{^3\text{H-tyrosine}}$
ME	0.52$\pm$0.01	0.657$\pm$0.029	4.37$\pm$0.23	44.6$\pm$3.7
ANA	1.92$\pm$0.02	0.308$\pm$0.014	4.89$\pm$0.22	10.69$\pm$0.83
RH	32.6$\pm$0.3	0.035$\pm$0.001	4.32$\pm$0.19	6.24$\pm$0.032

ME and ANA were preincubated for 10 min at 37 °C in 0 5 ml Krebs-Henseleit bicarbonate buffer, pH 7.2; RH, chopped in 0.3 mm slices with a McIlwain Tissue Chopper, in 2.0 ml of this buffer. Subsequently 50 μl buffer containing L-3,5-^{3}H-tyrosine (Radiochemical Centre, Amersham) of appropriate specific activity were added and incubation was continued for 45 min. The specific activity of the ^{3}H-tyrosine added was 21.0 Ci mmol^{-1} (ME), 9.8 Ci mmol^{-1} (ANA) or 1.16 Ci mmol^{-1} (RH); the final concentration of tyrosine in all incubation media was 8.6 μM. The incubation was stopped by addition of 4.0 ml ice-cold buffer. After centrifugation and a wash cycle the pellets were homogenised in 0.4 N $HClO_4$. Carrier tyrosine, noradrenaline and dopamine were added and ^{3}H-tyrosine, ^{3}H-noradrenaline and ^{3}H-dopamine were purified on Dowex 50WX4 and alumina columns as described previously[13]. Tissue medium ratios for ^{3}H-tyrosine were close to 3 6 in all cases. Accumulation of tritiated catecholamines from ^{3}H-tyrosine was linear for at least 45 min, and seemed to be directly proportional to the specific activity of the tyrosine added to the incubation medium. Thus, the ratio of ^{3}H-catecholamines (nCi per mg tissue) to ^{3}H-tyrosine (μCi per mg tissue) was taken as an index of ^{3}H-catecholamine synthesis. Results are expressed as mean values$\pm$s.e.m. Number of observations was 24–27.

studies dealing with pharmacological and endocrinological manipulation and catecholamine activity in localised brain structures.

We thank Mrs W. Spaapen-Kok and Mr H. Spierenburg for assistance. This study was partly supported by the Foundation for Medical Research (FUNGO), which is subsidised by the Netherlands Organisation for the Advancement of Pure Research (ZWO).

Rate of nucleologenesis as a measure of gene activity

THE nucleolus is not a permanent organelle in the life of a cell; at the initiation of a new cycle, the nucleolar formation seems to depend on RNA synthesis directed by nucleolar RNA polymerase[1]. We have compared the rate of nucleologenesis in meristem cells of Allium cepa L. and in those of four Vicia species with different numbers of ribosomal cistrons and different DNA contents[3,4] as well as the rate of nucleologenesis in four different cell populations lying side by side in the root of Zea mays. The rate of nucleologenesis per ribosomal cistron seems to be constant in the different species growing in similar conditions, but this mean rate was modified in metabolically different subpopulations in the same root.

We used primary root meristems of V. faba, V. narbonensis, V. sativa, V. villosa and A. cepa growing at 15 °C in constantly aerated water in the dark and Zea mays roots growing at 23 °C in damp sphagnum, similarly in the dark (see Fig. 1). Roots (2–4 cm long) were treated for 1 h with 0.1 % caffeine, which inhibits cell plate formation—cytokinesis—in those cells undergoing (during treatment) the final stages of mitosis and thus marked as binucleate at the start of a new cycle.

Telophase ⟶ Binucleate cell (new cycle)
Caffeine
Fig. 1 Experimental scheme. Caffeine labels those cells going through telophase during treatment Recording of the binucleate cells with fully organised nucleoli at successive hours after treatment provides a direct measure of the rate of nucleologenesis in these cells. *a*, Prenucleolar bodies in telophase; *b*, prenucleolar bodies and incipient nucleoli in early G_1; *c*, fully organised nucleoli.

The synchrony of these binucleate cells is excellent, particularly in the short term; and as nucleologenesis takes place precisely at those stages of the cell cycle which coincide with, or occur immediately after, caffeine labelling, these binucleate cells make suitable subjects to study the kinetics of nucleologenesis.

Figure 2 shows the appearance of fully organised nucleoli in the four *Vicia* species. The time at which 50% of the binucleate cells had fully organised nucleoli was estimated and the final nucleolar volumes on completion of nucleologenesis were scored (Table 1). In all species studied the maximum number of nucleoli was two, indicative of species with one pair of nucleolar organiser chromosomes. In 50% of cells these two nucleoli fused into one nucleolar mass. In *V. sativa*, however, only 3% of the nuclei showed two nucleolar masses.

We have estimated the rate of nucleologenesis per ribosomal cistron (Table 2), and found that in meristems of the four species of *Vicia* and in *A. cepa*, it is practically constant, with an average value of $2.0 \pm 0.2 \times 10^{-3} \, \mu m^{-3} \, h^{-1}$ per cistron.

The rate of nucleologenesis in stele 1 of maize roots is

Table 1 Nucleolar parameters

	Time of nucleologenesis* (h)	Nucleolar volume† (μm^3; mean ± s.e)

Zea mays		
Cap initials	0.3	7.8±0.6
Quiescent centre‡	1 1	5.4§
Stele 1	0.7	8.2±0.7
Stele 2	0.5	9.8±0.8

*Time when 50% of the binucleate cells have fully organised nucleoli.

†Volumes were measured the first full hour after the recorded timing of nucleologenesis (that is, in the fifth hour after caffeine in *V. villosa*; in the fourth hour in *V. sativa*, and so on).

Vicia and *Allium* roots were silver impregnated according to the scheme of Fernández-Gómez *et al.*[14]. This impregnation preferentially contrasts protein which accumulates in the fibrillar moieties of nucleoli and, to a lesser extent, in the granular zones[15] It gives a very good nucleolar image. Squashes were prepared of the terminal 2 mm of the root, where a fairly pure meristematic zone is found. *Zea* roots were silver impregnated as above [and, later dehydrated, embedded in paraffin, and sectioned at 5 μm. Median sections of 40 roots were scored. Stele 1 corresponds to steler cells just above the quiescent centre and stele 2 to a zone 200 μm further away.

‡Because of the small size of this population and its low proliferation rate, the timing of nucleologenesis has been taken from previous data, taking into account the frequency of cells with reorganising nucleoli and the cycle duration[16].

§Volume corresponds to mean nucleolar volume in the zone.

similar to that shown by the meristems of *Vicia* and *Allium*, whereas the rate of nucleologenesis in a stelar zone more remote from the quiescent centre (stele 2) is higher. An intermediate value between those found in steles 1 and 2 would probably be representative of total meristematic behaviour. According to Table 2 this intermediate value would be about $2.5 \times 10^{-3} \, \mu m^{-3} \, h^{-1}$ per cistron, that is, higher than that obtained for *Vicia* and *Allium*. This may be attributable to different growing temperatures (23 °C for maize and 15 °C for *Vicia* and *Allium*), as temperature may be an important factor in determining the duration of nucleologenesis—it certainly is in determining the duration of the cycle[6].

The fact that the nucleologenesis rate is similar in the root meristems of at least five different species could mean that all the ribosomal cistrons are operational and transcribed at a similar rate during this process. The mean rate per cistron, however, does not correspond to the optimum, as in cap initial cells in maize a rate of $4.2 \times 10^{-3} \, \mu m^{-3} \, h^{-1}$ per cistron was measured, that is, twice the average value obtained in complete meristems. Similarly, in the case of wild type *Xenopus*, 'normal' transcriptional activity is not the optimum, as studies[12,13] of rRNA synthesis in *Xenopus* mutants deficient in ribosomal cistrons have shown that a normal transcriptional rate could be achieved with half the wild type number of cistrons.

The study of nucleologenesis in *A. cepa* in the presence of metabolic inhibitors showed that inhibition of nucleolar transcription impedes nucleologenesis. Surprisingly, protein synthesis inhibition accelerates nucleologenesis[1,9]. Thus, nucleologenesis may be modulated by concurrent metabolic processes in the cell. In this respect, Clowes[6,7] and Barlow[8] have shown very different rates of incorporation of radioactive precursor into proteins and RNA between the maize populations studied. This could explain the divergence from the 'normal' rate in the quiescent centre and cap initials.

Significant differences in nucleolar transcriptional activity of ribosomal cistrons exist, for example, between pre- and postgastrula stages in *Xenopus*[2], and in mutants, even though this is not the case for other transcriptional modulations. Thus, Mukherjee and Beermann[10] demonstrated that in *Drosophila* there was dosage compensation for the transcriptional rate in the single X chromosome in males compared with the two X chromosomes in females. Similarly Ananiev *et al.*[11] studied the transcriptional rate in *Drosophila* genotypes differing in the proportion of X chromosomes to autosomes and showed that the dosage compensation of enzyme synthesis coded by sex-linked genes took place during transcription.

Fig. 2 Percentage of binucleate cells with fully organised nucleoli at successive hours after caffeine treatment. Time when 50% of these cells had completed nucleologenesis may be obtained from this graph. △, *V narbonensis*; ▲, *V. faba*; ●, *V. sativa*; ○, *V villosa*.
Table 2 Number of ribosomal cistrons and rate of nucleologenesis

Fig. 1 Schematic representation of 5S RNA secondary structure. Normal base pairs are connected by vertical lines, whereas G–U pairs are indicated by dots. The shaded portion of the molecule is that which has been identified as being involved in an interaction with specific 50S subunit proteins[19,20]. The structure is drawn with helices aligned along the long axis in accord with the suggestion of Connors and Beeman[30].

5S RNA secondary structure

NUMEROUS attempts have been made to deduce a secondary structure of 5S RNA[1-4]. Differing approaches have yielded various structures, but each turns out to be inconsistent with either physical, chemical, biochemical, or comparative evidence. Clearly the situation is not analogous to that which obtained for transfer RNA (tRNA). There is, however, at least one fundamental difference between the two molecules. The functional 5S RNA molecule is at all times an integral part of the 50S ribosomal subunit, whereas tRNA is a transient inhabitant of the ribosome milieu. Thus, it is possible that functional conformations of the 5S RNA molecule need only exist in the context of the ribosome, and consequently, may only exist therein. Thus, the interpretation of experimental investigations on the isolated 5S RNA molecule may have inherent difficulties.

A comparative analysis[5] of 5S RNA primary structure is one approach to defining functionally significant secondary (and tertiary) structure whose interpretation is not open to the above

caveat. A phylogenetically broad range of prokaryotic 5S RNAs have been shown to be functionally equivalent (that is, interchangeable)[6,7]. Thus, phylogenetic conservation of functionally significant features of the 5S RNA molecule is very likely. By including in such a study 5S RNAs isolated from organisms which occupy unusual ecological niches (extremes of temperature, pH, ionic strength, pressure or antibiotic tolerance), it should be possible not only to identify the normal constraints on the molecule's primary structure, but also to demonstrate how these constraints change under selective pressure. This in turn should provide clues to the functional significance of the constraints. A theoretical analysis of possible base-pairing schemes has been combined with an experimental programme of sequence determination to reveal the principal features of the architecture of this molecule and to provide insight into its mode of function[8,9].

It is the fundamental premise of this comparative approach that functionally equivalent molecules will exhibit the same secondary structure. Thus, if a helix is found in one primary sequence, it must be present in all other examples to be considered real. In addition, a base-paired region has been assumed to conform to a set of rules which are suggested by examination of tRNA secondary structures: only G–C, A–U and G–U base pairs are allowed; all helices consist of at least three base pairs without G–U pairs or four base pairs when G–U pairs are allowed; looped-out bases are assumed to be non-existent or very rare; and hairpin loops are assumed to contain at least three nucleotides.

Applying these rules, the diagonal method of Tinoco et al.[10] is used to predict all possible helices in any 5S ribosomal RNA (rRNA) molecule. Once a given helix is found to be universal, it greatly restricts the remaining helices which might exist. In the case of Escherichia coli 5S rRNA, 110 possible helices exist, and all but nine of these are ruled out by the secondary structure proposed here. None of these nine, including the largest (four base pairs, 25–29 with 104–107) are, however, universal. Thus, the structure proposed here is in this sense complete.

The general prokaryotic 5S RNA (Figs 1 and 2) contains four helices, herein referred to as the molecular stalk, the prokaryotic loop, the tuned helix, and the common arm base.

The molecular stalk is in all cases a contiguous stretch of base pairs (usually 10 or 11) which serves to tie together the two ends of the molecule[11]. The primary structure of this region is rather variable and often contains G–U pairs, for example, the three contiguous G–U pairs in the stalk of Bacillus megaterium 5S RNA[8].

The prokaryotic loop, E. coli positions 82–86 and 90–94, has been seen only in prokaryotic 5S RNAs; it comprises four to five base pairs (E. coli can be extended to eight when G–U pairs are included) and generally closes a tight hairpin of three pyrimidines or four unspecified nucleotides. Although its primary structure is somewhat variable, it contains a high

Fig. 2 Ten known sequences of the 5S RNA molecule which differ substantially are divided into two groups—corresponding to prokaryotes and eukaryotes[1,8,9,11,17,18,31–35]. The alignment is adjusted to juxtapose secondary structural features. Vertical lines indicate regions of base pairing and brackets enclose regions of high phylogenetic conservation. Parentheses indicate regions of base pairing in the 3' half of the eukaryotic molecule[1,17]. The sequences are as published elsewhere with the exception of *B. stearothermophilus*, the unsequenced portions of which are arranged in a manner consistent with the proposed structure. In this case also, a correction is included—the oligomer UCUCCAUCCCG is replaced by UUCCCAUCCCG. Position numbers in the *E. coli* sequence are included as subscripts, as used in the text.

portion of G–C pairs in those cases so far examined; and in the case of *E. coli*, has been reported to be rather resistant to nuclease attack[11]. This loop, too, has been included in many previous models, although a possible alternative pairing between *E. coli* positions 33–42 and 79–88 has frequently been suggested[12]. Comparative study makes the latter unlikely (as both the precise location and length of the pairing would have to

vary considerably). Until this alternative can be eliminated, however, the proposed structure cannot be claimed to be unique.

The third helix, *E. coli* positions 18–23 and 60–65, is referred to as 'tuned' because its thermodynamic stability as estimated by the method of Tinoco *et al.*[13] seems to be under energetic constraints. This constraint is quite unique to this helix and varies from extreme weakness in marine prokaryotes (four

examined so far), to intermediate values in non-marine pro-karyotes, and to quite stable structure in all eukaryotes[9]. As the total length of this helix, six base pairs, is highly conserved (*B. stearothermophilus* represents either an exception or a sequencing problem), the energetic control is obtained by significant variations in composition. The terminal G–C pair (*E. coli* positions 23 and 60) is, however, found in all organisms examined so far.

Finally, the common arm base, *E. coli* positions 31–34 and 48–51, is so termed because it closes a 12–13 base loop which contains in all prokaryotes examined so far the sequence CGAAC, which reportedly interacts with the tRNA common arm sequence GTΨCG (refs 14–16). The common arm base comprises four base pairs in all cases except yeast, which seems to contain only three [17,18]. If the loop closed by this helix does interact with the common arm of tRNA, a contiguous stretch of at least eight base pairs could result (four within the 5S RNA and four or five between the tRNA and 5S RNA). The effect of the formation of such an intermolecular helix on the tRNA common arm geometry and thus overall tRNA tertiary structure would be quite drastic.

Whereas primary structure is not generally highly conserved in the four double-stranded regions, two single-stranded regions in the molecule are, in fact, strongly conserved. The smaller of these, GCGCC^G_AAUGGUAGU (*E. coli.* positions 67–80), is found in that region of the molecule protected by three 50S ribosomal proteins (see Fig. 1)[19,20]. This sequence is found in all published bacterial 5S RNA structures, but is not entirely universal, being absent in the eukaryotes and *Anacystis*. The second, larger region of high conservation, positions 28–59 in *E. coli*, includes the common arm base and, near its middle, the universal prokaryotic sequence CGAAC. The molecule (Fig. 1) can thus be crudely pictured as consisting of two regions, both containing strongly conserved sequences; one of recognised functional importance (5S–tRNA interaction), the other apparently of structural importance (perhaps 5S interaction with the 50S particle). Separating these two large regions is the tuned helix.

Two additional general constraints which have been observed in the nine existing 5S RNA sequences are: the first four nucleotides in the loop defined by the common arm base, although variable, are in all cases pyrimidines (four different examples thus far); and a stretch of at least four purines exists about twenty nucleotides from the 3′ end. Pace *et al.* have suggested the latter to be a recognition signal for a posttranscriptional modification enzyme in *B. subtilis*[21,22].

The proposed model for prokaryotic 5S RNA secondary structure is quite consistent with the comparative evidence. Each helix has been substantiated by examples wherein significant base changes in its primary structure have occurred without violating the proposed base-pairing constraint. In addition, it is in agreement with most of the evidence obtained by physical and chemical methods. In particular, the recent high resolution nuclear magnetic resonance prediction of 28 base pairs, including four A–U in *E. coli*, is in excellent agreement with the proposed structure, that is, 25 base pairs, five of which are A–U. Chemical modification studies using a variety of reagents yield no examples of definitively placed modified nucleotide residues that occur in proposed double-stranded regions.

Oligonucleotide binding studies[23], however, suggest that in *E. coli* regions 9–10 and 59–65—both involving proposed helices—can pair to external tri- and tetranucleotides. The interpretation that these regions are, therefore, not base paired in the intact molecule is based on the assumption that external tri- and tetranucleotides cannot perturb secondary structure. This assumption seems questionable in the former instance at least where the final two base pairs of the molecular stalk (one a G–U pair) would be replaced by a tetramer pairing that not only stacks on the remaining (eight) pairs of the stalk, but consists itself of four G–C pairs. Also, if Lewis and Doty[24] were not working with the native or A form of 5S RNA, their

conclusion regarding region 59–65 would not apply to that form.

The results of Vigne and Jordan[25] are also inconsistent with the present model only if one assumes that two or more breaks in the molecular backbone never disrupt secondary structure, which again is highly questionable.

Although the eukaryotic 5S RNA molecule is quite similar[1], it is distinctly different from its prokaryotic counterpart in that it lacks the prokaryotic loop and the universal sequence CGAAC. This is highly suggestive of a subtle divergence in the mechanism of protein synthesis which has been consistently hinted at in other comparisons of eukaryotic and prokaryotic ribosomes[26].

We feel that the tuned helix has a crucial role in 5S RNA structure and, consequently, function. Perhaps the most convincing evidence of this comes from studies involving the 'native' (and closely related A form) against the B form of this molecule[24,27]. There are specific points of chemical modification characteristic of each form[28]. Similarly, defined points readily accessible to enzymatic attack characterise each form[29]. One notable difference between the two forms is the accessibility to attack of bases in the tuned helix; that is, in the native form they seem to be paired, whereas they seem to be uncoiled in the B form. Although there is at present no evidence that these two forms are functionally significant, it does seem clear that the tuned helix is thermodynamically sensitive and is a major determinant in 5S RNA conformation.

This observation, the apparent energetic constraint, and the central position of the tuned helix suggest that the coiling and uncoiling of that structure is a key element in 5S RNA function. As the tuned helix could control the position of the common arm base which it encloses, it could therefore control the position and(or) conformation of the tRNA molecule. Thus, this coiling/uncoiling event would make possible a cyclic (and possibly time-symmetric) interaction of the 5S RNA with the two tRNA molecules during protein synthesis.

Differential effect of plasma fractions from normal and tumour-bearing rats on nuclear RNA restriction

WE have already presented preliminary evidence[1] that crude plasma from tumour-bearing rats contains elevated concentrations of macromolecules which stimulate the release of messenger RNA (mRNA) from isolated nuclei. The detection of these putative regulatory components was facilitated by a cell-free system developed originally to study messenger[2-5] and ribosomal[6,7] RNA (rRNA) processing and transport *in vitro*. Since both maximal RNA transport and normal nuclear RNA restriction *in vitro* (that is, equivalence between messengers released from nuclei *in vivo* and *in vitro*) require the presence of macromolecules from homologous cytosol[2,8] it is possible that the tumour cell cytoplasm is the source of the putative regulatory macromolecules in the peripheral blood of tumour-bearing animals. This possibility is supported by evidence[9,10] that factors involved in the regulation of cellular proliferation are released to circulation from tumour cells, and by the observation[11] that the enzyme composition of the host liver of tumour-bearing rats converges to that of the tumour. The spectrum of messengers transported from normal rat liver nuclei in homologous cytosol is significantly different from that transported in hepatoma cytosol[3], suggesting that differences exist in these putative regulatory components of the two tissues.

This study evaluates the relative RNA transport activity of the plasma from normal and tumour-bearing rats following partial purification of the putative regulatory components on a DEAE-cellulose column and attempts to rationalise their increase in tumour-bearing animals. Sixfold higher transport activity of a plasma fraction from tumour-bearing rats is relevant to the problem of the host–tumour relationship and emphasises the potential usefulness of this assay in diagnosis. The differences in the RNA sequences transported in response to plasma fractions from normal and tumour-bearing rats is compatible with the theory that some originate from the tumour cells.

Heparinised plasma from normal rats of the Sprague–Dawley strain, or from rats bearing the Novikoff ascites hepatoma intraperitoneally, or the Morris hepatomas 9618A or 5123D intramuscularly in the hind legs[12], was passed through a Sephadex G-25 column before testing or fractionation on DEAE-cellulose. The cell-free test system contained normal rat liver nuclei (prelabelled *in vivo* for 30 min with 6-^{14}C-orotic acid) in homologous cytosol fortified with components (see Fig. 1). The concentration of the components were identical to the standard nuclear restriction assay[3,4] with the exception of cytosol protein, which was reduced from a concentration of 12.0 to 4.0 mg ml^{-1}; this modification increased the sensitivity of the assay to exogenous sources of putative regulatory components, yet was sufficient to maintain both an effective concentration of ribonuclease inhibitor and the integrity of the nuclei[7]. The labelled RNA transported in 30 min at 30 °C, the bulk of which is messenger[2-5], was precipitated from the nuclei-freed supernatants in the presence of carrier yeast RNA with 5% trichloroacetic acid, washed with 95% ethanol and assayed in liquid scintillant. The sequence homology of the transported messengers was determined by competitive RNA–DNA hybridisation as described previously[3,4,8]. Shown in Fig. 1*a* is the DEAE–cellulose elution profile of protein (A_{280}) in plasma from normal rats (controls) and rats bearing the Morris hepatoma 5123D (approximately 1.0 cm in diameter; bilateral), which has a transplant generation time of 1 month. The plasma elution profiles (not shown) of rats bearing the Morris hepatoma 9618A (approximately 1.0 cm diameter; bilateral) or the rapidly growing Novikoff
Fig. 1 *a*, DEAE–cellulose elution (A_{260}) profiles of plasma proteins from normal rats (- - -), bearing an 18-d (non-palpable) hepatoma 5123D (. . . .) and rats bearing a large (1.0 cm) hepatoma 5123D (———). In each case, the equivalent of 1.0 ml of plasma was passed through a Sephadex G-25 column and the proteins were adsorbed on a DEAE-cellulose column (1.0 × 20 cm) equilibrated with 0 02 M K$_2$HPO$_4$ (pH 7 4); the adsorbed protein was eluted with a linear (0.0–0.5 M) gradient of KCl in 0.02 M phosphate buffer and 3 0 ml fractions were collected. *b*, Enhanced mRNA release in response to the plasma fractions in *a* The data shown in the bar graph represent the net enhancement of mRNA release from prelabelled nuclei as % nuclear c.p m. by the addition to the minimal transport system of 0.3-ml aliquots of fractions 4, 8, 10, 11, or 12 of plasma from normal (hatched bars) or tumour-bearing (open bars) rats. The minimal transport system contained 4.5 × 10[6] prelabelled liver nuclei per ml of medium containing 4 mg ml^{-1} of dialysed cytosol protein, 50 mM Tris HCl (pH 7 6), 25 mM KCl, 2 5 mM MgCl$_2$, 0 5 mM CaCl$_2$, 0 3 mM MnCl$_2$, 5 0 mM NaCl, 2 5 mM K$_2$HPO$_4$, 5 0 mM spermidine, 2.0 mM dithiothreitol, 3 0 mM ATP, 2.5 mM phosphoenol pyruvate, 35 units of pyruvate kinase and 300 mg of yeast RNA per ml, the total volume of the assay being 5.0 ml. The incubation was carried out at 30 °C for 30 min with the further addition of 1.0 mM phosphoenol pyruvate after 10 min and again after 20 min of incubation. To determine the percentage total of labelled nuclear RNA released during incubation, the RNA was precipitated from the nuclei-freed supernatants in the presence of carrier yeast RNA with 0.1 volume of 50% trichloroacetic acid, dissolved in solubiliser and counted in liquid scintillant[3]. During a 30-min incubation the release of total nuclear counts (± s.d.) for the minimal system was 4 7 ±0.2. Results are tabulated in terms of increment in % nuclear c.p.m. transported in the presence of the added plasma components over that released to the minimal system, and represent the average of two determinations which duplicated to within 10%. Essentially similar results were obtained whether or not the whole plasma was purified of low molecular weight components on Sephadex G-25. The experiments on normal serum and on hepatoma 5123D-bearing rats duplicated to within 10% They were also confirmed using hepatoma 9618A and the Novikoff hepatoma-bearing rats

hepatoma, with transplant generation times of 8 months and 1 week, respectively, were identical to that of the 5123D hepatoma. Also shown is the protein elution profile of the plasma from hepatoma 5123D, 18 d after inoculation, that is, when the tumour is not yet palpable. The protein elution profiles (Fig. 1) of the plasma from normal and hepatoma-bearing rats are markedly different. Thus, whereas the peak elution in the void volume (fractions 2–6) is common to the plasma of both the normal and tumour-bearing rats, the other two peaks are not. In fact, the protein components eluting at a mean KCl concentration of 0.05 M (fractions 7–10) disappears during the growth of the tumour, being decreased in the plasma from animals during the early stages of tumour growth and essentially absent during the later stages. In contrast, the protein components eluting at a mean KCl concentration of 0.125 M may be present at a very low level or essentially absent in normal rat plasma, but increase markedly during the development of the tumour. Identical results were obtained with animals bearing the Novikoff hepatoma, or hepatoma 9618A.

Shown in Fig. 1b is the ability of selected DEAE–cellulose fractions of plasma from a normal rat and a rat bearing hepatoma 5123D (tumour diameter of 1.0 cm) to enhance the transport of mRNA in the cell-free system. Fractions 4, 8 and 10 from both the normal and tumour-bearing animals showed comparable, but low transport activity. In contrast, fractions 11 and 12 had marked RNA transport activity when the plasma was derived from the tumour-bearing rat; the activity of the corresponding fractions from normal plasma was approximately one sixth that of plasma from the tumour-bearing rat. Again, the results obtained with rats bearing the Novikoff and 9618A hepatomas were identical to those reported for hepatoma 5123D. In contrast to the sixfold difference in transport activity observed when fractions 11 or 12 of the plasma from normal and tumour-bearing rats were compared, a difference of only threefold was observed when the crude plasmas from the two sources were compared.

The relationship, if any, between the disappearance during tumour growth, of the protein peak eluting from DEAE–cellulose at 0.05 M KCl and the appearance of the protein peak eluting at 0.125 M KCl, as well as the mechanisms underlying these changes are at present unknown. The possibility that the components eluting at 0.05 M KCl modify the transport activity of components eluting at 0.125 M KCl, however, was tested in the concentration range 1.0–3.0 mg ml^{-1}, with negative results.

The differential effect of active plasma fractions from normal and tumour-bearing rats on nuclear RNA restriction *in vitro* was tested by competitive RNA–DNA hybridisation. ^{14}C-labelled RNA transported from prelabelled liver nuclei in response to 4.0 mg ml^{-1} of homologous cytosol protein, fortified with 1.0 mg ml^{-1} of protein from fraction 12 (Fig. 1a) obtained by chromatographing the plasma of a Novikoff hepatoma-bearing rat, was competed against unlabelled RNA transported from unlabelled liver nuclei in response to homologous cytosol protein (4 0 mg ml^{-1}) plus fraction 12 (1.0 mg ml^{-1}), derived from normal plasma. Only 75 % of the messenger-like RNA sequences transported were identical in both systems, 25 % of the messenger-like RNA transported in the presence of the plasma protein fraction from normal animals being different from that transported in the presence of the comparable fraction from tumour-bearing rats. Furthermore, analysis of the transported labelled RNA in sucrose density gradients (results not shown) indicated that mRNA transported in the presence of plasma fractions of the hepatoma-bearing, in contrast to the normal rats, had a size distribution which was distinctly skewed to the heavier species; this abnormal size distribution was not normalised by active fractions from normal plasma.

Both the hybridisation and density gradient studies suggest that there are qualitative differences in the regulatory macro-molecules of the plasma from normal and tumour-bearing rats; it is not merely an increase in normal components. Since

analogous differences were observed[3] between the RNA transported to normal and tumour cytosols, some of the plasma components may originate from the tumour. It has been established[13,14] that certain RNA sequences are confined to the nucleus in normal cells but that this restriction is lost in cancer cells[15]. It has also been shown[11] that the enzyme composition of the host liver in animals bearing tumours shows a convergence to that of the corresponding tumour. Thus, our finding in the circulation of a regulatory component altering nuclear restriction is not surprising. Furthermore, there are several[16,17] recent reports of specific serum components disappearing as a tumour develops although as yet neither these components nor the factor eluting from DEAE–cellulose at 0.05 M KCl have been well characterised.

Although normal plasma also contains components which enhance RNA transport, they are present in low concentration compared with tumour plasma and elicit the transport of messenger-like RNA species which are different from those transported in the presence of plasma from tumour-bearing rats. Furthermore, the protein peak containing the highest transport activity in the plasma from tumour-bearing rats is essentially missing from normal plasma; it is also low (non-detectable) in the plasma of rats with regenerating liver (unpublished observations). These results strongly suggest, but do not prove that the increased transport activity in plasma from tumour-bearing animals is due to the release of macromolecules from tumour cells to circulation. The observation that the difference in transport ability of plasma from normal and tumour-bearing animals is enhanced by preliminary fractionation on DEAE–cellulose is relevant to the adaptation of the nuclear RNA restriction assay as a tumour detection test. But further correlative studies on animals bearing a wide range of transplantable, induced primary and autochthonous tumours of various sizes are required to establish the usefulness and limitations of this test system.

Early role during chemical evolution for cytochrome P450 in oxygen detoxification

IT is generally held that early in the evolutionary history of the Earth, when abiogenic chemicals were forming associations possessing attributes by which we now define living organisms, this planet had a reducing atmosphere. The

subsequent appearance of free or molecular oxygen must have had a profound effect on such poorly specialised life forms and many would have perished. It was long assumed that the adaptive enzymatic changes of the successful forms were chiefly the elaboration of the respiratory chain enzymes, peroxidases and catalase. Research on superoxide dismutase[1] has suggested that this enzyme may also have controlled oxygen toxicity in ancient living tissue. We have studied cytochrome P450, which also metabolises oxygen, and believe that this protein may possibly be more primitive than those considered previously and may even have emerged before the advent of atmospheric oxygen.

Cytochrome P450 is an unusual haemprotein found in animals, plants and microorganisms. In animals, this b-type cytochrome is membrane-bound and is present in the mitochondria of certain endocrine glands and in the microsomes of cells of, among others, certain endocrine glands and the liver. Microsomal cytochrome P450 is the major hepatic haemprotein, reaching concentrations of 0.1 mM in the cell or five to ten times that of any mitochondrial (respiratory chain) cytochromes[2]. In certain conditions, cytochrome P450 constitutes 20% of the microsomal protein or 2–3% of the hepatic protein content[2]. The *Pseudomonas* enzyme, in contrast, is a soluble protein[3,4].

The cytochromes P450 possess active sites effecting hydroxylation reactions

$$R-H + O_2 + 2e = R-OH + H_2O$$
The two electrons or reducing equivalents are furnished by NADPH and (or) NADH (ref. 5). The first reduction is of a flavoprotein but iron–sulphur proteins also participate in electron transfer for mitochondrial and bacterial hydroxylases[5,6]. The biological functions of cytochrome P450-dependent hydroxylases include the hydroxylations (often detoxifications) of many structurally dissimilar substances such as steroids and fatty acids and xenobiotics such as drugs, carcinogens, pesticides, cannabinoids and a variety of substituted and unsubstituted hydrocarbons[5,7-10]. Cytochrome P450 may also act as a microsomal peroxidase[11].

Both iron–sulphur proteins and cytochrome P450 possess low redox potentials[6,12,13], close to that of the hydrogen electrode (−420 mV), unlike other cytochromes and other terminal oxidases. They could thus have functioned enzymatically at a time when the Earth's atmosphere was mainly composed of hydrogen, nitrogen, methane, ammonia, carbon monoxide and carbon dioxide[14,15], and also after free oxygen had appeared. Both are relatively small, single polypeptides (iron–sulphur proteins, molecular weight 6,000–12,000; bacterial cytochrome P450, 45,000) with low isoelectric points; have a large content of amino acids which can be synthesised abiologically[14]; and can be reconstituted from their apoproteins *in vitro*[4,16,17]. Both types are widely distributed in microorganisms, plants and animals[5,6,18] and participate in the metabolism of a large range of substrates[5,6,9]. The above characteristics have led some to consider that the iron–sulphur proteins may have been among the earliest to evolve and that this process took place in reducing conditions[6].

The gradual appearance of molecular oxygen would have led to the development in primitive organisms of biochemical mechanisms either as lines of defence (for example, utilisation of porphyrins[19]) or to benefit from the alteration in environment (for example, development of the energy-yielding respiratory process). Although molecular oxygen is itself damaging to living matter (for example, enzymes which are labile to aerobic conditions[17], autoxidation of lipids and oxidation of free sulphydryl groups of proteins), products of oxygen metabolism such as superoxide anion, H_2O_2 and OH^0 are also highly reactive and toxic to the living fabric It seems unlikely that the toxicity of

oxygen[19,20] is caused by a single toxic action, and the development of tolerance is probably multifactorial[20]. The rate of production of the superoxide radical by some enzymes has also been shown to depend on oxygen tension[20]. The early organism may thus have developed different lines of defence against damage by the steadily increasing atmospheric oxygen. Initially, cytochrome P450 alone may have been adequate to 'mop up' traces of unwanted oxygen which entered the cell. Later, cytochrome P450 activity may not have been adequate by itself to remove all the excess oxygen but would have still performed a valuable 'buffering' or attenuating role in lowering the production of H_2O_2 and superoxide anion to within limits which could be effectively detoxified by other enzymes. This activity may also have provided the time necessary for the induction of enzymes such as superoxide dismutase[1] whenever the organism was challenged by elevated oxygen levels in the immediate environment. Occasionally, enzyme systems may produce under certain chemical constraints some reactive metabolites of oxygen such as H_2O_2 and superoxide anion. These would have been balanced by the concerted action of enzymes such as cytochrome P450, superoxide dismutase and catalase, thus reducing the longevity of these toxic species in the cellular substance. Catalase is possibly of lesser importance in protecting bacteria against oxygen toxicity[1] and the innocuous nature of the products of the activity of cytochrome P450 may be of advantage. The superoxide anion and peroxide which may be produced in certain conditions *in vivo* by cytochrome P450-dependent enzyme systems (but see ref. 11), however, would at that time, as now, have required rapid detoxification by superoxide dismutase, peroxidase and catalase.

The apoprotein of cytochrome P450 could have been derived from abiogenic amino acids, and Calvin[16] has discussed how certain haemproteins may have been formed abiologically. The system would have been insensitive[7,8] to the levels of cyanide present in the primaeval oceans[14,15]. Chemical (or photochemical[6]?) reduction of an associated iron–sulphur protein suffices for the supply of electrons to cytochrome P450 in the absence of flavoproteins and reduced cofactors[6]. Although such reduction of an associated protein may have produced electrons for early cytochrome P450-dependent activities, Oparin[21] considers that cofactors must have appeared very early in chemical evolution. It is also relevant that the haemprotein complexes with phospholipids to form a proteolipid which is soluble in hydrocarbon solvent and may be functional in lipid surroundings[22]. This could be pertinent to the theories that primordial cells were highly lipid in nature[15].

The carbon monoxide in the atmosphere and the absence of oxygen[14,15] would have made unlikely the activity of cytochrome P450 as a hydroxylase very early in the evolution of life although the photochemical action spectrum of these hydroxylation reactions[5] has shown that illumination at certain wavelengths does reverse the inhibition caused by carbon monoxide. The solar energy which traversed the primitive atmosphere to reach the Earth's surface was very large[14,15]—sufficient to dissociate any carbon monoxide bound on to early forms of cytochrome P450. Cytochromes are proposed to have been among the active proteins which had evolved before the advent of the oxygen atmosphere[23,24], and, in spite of the aerobic conditions in the liver cell, a subsidiary function of the contemporary hepatic microsomal enzyme may be in reductive reactions[10]. The low redox potentials of this cytochrome and associated proteins would have enabled similar reductive activities of early cytochrome P450 to have taken place in an anaerobic hydrogen atmosphere. Contemporary cytochrome P450 may also have a role in nitrogen reduction and appears in *Rhizobium* sp. bacteroids by the time of active nitrogen fixation, which requires both nitrogen and oxygen[3,25]. Although research on cytochrome P450 has focused mainly

on its activities in an aerobic environment, it would be significant to demonstrate that this haemprotein exists in contemporary bacteria living in anaerobic conditions.

Pseudomonas and mitochondrial cytochromes P450 differ from microsomal cytochrome P450 in requiring the functioning of iron–sulphur proteins[5]. Both the mitochondrial cytochrome P450 and the associated iron–sulphur protein are located on the inner mitochondrial membrane[17]. Mitochondria may have been symbiotic inclusions in eukaryote development[26], and this fundamental difference between mitochondrial and microsomal cytochromes P450 would further suggest that cytochrome P450-dependent enzyme systems were evolutionary entities which had developed along separate lines in different prokaryotes before the formation of the eukaryotic cell. Possibly relevant here is the hypothesis[27] that the ancestors of the prokaryotes were simple abyssal organisms The ancestors of the eukaryotes, however, developed near the surface of the waters where they were exposed to light and, in due course, to the oxygen atmosphere. The exposure to light of the surface organisms would have reversed any inhibition of cytochrome P450 by atmospheric carbon monoxide[5] in the early period, and the proximity to atmospheric oxygen at a later stage may have favoured surface organisms possessing cytochrome P450. Note also that this enzyme has been found in a variety of contemporary higher organisms but few microorganisms[5,18].

If the hypothesis presented here is correct, a form of cytochrome P450 has been present in life forms for billions of years[15,26] and probably before the advent of free oxygen and the development of other respiratory haemproteins. When its protective value in detoxifying oxygen was superceded by subsequent development of aerobic organisms[26], the hydroxylase was retained because of its usefulness in biosynthetic processes and in the degradation of varied complex molecules.

We thank Dr J. Canick for comments and discussion. This work was supported by the National Cancer Institute, NIH.

Human embryonic haemoglobins including a comparison by homology of the human ζ and α chains

DURING the first 10 weeks of human embryonic life, there exist unique haemoglobins designated Gower 1 and Gower 2, and it has been suggested that Hb Gower 1 is a tetramer consisting of ε chains (ε₄) (ref. 1). Haemoglobin Portland has also been described in infants with developmental abnormalities[2] and neonates with severe α–thalassaemia, the Bart's hydrops foetalis syndrome[3,4]. Hb Portland is composed of two γ chains and two ζ chains[5].

The data of Capp, Rigas and Jones[5] on the ζ chain tryptic peptides suggested an α chain-like structure because of the presence of the dipeptide Tyr–Arg, which is unique for the C-terminal part of the α chain, rather than Tyr–His which is unique for human non-α chains. A more specific unique property of the α chain is its lack of the D helix (residues 50–56), and when in a second analysis of the ζ chain the alignment of the peptides was incompatible with the presence of the D helix, this strongly suggested that the ζ chain was indeed an early α chain[6]. Haemoglobin function requires two α and two non-α chains[7] and because embryonic and foetal cells showed similar

Fig. 1 Maps of the soluble tryptic peptides (a) and the peptic peptides (b) of the tryptic "core" from 8 mg of globin from Hb Portland, prepared as described previously[9], electrophoresis at pH 6.4 for a and pH 3.5 for b. Tryptophan-containing peptides were located under an ultraviolet lamp, and the positions of the remaining peptides were determined using fluorescamine. The ζ-chain peptides are shaded. Peptides A (Ala₂, Phe, Arg) and B (Ala₂ Arg) could not be aligned with any of the known α-chain sequences and are suggestive of a sequence Phe–Ala–Ala–Arg, Peptide Y described earlier[5,6] is suggestive of the α-chain elongation in Hb Icaria[8,18]

Fig. 2 Alignment of ζ-chain peptides with the amino acid sequences of three human haemoglobin chains. The chains have been arranged so as to maximise homologies, also taking into account the polarity and size of the residues, the haem contacts and the intramolecular contacts of α and β chains according to the model of Perutz as applied to man[19,20]. The alignment suggests that the ζ chain is very closely related to the α chain. O, α1β1 contacts; ●, α1β2 contacts; Δ, haem contacts.

oxygen dissociation curves, Huehns and Farooqui[8] concluded that the ζ chain ought to resemble the α chain.

We have examined human embryos aged 5–10 weeks and neonates with the Hb Bart's hydrops foetalis syndrome for Hb Gower 1 and Portland. The Hb Gower 1 fraction contains α chains and therefore Hb Gower 1 is unlikely to be a tetramer of ε chains. In the case of Hb Portland we have been able to obtain further evidence for resemblance of the ζ chain to the α–chain.

We obtained blood from 67 embryos. The red cells were washed several times in excess physiological saline and haemolysed as previously described[9]. The haemolysates were pooled and chromatographed on DEAE–Sephadex[10] and the fractions eluting earlier than Hb A₂, were pooled, concentrated by ultrafiltration, then electrophoresed on paper at pH 8.9 to isolate the embryonic haemoglobins. Fractions corresponding to Hb Gower 1 and Gower 2 were eluted with water and pooled separately and concentrated by ultrafiltration at 40 °C.

When the Gower 1 fraction was chain separated on a CM cellulose column[11] the major peak which was obtained gave on subsequent fingerprinting and amino acid analysis, peptides with amino acid compositions consistent with the structure of carbonic anhydrase B[12]. A tryptic dipeptide Gly-Arg which has been cited as an example of an ε-chain peptide[13], is also found in carbonic anhydrase B. The peak in position of the α chain was a haemoglobin α chain from fingerprinting and amino acid analysis of all soluble peptides.

To investigate the ζ chain, blood was obtained from two Hb Bart's hydrops foetalis neonates and Hb Portland was isolated by paper electrophoresis; haem was then removed and the globin dried under nitrogen[9]; 8 mg were digested with trypsin

and pepsin and fingerprints prepared (Fig. 1); 1 mg was used for the terminal amino acid sequence, using the modified dansyl technique of Gray[14,15]. Glycine only was released. Most of the peptides reported by Capp et al.[5] were obtained and the alignment of peptides is similar to that reported previously[6]. We have been able to align 14 additional residues and the only part of the α chain for which no peptide suitable for alignment was found are residues 41–46. We have, however, interchanged Phe and Leu for positions 47 and 52, because of the alignment of a dipeptide Gly–Leu to positions 51–52 (Fig. 1).

It is suggested from the electrophoretic mobility of peptide X aligned with residues 1–7, that the N terminus may be blocked, possibly through acetylation as it is in some γ chains. The corresponding non-blocked peptide with the expected electrophoretic mobility was not found. Of the 15 haem contacts available for comparison, (that is residues 32, 39, 58, 62, 83, 86, 87, 91, 93, 97, 98, 101, 129, 132 and 136) 12 can be aligned to be identical to those of α chain. Of the 30 internal residues available, 22 are alike, 7 very similar and only one dissimilar to those of α chains (α32). Of the subunit contacts, the 16 α1β1 contact alignments accommodate identical residues at 11 positions; the five others are 106 Leu/Gly, 107 Val/Lys, 114 Pro/Tyr, 119 Pro/Ile and 122 His/Asx. All the 10 α1β2 contacts available for comparison are identical to those of α chains.

To determine whether substantial amounts of Hb Portland occur in normal embryos, three additional embryos below the age of 10 weeks were later obtained and from the haemolysates, separated globins were prepared, digested with trypsin and fingerprints were prepared as above. No ζ chain peptides were detected. If Hb Portland occurs in normal embryos, it must occur at a concentration well below 10%. Purified Hb Portland

is known to have a cooperative oxygen dissociation curve with a reduced alkaline Bohr effect[16]. If it formed 40% of the haemoglobin in embryonic cells[17] it would be expected to affect their Bohr effect and cause them to differ from foetal cells rather than resemble them, as has been reported[4]. Hb Gower 1, if it is an ε_4 tetramer, should raise the oxygen affinity, as tetramers of like chains have very high oxygen affinities[7]. We conclude that if erythrocytes of young human embryos, aged 5–10 weeks resemble foetal cells in oxygen affinity and Bohr effect[8] they are unlikely to contain substantial amounts of Hb Portland and Hb ε_4.

Lycorine as an inhibitor of ascorbic acid biosynthesis

LYCORINE, an alkaloid extracted from Amaryllidaceae[1,2], is a powerful inhibitor of growth in higher plants, algae and yeasts. At the very low concentration of 10^{-6} M, lycorine inhibits cell division in higher plants, red algae and yeasts, and the cell cycle is arrested in the interphase stage[3]. No inhibition of cell division was observed in Escherichia coli (O. A., unpublished).

Lycorine also inhibits expansion growth in higher plants[3].

At 10^{-4} M, while strongly inhibiting expansion growth, lycorine induces the following metabolic responses[4]: inhibition of ^{14}C-leucine incorporation into proteins; subsequent significant inhibition of ^{3}H-uridine incorporation into RNA; and a massive drop in the ascorbic acid (AA) content and a corresponding increase in dehydroascorbic acid (DHA). The effect of lycorine on protein synthesis was clearly an indirect one, as isolated polysomes were found to be lycorine-insensitive. Because RNA synthesis is only inhibited as a long term effect, it was suggested that the primary inhibiting effect of lycorine could be its action on the ascorbate system[3,4].

To demonstrate lycorine–ascorbic acid interaction, attempts were made to remove the effect of lycorine by exogenous administration of AA. This kind of experiment was not successful in higher plants, however, because AA was promptly oxidised by the tissue, mainly at the cut surfaces, and DHA accumulated in the cell, thus inhibiting plant growth. In contrast, the inhibition of growth induced by lycorine in red algae was almost completely overcome by the addition of external AA[5]. This was obtained because AA is very slowly oxidised to DHA on the cut surfaces so that there is no DHA accumulation in the cell, whereas AA does accumulate and thus overcomes the lycorine effect. These results show that lycorine does not interfere with AA utilisation in red algae and strongly suggest that the effect of lycorine on plants could be the result of its ability to inhibit AA biosynthesis.

To determine the effect of lycorine on AA biosynthesis, 3-d-old seedlings of Pisum sativum, 2 cm long and deprived of their roots, were kept in distilled water (or in lycorine, where indicated) in the dark for 18 h (starvation) and were subsequently exposed to light for 14 h. AA content of seedlings diminished during starvation: the total amount of AA+DHA decreased from 6,763 γ per g dry weight to 3,672 γ per g dry weight (Table 1). This means that a large amount of AA is utilised in cell metabolism[6]. Cells corresponding to 1 g dry weight utilise about 172 γ h^{-1} AA in their metabolism and growth.

Actually, the amount of AA utilised in cell metabolism is higher; in fact the decrease in AA content is stronger in the presence of lycorine. With 6×10^{-5} M lycorine present during starvation, the total amount of AA is only 1,305 γ per g dry weight (Table 1). These data seem to suggest that the seedlings synthesise a certain amount of AA during starvation in the dark, as they utilise the reserve carbohydrates that are present in parenchymatous cells; this does not occur with lycorine and the AA content is consequently lowered at the end of starvation. AA biosynthesis inhibition by lycorine is better evaluated when the seedlings are illuminated after the starvation period (Table 2) In these conditions the controls synthesise a considerable amount of AA: total content (AA+DHA) rises from 3,646 to 4,776 γ per g dry weight. Lycorine present in the medium during light exposure strongly inhibits AA biosynthesis, the rate of inhibition being 41% at 5×10^{-6} M and 90% at 2×10^{-5} M. Considering that lycorine enters the seedlings only through the lower cut surface of the stem, it is very likely that lycorine concentration is quite low in the leaves where large amounts of AA are synthesised.

	Table 1 Effect of lycorine on AA content in rootless pea seedlings during starvation				
Time	Treatment	AA	DHA	Total	AA + DHA utilised
0		5,411	1,352	(γ per g dry weight) 6,763	in metabolism —
Starvation	Water	2,800	872	3,672	3,091
Starvation	Lycorine 10^{-5} M	2,300	640	2,940	3,823
Starvation	Lycorine 3×10^{-5} M	1,910	535	2,445	4,318
Starvation	Lycorine 6×10^{-5} M	905	400	1,305	5,458

Seeds of Pisum sativum var Alaska, soaked 18 h in tap water, were planted in vermiculite wetted with water, and then placed in a dark environmental chamber at 27 °C; 3-d-old seedlings, 2 cm long, were deprived of their roots and starved in the dark, at 27 °C for 18 h The seedlings were arranged on Petri dishes through the perforated cover (25 for each dish). AA and DHA were assayed on the apices of seedlings; 50 apices for each sample, about 250 mg fresh weight, were homogenised in 8 ml 5% metaphosphoric acid and centrifuged. The supernatant was used for AA and DHA assay using 2,4-dinitrophenylhydrazine reaction[5,10,11]. All values reported are average determinations on triplicate samples.

Table 2 Effect of lycorine on AA synthesis in pea seedlings

Time	Treatment	AA	DHA	Total (γ per g dry weight)	AA + DHA synthesised	Inhibition (%)
0		5,338	1,332	6,670	—	—
Starvation		2,782	864	3,646	—	—
14 h exposure to light	*Water	3,679	1,097	4,776	1,130	—
14 h exposure to light	*Lycorine 5 × 10⁻⁶ M	3,334	978	4,312	666	41
14 h exposure to light	*Lycorine 10⁻⁵ M	3,250	893	4,143	497	56
14 h exposure to light	*Lycorine 2 × 10⁻⁵ M	3,031	728	3,759	113	90

* After 18 h starvation in water the seedlings were transferred on to other Petri dishes containing either water or lycorine and placed in an aerated chamber at 1,000 lx and 27 °C for 14 h.

Table 3 Effect of lycorine on AA synthesis in potato slices

	Treatment	AA	DHA	Total (γ per g dry weight)	AA + DHA synthesised	Inhibition (%)
Fresh slices		585 8	30.2	616	—	—
Activated slices	Water	839	47	886	270	—
Activated slices	Lycorine 5 × 10⁻⁷ M	760	50	810	194	28
Activated slices	Lycorine 10⁻⁶ M	704	49	753	137	50
Activated slices	Lycorine 3 × 10⁻⁶ M	600	45	645	29	89

Tuber slices of *Solanum tuberosum* L. were prepared as follows: cylinders of potato tissue (0.9 cm diameter) were removed with a cork borer and sliced on a sliding microtome. Slices (1 mm thick) were washed repeatedly in tap water and these were indicated as 'fresh' slices, whereas 'activated' slices[12] were those placed either in water or in lycorine for 24 h with air bubbled into the medium. AA and DHA determinations were made on 20 slices, about 2,500 mg fresh weight for each sample, and homogenised in 12 ml 5% metaphosphoric acid. All values reported are average determinations run on triplicate samples

Table 4 Effect of lycorine on AA synthesis in *Clivia* leaves

Time	Treatment	AA	DHA	Total (γ per g fresh weight)	AA + DHA synthesised	Inhibition (%)
0		1,584	104	1,688	—	—
Starvation		915	85	1,000	—	—
14 h exposure to light	Water	1,395	92	1,487	487	—
14 h exposure to light	Lycorine 10⁻⁵ M	1,410	90	1,500	500	—
14 h exposure to light	Lycorine 5 × 10⁻⁵ M	1,312	86	1,398	398	18

Young leaves of *Clivia miniata* Reg. were kept for 18 h in dark environmental chamber at 27 °C (starvation) The leaves were then placed in aerated chamber at 1,000 lx and 27 °C for 14 h. AA and DHA were assayed as indicated in Table 1, by homogenising 1 g fresh weight in 16 ml 5% metaphosphoric acid.

A demonstration of the extreme sensitivity of the AA biosynthesis system to lycorine has been provided using potato slices[7]. In contrast to pea seedlings, there are no permeability problems. In 'activated' slices, 5 × 10⁻⁷ M lycorine already inhibits 28% AA biosynthesis; almost complete inhibition is obtained at 3 × 10⁻⁶ M lycorine (Table 3).

Considering that AA biosynthesis is highly sensitive to lycorine (3 μM lycorine inhibits 89%); that lycorine does not interfere directly with protein and nucleic acid synthesis[4]; it does not affect either permeability or phosphorylation in mitochondria and chloroplast (O. A., unpublished); it does not affect animals that are not capable of synthesising AA but does induce scurvy-like symptoms in AA-synthesising animals[8,9], it seems possible to conclude that lycorine is quite a specific inhibitor of AA biosynthesis in both plants and animals, and that its biological effects are probably the result of this peculiar action.

Finally, within the Amarillidaceae, results show that AA biosynthesis is much less affected by lycorine in *Clivia miniata*—an Amarillidacea containing lycorine in both leaves and rhizomes[13]—than it is in pea and potato. Lycorine (10⁻⁵ M), although inhibiting 56% in pea seedlings and 100% in potato slices, does not affect AA biosynthesis in *Clivia* leaves: at lycorine concentrations five times higher, the inhibition is only 18% (Table 4).

These data raise an interesting question, particularly in view

of the phylogenetic implications—what is the relationship between the AA biosynthetic pathway and the presence of lycorine in Amarillidaceae? Before any conclusions can be drawn, however, our data should first be confirmed using the isolated AA biosynthetic system.

Intracellular killing of *Listeria monocytogenes* by activated macrophages (Mackaness system) is due to antibiotic

THE classic *in vivo* studies of Mackaness[1] showed that the macrophage could be activated to kill intracellular organisms such as *Listeria monocytogenes*. This led to a series of experiments to determine the process by studying killing of this organism by macrophages both *in vivo* and *in vitro*[2-6]. Subsequent experiments carried out with Mackaness[1] system *in vitro* have required antibiotic or suitable serum in the culture medium to control extracellular growth of the organism which otherwise overruns the culture[7,8]. Antibiotics have been shown
Fig. 1 The effect of antibiotic on microscopically visible avirulent intracellular *Listeria monocytogenes*. Glass-adherent cells from peritoneal washings of 10-week-old, female BALB/c mice were infected with an avirulent derivative of the *L. monocytogenes* strain NCTC5214 at a multiplicity of infection of 10. Cultures were washed and incubated in medium 199 with 20% heat-inactivated foetal calf serum in the absence (*a*) or presence of 0.8 μg ml⁻¹ benzyl penicillin (*b*). ●———●, Avirulent *Listeria* count per infected peritoneal cell (left-hand vertical axis scale); ● ─ ─ ─ ●, % infected peritoneal cells (right-hand vertical axis scale). Each point represents the mean ± s.d of triplicate cultures in which 100 peritoneal cells were counted.

Fig. 2 The effect of antibiotic on peritoneal cell survival in cultures infected with avirulent *Listeria*. ●———●, Uninfected culture without antibiotic; □———□, *Listeria*-infected culture without antibiotic; ○———○, *Listeria*-infected culture with 0.8 μg ml⁻¹ penicillin. Each point represents the mean of triplicate cultures in which 100 high power fields were examined.

In the absence of antibiotic in the medium, apparent 'proliferation' of avirulent *L. monocytogenes* within the peritoneal cells occurs (Fig. 1) and the culture undergoes premature destruction (Fig. 2). To preserve the cell culture it is necessary

Fig. 3 Microscopically visible intracellular *Listeria* in cultures with antibiotic (benzyl penicillin 0.8 μg ml⁻¹). ■, *Listeria* strain NCTC5214 of intermediate virulence; ▼, virulent derivative of *Listeria* NCTC5214; ———, *Listeria* count per infected peritoneal cell (left-hand vertical axis scale); ─ ─ ─, % infected peritoneal cells (right-hand vertical axis scale). to enter peritoneal cells[9] and affect bacterial proliferation[10-12], although there is evidence that the intracellular environment to some extent protects bacteria against the effects of antibiotics[13,14]. It has always been uncertain, therefore, whether any intracellular killing observed has been a result of antibiotic rather than activated cellular processes. Furthermore, antibiotic might be expected to enter activated cells more than resting ones, thereby causing an apparently increased intracellular killing by the former. Thus, in order to validate the system, it is necessary to prove that antibiotic is not involved in the killing of the organism. The crucial, but hitherto absent, control that is required must show true intracellular proliferation of the organism within activated cells in the face of antibiotic in the medium.

Fig. 4 Viable intracellular *Listeria* in normal and activated peritoneal cultures in the presence of antibiotic. Activated peritoneal cells consisted of glass-adherent peritoneal exudate cells induced by 2 ml of 10% proteose–peptone i.p. for 72 h. Viability assay, read at 36 h, was carried out by pour-plate dilution method in tryptose–soya agar after the cultures had been scraped with a rubber policeman, the cells lysed in distilled water and the lysate sonicated. Triplicate assays were carried out from each culture. ●———●, Avirulent *Listeria* within normal peritoneal cells; ■———■, intermediate-virulence *Listeria* (NCTC 5214) within normal peritoneal cells; ▼———▼, virulent *Listeria* within normal peritoneal cells; ◆ – – – ◆, virulent *Listeria* within activated peritoneal cells. Each point represents the mean ± s.d. of triplicate cultures.

to add antibiotic (penicillin at twice the minimal inhibitory concentration (MIC) for the organism) to the culture medium, thereby suppressing extracellular growth of the organism. This results in quite the reverse of intracellular proliferation, for both microscopy (Fig. 1) and viable intracellular counts (Fig. 4) indicate that death of the organism occurs within the cells—raising the question of whether this killing is due to antibiotic penetration of the peritoneal cell.

There is evidence for penetration of antibiotic into peritoneal cells[9] and even for concentration of it within such cells[15]. It could cause *Listeria* killing within the cells in two ways. Either it could act bactericidally or it could prevent proliferation of the organism (bacteriostasis), enabling the peritoneal cells to do the actual killing. The only way to show that antibiotic does not act in these ways is to demonstrate a proper control of genuine intracellular proliferation of *L. monocytogenes* in the face of such antibiotic. Studies of strain NCTC5214 of intermediate virulence did not resolve the question. In the absence of antibiotics, strain NCTC5214 behaved identically to the avirulent derivative, but on addition of antibiotics it persisted in a viable state within the cells (Figs 3 and 4) instead of being destroyed. Nevertheless, it did not proliferate and so was not a proper control.

Proof of the ability of *L. monocytogenes* to undergo true

intracellular proliferation in the face of antibiotic in the medium was furnished by a series of experiments using a more virulent strain derived from NCTC5214 by modification of the technique of continuous passage in mice. Using this strain it was evident from microscopy (Fig. 3) and viability assay (Fig. 4) that true proliferation had occurred. Furthermore, as the MIC of antibiotic for all three strains of organism was identical (0.4 µg ml⁻¹) the different behaviour of the three strains within the peritoneal cells cannot be explained by the effects of antibiotic alone.

When peritoneal cells are activated by various methods their permeability to antibiotic may increase and therefore enable greater intracellular concentrations to occur. Thus, the apparent killing of intracellular organisms in the activated cell may still be due to antibiotic rather than true cellular killing.

Repeating the experiment with activated peritoneal cells and using the same three strains of *L. monocytogenes* resolved the problem. This time the behaviour of the organisms was different — the avirulent strain was killed more rapidly, the NCTC5214 strain was killed (whereas in normal peritoneal cells it had remained in stationary phase), and the virulent strain proliferated, but at a slower rate than in non-activated peritoneal cells (Fig. 4). Again, as the MIC of penicillin for these strains was identical, the increased rates of killing of the avirulent derivative and NCTC5214 strain and the slowed proliferation of the virulent strain must have been a result of factors unrelated to the antibiotic permeability of the peritoneal cells.

A dose–response experiment (collected after 18 h culture) showed that if a penicillin concentration of 1.2 µg ml⁻¹ or more were achieved in the extracellular medium the virulent strain of *L. monocytogenes* was killed intracellularly. This confirms that penicillin enters the cells and can have a bactericidal effect—making a proper control mandatory.

A further problem in the interpretation of experiments previously reported is the fact that during the first 4 h of culture

Fig. 5 Dose–response effect of antibiotic on intracellular proliferation of the virulent derivative of *Listeria* after an 18 h culture. Each point represents the mean ± s.d. of triplicate cultures
there is an 'apparent' increase in the microscopical counts of bacteria (Fig. 3) within peritoneal cells in spite of the presence of antibiotic in the medium. The viable counts (Fig. 4) do not reflect this; therefore this apparent increase is due to the phagocytosis of dead or dying organisms from the extracellular medium in the period following addition of the antibiotic at the end of the infecting phase. If only short term cultures are carried out, without close attention to viable counts of intracellular organisms, a misleading impression of intracellular proliferation may be gained.

We have shown that omission of antibiotic, because it enables uncontrolled extracellular proliferation of the organism, results in misleading data indicating more exuberant intracellular proliferation of *L. monocytogenes* than is in fact occurring. On the other hand our data show that concentrations of penicillin of 1.2 μg ml^{-1} or more kill the strain of *L. monocytogenes* used within activated mouse macrophages. As the MIC of penicillin for all sensitive strains of *L. monocytogenes* tested to date has been less than 0.5 μg ml^{-1}, it is highly likely that the critical concentration of penicillin in the culture medium for most strains of this organism in this system approximates to 1.2 μg ml^{-1}; but it is likely also to depend on the kind of macrophages used and (or) their level of activation. Where experiments have been carried out using higher concentrations of antibiotic it is doubtful whether activation of the macrophages *per se* has contributed to the observed killing.

The necessary control consists of true intracellular proliferation of the organism in the face of antibiotic in the medium. We have found that concentrations of penicillin less than 1.2 μg ml^{-1} enable both the intracellular proliferation of *L. monocytogenes* and the demonstration of the bactericidal property of activated macrophages.

Electron spin resonance measurements of molecular interactions in mouse olfactory epithelium

THE mechanism by which molecules interact with, and so stimulate, the surfaces of olfactory receptor cells has given rise to much speculation. Since oil-soluble substances are often very effective odours, it has been proposed that olfactory transduction occurs when an odorant molecule perturbs the lipids of the sensory membranes. Conversely, the known steric aspects of odorant molecule interactions argue for a more specific binding for which a protein would be a more suitable receptor[1–4].

These theories are based mainly on inferences of how odorants of known chemical structure should behave in biological membranes but there is a lack of direct measurements on olfactory tissue in support of either view. Here we report the use of electron spin resonance (ESR) spectroscopy using spin-labelling techniques[5,6] to investigate the molecular interactions of odorants at olfactory and other membrane surfaces.

Solutions of spin-labelled nitroxide compounds in saline or Ringer's (10^{-3}–10^{-5} M) were injected into the nasal chamber of mice immediately after death by cervical dislocation or an overdose of Nembutal, and after 3–5 min olfactory tissue was removed, and placed in saline or Ringer's in an ESR tissue cell. The spectra were measured on a Varian E9 ESR spectrometer operating at the X band. Long scan times were essential to resolve the spectra. Respiratory mucosa from the nasal chamber and mucosa from the small intestine were used as tissue controls.

In the case of the four odourless spin-labelled compounds investigated using the olfactory epithelium (Fig. 1),
Fig. 1 ESR spectra of four odourless spin labels in the mouse olfactory epithelium. *a*, 3-Carbamoyl-2,2,5,5-tetramethylpyrrolinooxyl; *b*, 3-carbamoyl-2,2,5,5-tetramethylpyrrolidinooxyl; *c*, 4-acetylamino-2,2,6,6-tetramethylpiperidinooxyl; *d*, 4-hydroxy-2,2,6,6-tetramethylpiperidinooxyl.

the three amides showed spectra characteristic of their presence in an aqueous environment; since there is no evidence of molecular association with the cell membranes they are therefore assumed to remain in the mucus layer. The spectrum of the fourth spin-labelled compound (4-hydroxy) shows a splitting of the high field line (characteristic of the partitioning of a spin label between aqueous and lipid phases), and in addition a weak, strongly immobilised component.

Most of the odorous spin labels give partially immobilised spectra indicative of their solution in the membrane lipid (Fig. 2), whereas, of those compounds remaining (also the strongest odours), the isothiocyanate and *p*-toluene sulphonate ester derivatives are strongly immobilised (Fig. 3*a* and *b*), and the 4-piperidone shows a strongly immobilised component ($g=2.008$ and 1.999; Fig. 3*c* and *d*). Isothiocyanates readily react with free primary amino, thiol or hydroxyl groups, and in this instance, the isothiocyanate is probably so bound to mem-

brane proteins. The spin labels of each class gave spectra with the control tissues which were similar to those with the olfactory epithelium.

Previous experiments have shown a good general correlation of the odour thresholds of various mammals and of man although they cannot be claimed to be identical[7].

Since the spectra of sensory and non-sensory tissues were closely similar it does not seem that any special features of the olfactory epithelium can be detected with this technique, but we can in broad terms draw a parallel between the olfactory potency of a compound and the extent to which it interacts with the lipids and other components of cellular membranes in general.

Recent experiments on frogs[8,9] indicate that receptor sites on olfactory endings consist at least in part of proteins. We suggest that such proteins may be buried in the lipid of the olfactory membranes or sited at their inner surface so that an odour–lipid interaction is needed before an odour can reach the receptor site. This inaccessibility would provide a greater degree of biological specificity.

In the case of the strongest odours, a strong interaction, in some instances chemical bond formation, probably occurs between odour and membrane protein, such as to pro-

Fig. 2 ESR spectra of five odourous spin labels in the mouse olfactory epithelium. *a*, 4-Amino-2,2,6,6-tetramethylpiperidino-oxyl; *b*, 4-isocyano-2,2,6,6-tetramethylpiperdinooxyl; *c*, 4-acetyloxy-2,2,6,6-tetramethylpiperidinooxyl; *d*, 4-benzyloxy-2,2,6,6-tetramethylpiperidinooxyl; *e*, 2,2,6,6-tetramethylpiperidinooxyl.
Fig. 3 ESR spectra of three pungent spin labels in the mouse olfactory epithelium. *a*, 2,2,6,6-Tetramethyl-4(4'-toluene sulphonate) piperidinooxyl; *b*, 4-isothiocyanato-2,2,6,6-tetramethylpiperidinooxyl; *c*, and *d*, 4-oxo-2,2,6,6-tetramethylpiperidinooxyl.

mote a conformational change, and so initiate olfactory transduction. Similar mechanisms may operate for the less reactive but lipophilic odours. The absence of appreciable odour in the case of the 4-hydroxy compound suggests, however, that penetration of the membrane is not in itself a sufficient condition for stimulation. This evidence therefore argues against a purely lipid–odour interaction in olfaction. Further experiments are in progress to test these conclusions, and a theoretical treatment of these results, in terms of current theories of cooperative phenomena in membranes, is in preparation.

matters arising

The design of wildlife preserves

MAY[1] has drawn attention to the need to make nature reserves sufficiently large, arguing from both theory and observations on island biogeography I would like to add two comments to reinforce his case. The first is that a similar species–area relationship is found in quadrats of different size and in other studies of continuous ecosystems, as well as across sets of islands. This means that when a boundary is drawn around a nature reserve in a larger area of the same habitat, the number of species in the reserve will be less than that in the region as a whole. The other point is that if the remainder of the habitat is then cleared away, there will be an edge effect around the new reserve. Species suited to the edge will frequently be different from those suited to the centre of the reserve. If the reserve is intended to maintain the 'central' species, then its effective size is smaller than its apparent area.

Sudden death in infancy

I AM pleased to learn that Carpenter and Emery[1] have succeeded in identifying a limited number of high-risk cases in the field of child-death prevention. But their conclusion that "there are encouraging indications that the study may be preventing some deaths" is not supported by the data.

Carpenter and Emery[1] compared a high-risk group which was not selected for follow-up health care with a sample of a low-risk group, and found that the former had significantly higher mortality. But this result merely reflects the original group assignments. The relevant issue is rather, whether or not the high-risk group which was followed up differs from the high-risk group which was not selected.

I have reanalysed Carpenter and Emery's data (Table 1) using χ-square tests corrected for continuity. Two groups (high-risk subjects not selected, and high-risk subjects either not selected or not participating) are compared separately with the high-risk group receiving aftercare. The null hypothesis for each test is that mortality will be at least as great in the follow-up group as in the non-treatment group. As statistical convention requires significance at the 0.05 level, the null hypothesis cannot be rejected in either case.

Perhaps a larger sample will yield different results in the future.

STEPHEN MAGURA

Trenton, New Jersey 08625

[1] Carpenter, R G , and Emery, J L., *Nature*, 250, 729 (1974)

CARPENTER AND EMERY REPLY—

Magura[1] is mistaken when he says that the significant difference we reported[2] "merely reflects the original group assignments". The group assignments were based on a discriminant function that had been constructed before the prospective study began. The significant difference referred to is fundamental to our main point, which is that it is possible to identify babies who will be at risk of sudden death in infancy within 24 hours of their birth. We also showed that the high-risk group is sufficiently sharply defined that it can be studied prospectively.

Magura shows that the observed difference in mortality rates between the high-risk group followed up and the high-risk controls is compatible with the null hypothesis, as we were well aware. But the data are equally compatible with the alternative hypothesis that the follow-up study is preventing deaths, and on a likelihood-ratio criterion the latter hypothesis is more strongly supported than the

former. This common sense view is also reinforced by case reports[3]. We think that our conclusion that "there are encouraging indications that the study may be preventing some deaths" summarised this situation accurately.

We are confronted with a difficult ethical problem. To know whether or not the discriminant function and the follow-up study are effective a high-risk control group is essential. But in the light of results such as those summarised by Magura, for how long does it remain ethical to exclude high-risk babies from the follow-up study? The classical significance test approach followed by Magura gives one answer to the problem. It would be interesting to know if this view is generally shared by your readers.

Proterozoic supercontinent: time duration and the Grenville problem

THE reconstruction of the Proterozoic supercontinent has been devised[1] by superimposing 2,000–1,100 Myr palaeomagnetic poles from two regions and was derived by rotating North America anticlockwise 146° about a Euler pole at 138°E, 73°N. With this operation most dated, Precambrian, palaeomagnetic poles from Africa correlate with comparable poles from North America with fields of agreement illustrated in a qualitative way in Fig. 1. The new data of McGlynn *et al.*[2] enable further comparison and the 2,090 Myr Indin dykes pole agrees closely with several poles 2,070–2,090 Myr in age from Africa[3]. Also, 2,150 Myr poles from western Africa correlate with some poles from the Nispissing diabase and Abitibi dykes (~2,150 Myr). It is not yet possible to match 2,200–2,300 Myr poles from Africa with North American data, and there are clearly two possibilities: either the reconstruction is not valid earlier than 2,150 Myr or apparent polar movements are more complicated than recognised.

The latter explanation is probably

Table 1 Number of infants and number of sudden deaths among high-risk groups

	No. in group	No of deaths	Significance (one-tailed test)
Followed up	354	0	
Not selected	477	4	$0.15 > P > 0.10$
Not selected or not participating	557	5	$0.10 > P > 0.05$

correct for three reasons. First, there is general agreement between pre-2,400 Myr poles on the supercontinent reconstruction (Fig. 1). This grouping seems to be definitive: the new 2,692 Myr pole from the Dogrib dykes of North America[4] falls in the same group and close to the 2,630 Myr pole from the Modipe gabbro of Botswana. Second, palaeomagnetic studies of the ~2,160 Myr Nispissing diabase and Abitibi dykes yield discordant poles defining similar tracks[2], implying rapid apparent polar movement at the time of their intrusion. Third, Archaean foliated anorthosites seem to occupy a single linear belt[5,6] on the reconstruction.

The Proterozoic supercontinent reconstruction reconciles what has become one of the most intractable problems of North American Precambrian palaeomagnetism. Pole positions from rock units within the Grenville Province form a group practically distinct from pole positions derived from elsewhere in the Canadian Shield[7]. It is argued that the Grenville poles are essentially contemporaneous with quite different pole positions from rock units north of the Grenville Front[7,8] and that they may be explained in terms of plate collision between the Grenville Province and the remainder of the shield at about 1,000 Myr. This explanation is difficult to reconcile with the protracted history of the province and the correlation of features across the line of the Grenville Front well into the Grenville Province (see ref. 9). The plate tectonic hypothesis has become virtually untenable in the light of new palaeomagnetic work[10] yielding Grenville-type poles from a region close to the Grenville Front where there seems to be little possibility of a plate suture between the province and the shield, and also from identification of Grenville-type palaeomagnetic directions within the Canadian Shield and remote from the Province[11].

In Fig. 2 the Grenville Province poles from the compilation of ref. 7 are plotted on the supercontinent reconstruction where it is seen that they straddle the apparent polar wander curve recognised from African data between about 1,040 and 800 Myr consistent with abundant radiometric data from the province. It implies that the Grenville Province was an integral part of the Proterozoic supercontinent; it also suggests that this supercontinent existed as such to about 800 Myr BP.

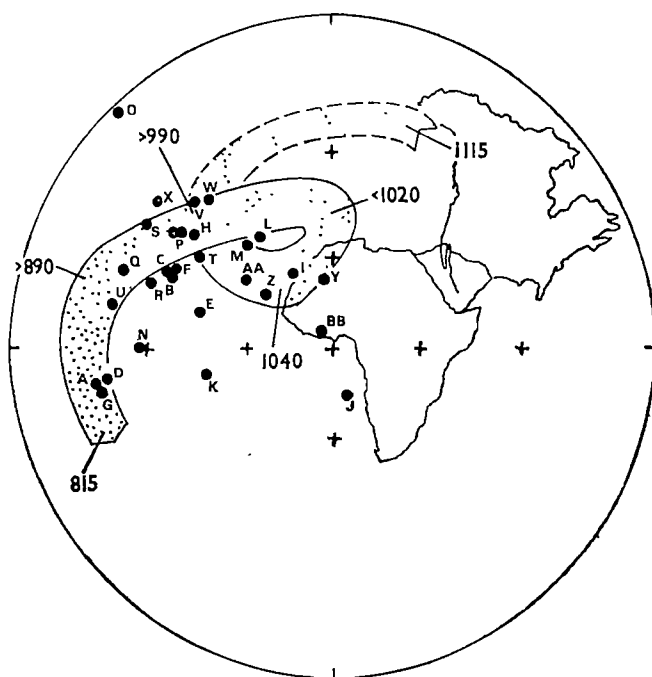
Fig. 1 Fields of agreement between African and North American Proterozoic palaeomagnetic poles on the supercontinent reconstruction. Figures give ages in millions of years. The <1,730 Myr field is defined by redating of the Mackenzie III dykes[12]. Pre-2,400 Myr poles from Africa (squares) and North America (circles) are plotted and their ages indicated in millions of years.


Fig. 2 Pole positions from rock units within the Grenville Province of North America plotted on the supercontinent reconstruction. The apparent polar wander path derived from African data between 1,115 and 800 Myr BP is also indicated by the stippled swathe (refs 1 and 3); this path is derived in part from stratigraphically-controlled series of poles and the figures are assigned ages in millions of years. The poles are: A, Allard lake; B, Frontenac dykes; C, Grenville gneisses; D and E, Haliburton basic rocks; F, Lake St Jean anorthosite; G and H, Morin anorthosite, I, Morin dykes; J, Magnetawan metasediments; K, L, and M, Mealy Mount; N, Larrimac and Bryson diorites; O, Tudor gabbro; P, Unfraville intrusive; Q, Wilberforce pyroxenites, R, S and T, Whitestone anorthosite; U, Whitestone diorite; V, Grenville front anorthosites; W, Michael gabbro; X, Seal and Croteau igneous; Y, Seal group red beds; Z, AA and BB, Shabogamo gabbro.

Bottom life under Antarctic ice shelves

WITH reference to the article by Heywood and Light[1], it should be pointed out that the existence of a relatively rich and diversified benthic fauna under an Antarctic ice shelf was first demonstrated by Littlepage and Pearse[2] in 1962 for the Ross ice shelf During November and December 1961 they collected various representatives of 16 major zoological groups (including the fish *Trematomus* sp) using traps and grabs inserted through cracks in the shelf ice at distances of 22 and 28 km from the open sea

As those samples included some typical 'suspension-feeders' (Porifera, Ectoprocta, Sabellida and so on), a water current able to transport the food items evidently exists and may explain the development of a rich bottom fauna under the Ross Ice Shelf. No doubt, such a current is also present under the Shelf ice of King George VI Sound, according to the shape and two openings of this ice covered body of water

In fact, I see no reason why a substantial bottom fauna should not live anywhere under any floating Antarctic ice shelf, as many Antarctic invertebrates and fish are adapted to an opportunistic diet (including even necrophagy)[3]. Furthermore, there is no longer any reason to expect a peculiar (specific) fauna under Antarctic ice shelves, as it is now admitted that the Antarctic shelf has been covered by the edges of the Wurmian ice sheet. So, the main biological interest of the Ross Ice Shelf Project (RISP), when drilling at a distance of 450 km from the seaward edge of the Ross Ice Shelf, would be to obtain an insight into adaptations and relationships among the biota of these obscured areas of the Antarctic shelf.

[1] Heywood, R B., and Light, J J , *Nature*, 254, 591 (1975)
[2] Littlepage, J L , Pearse, J. S , *Science*, 137, 679 (1962)
[3] Arnaud, P M , *Third Symposium on Antarctic Biology, Washington* (in the press)

HEYWOOD AND LIGHT REPLY—We are grateful to Arnaud for drawing our attention to the paper by Littlepage and Pearse, an unfortunate oversight on our part We note from this paper the *Trematomus* sp. was found by DeVries and Kooyman We agree of course with the ecological comment of Arnaud. We prefer, however, to keep an open mind on whether a substantial bottom fauna can live anywhere under a floating Antarctic

ice shelf—the problems of obtaining enough food at a distance of 450 km from the open sea could be far greater than when merely 28 km away. We believe this justifies our remarks that the first biological aim of RISP is to determine whether a biome can exist at a considerable distance from the open sea, and that a biome found under ice 100–500 m thick, at least 100 km from the open sea, is " remarkable ".

Monks Wood Experimental Station, Abbots Ripton, UK

Random packing of equal spheres

THE recent article of Gotoh and Finney[1] has drawn my attention to this interesting problem. I have been impressed by the amount of experimental work carried

Fig. 1 Packing of circles and triangles.

on in this field, but at the same time I am wondering why similar experimental work has not been done—as far as I know—on the theoretically simpler problem in two dimensions to provide some evidence. I have also noticed several more or less explicit pleas to mathematicians to 'invent a statistical geometry'. None of the authors seems aware that such a geometry does indeed exist. It is usually called "integral geometry" (see, for example, ref. 2) and its methods should certainly be relevant to this problem.

The origin of integral geometry can be traced back to the famous 'Buffon's needle' problem. A needle of length *l* is thrown on a board ruled with parallel lines at distance *d*. One can show that the average number *n* of contacts of the needle with the lines is

$$n = (2/\pi)(l/d) \qquad (1)$$

Integral geometry has several theorems such as (1) in which the constant $2/\pi = 0 6366197 \ldots$ appears. Could this be the "maximum packing density" given in ref. 1 as 0.6366 ± 0.0008 and 0.6366 ± 0.0004 in two different experiments? It is certainly a conjecture worth pursuing.

In the meantime I would like to suggest an elementary explanation of the random loose packing density Let us start from the two-dimensional case.

Circles and triangles take the place of spheres and tetrahedra. In the language of Gotoh and Finney we have a triangle —formed by an arbitrary circle and two supporting circles—which is completely specified by the angle *a* (see Fig. 1). To compute the packing density it is convenient to add a circle on the bottom to make the drawing more symmetrical. We can then easily see that the packing density of the configuration is the area of one circle divided by the (hatched) area of the parallelogram. Assuming a uniform probability density for the angle *a*, the average area *A* of the parallelogram is then

$$A = \frac{\int_{\pi/3}^{\pi/2} 4r^2 \sin a \, da}{\int_{\pi/3}^{\pi/2} da} = (12/\pi)r^2 \qquad (2)$$

The limit $\pi/3$ corresponds to the case of the two supporting circles in contact; angles greater than $\pi/2$ give a configuration equivalent to one rotated by 90°. The average packing density *d* is then

$$d = (\pi r^2/A) = (\pi^2/12) \sim 0.8225 \qquad (3)$$

All configurations being taken as equally likely with no correlations this density
should correspond to the case of random loose packing of equal circles. The three-dimensional problem can be solved in a similar way. Figure 1 should be changed into the Gotoh and Finney spheres and tetrahedron, and show a hatched parallelepiped. The three vectors from the centre of the supported sphere to the centres of the supporting spheres will then mark the vertices of a spherical triangle on a sphere of radius $2r$ (Fig. 1c). Since the probability of a configuration with b, c, A in the range $dbdcdA$ is proportional to

$$\sin b \ \sin c dbdcdA,$$

using the formula

$$\cos a = \cos b \ \cos c + \sin b \ \sin c \ \cos A$$

one obtains

$$\sin b \ \sin c dbdcdA \qquad (4)$$
$$= (\sin a \ \sin b \ \sin c dadbdc)/U$$

with $U = (1 - \cos^2 a - \cos^2 b - \cos^2 c + 2\cos a \ \cos b \ \cos c)^{1/2}$. The volume of the hatched parallelepiped turns out to be $8r^3 U$.

The average volume of the parallelepiped is therefore (by analogy with equation (2))

$$V = \frac{8 \displaystyle\int_{\pi/3}^{\pi/2} \int_{\pi/3}^{\pi/2} \int_{\pi/3}^{\pi/2} \sin a \ \sin b \ \sin c dadbdc}{\displaystyle\int_{\pi/3}^{\pi/2} \int_{\pi/3}^{\pi/2} \int_{\pi/3}^{\pi/2} \sin a \ \sin b \ \sin c dadbdc/U} \qquad (5)$$

With a simple change of variables ($x = \cos a$, $y = \cos b$, $z = \cos c$) we get for the density d (by analogy with equation (3))

$$d = (4/3)\pi \int_0^{1/2} \int_0^{1/2} \int_0^{1/2} dxdydz/(1 - x^2 - y^2 - z^2 + 2xyz)^{1/2} \qquad (6)$$

With a numerical integration I found $d \sim 0.596$, in excellent agreement with the experimental random loose packing density.

A. GAMBA

1 Gotoh, K., and Finney, J. L., *Nature*, 252, 202 (1974).
2 Santaló, L. A., *Introduction to Integral Geometry* (Hermann, Paris, 1953).

GOTOH AND FINNEY REPLY—We are aware of the numerical closeness of $2/\pi$ and 0.6366, but until now had no good nonnumerological reason for asserting its significance. We are grateful to Gamba for pointing out the possible use of integral geometry, and will follow up the references quoted.

We stress the dangers of using two-dimensional analogues[1], for the geometries of two and three dimensions are essentially different. The two-dimensional Ising problem has been solved, although the three-dimensional one has not[2], and the third dimension changes the nature of percolation problems[3]. The average number of edges per Voronoi polygon can be shown to be exactly six for any two-dimensional array of points[4], a fact which blurs the distinction between a two-dimensional "liquid" and crystal. The corresponding three-dimensional case in unsolved, and a discontinuous transition in the number of faces per polyhedron occurs on melting of a three-dimensional liquid[5]. Thus it is difficult to define states in two dimensions that may be equivalent to random loose or close packings in three dimensions[6].

The simplicity of Gamba's explanation of random loose packing density is attractive, but we think it erroneous. In two dimensions, the addition of a fourth circle introduces excessive symmetry, and implicitly assumes that the covering can be considered equivalent to a covering of touching rhombuses. In a real two-dimensional non-crystalline packing, in contrast to a dislocated solid, triangles and polygons occur. Similarly, in the extension to three dimensions, Gamba implicitly assumes that the ran-dom loose packing can be replaced by a space-filling set of touching parallelepipeds. The parallelepiped is an octahedron with two tetrahedral caps, and immediately gives too many octahedra in comparison with the random packing. Moreover, they are distributed in too orderly a manner. The parallelepiped is bounded by six planar faces, each one being defined by four coplanar spheres. This does not fit with the reality of random packing: the extra freedom given by the third dimension leads to a low occurrence of such special arrangements, and a consequent reduction in the local symmetry within the aggregate.

The assumption of a uniform probability density for the angles a, b and c takes no account of the local geometrical restrictions on space occupation (for example, a peak near the icosahedral angle of 65°?) although as we admitted in our original paper, we were unable to take adequate account of these ourselves. We tried to find an "average" density by the admittedly non-rigorous method of finding the "average" dimensions of an "average" tetrahedron We tried to build in the condition that the tetrahedra, of which we try to consider the average, fill space. Thus an integral number meet at an edge, an integral number meet at a vertex, and each face is shared by two tetrahedra. In addition to these basic geometrical constraints, we also considered quasi-physical constraints, such that each sphere should make six contacts on average, and that there should be at least three contacts in any arbitrary hemisphere. Gamba, while he has taken plausible averages, does not take these or equivalent conditions into account. Moreover, by adding a similar unit to the original in a symmetrical manner to facilitate density measurement, he calculates an average over the unit cell of a primitive crystal lattice. It seems to us that his two-dimensional density is a weighted average over all possible unit cells from the square (density 0.785, $a = 90°$) to the hexagonal (density 0.907, $a = 60°$), whereas the three-dimensional value is an average over all possible primitive unit cells from the simple cubic (density 0.524, $a = b = c = 90°$) to the hexagonal and face centred cubic (density 0.704). We do not think this represents random packing

Matters arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

reviews

COSMOLOGY is a subject with long traditions, and general relativistic cosmology in particular has been developed in detail, both mathematical and physical, in many textbooks. In recent years there has been a distinct resurgence of interest in the subject, partly resulting from the stimulus of impressive observational discoveries (the microwave background, quasars, and so on) and partly from the elegant new mathematical techniques which have been constructed. Not least among these are the theorems of Hawking, Penrose and Geroch, which predict in very general circumstances that spacetime can develop singularities or 'edges'.

The demand for well written books covering cosmology from this new perspective is growing. Ryan and Shepley have made a useful contribution in this latest volume in the Princeton Series in Physics. An earlier volume by Peebles, called *Physical Cosmology*, deals with observational aspects, whereas this book concentrates on the mathematical side. The authors restrict themselves to models of the Universe which are homogeneous in space. These models, being a good approximation to the large scale structure of the real Universe, are simple enough to allow a tractable mathematical description, but rich enough to confront some of the more challenging and bizarre physical problems.

The early part of the book builds up the terminology and formalism of modern tensor analysis, moving straight into the Robertson–Walker isotropic

Heavenly views
P. C. W. Davies

Homogeneous Relativistic Cosmologies. By Michael P. Ryan Jr and Lawrence C. Shepley. Princeton Series in Physics. Pp. xv+320. (Princeton University Press, Princeton, New Jersey, 1975.) $15.00.

models and the big-bang Friedmann solutions. One of the major themes of the book is then taken up with a fairly detailed description of singularities. Much of this discussion is rather sophisticated, and the new student may feel a certain frustration that very recent developments are not explained in greater detail.

Following the singularities, more traditional work is outlined on the subject of Killing vectors and isometry groups, enabling discussion of the full range of homogeneous cosmological models. Well known examples are described in some detail, though the authors have a tendency to concentrate rather too much on the more bizarre aspects. Godel's model, which apparently allows observers to visit their own past, and the mysterious and baffling Taub-NUT and T-NUT-M spaces, each command a whole section. Some further work on singularities in homogeneous models then follows, leading naturally to the thorny subject of quantum cosmology. In Chapter 10 the authors state that "All explicitly known models which can serve as cosmological models are mathematically

singular", and point out that classical physics runs into a barrier here. The hope that quantum theory will open that barrier is long standing, but current results are still very superficial.

Some of these results are dealt with by Ryan and Shepley. They first build up the idea of 'Hamiltonian cosmology' —treating the Universe as a physical entity moving in a highly simplified fashion with a small number of degrees of freedom only. Quantisation of this simple system is then briefly alluded to. An entire chapter is devoted to the simplest of the anisotropic models, the Bianchi types I and IX, and the so-called mixmaster Universe, in which an initially chaotic motion smooths itself out into the more uniform, isotropic form observed in the real Universe today. A final chapter treats some problems in perturbation theory.

As a teaching textbook, this volume will prove useful. It is inclined to read a little breathlessly, and the level of discussion is somewhat variable, but graduate students and researchers will find it valuable for both reference and instruction. An extensive bibliography is provided, together with some exercises for the more ambitious reader. A little homespun philosophy creeps in here and there, to add a needed touch of perspective on this rather esoteric of subjects.

In summary, this book manages to get to grips with very recent results in cosmology at a time when the subject is undergoing rapid development. It is to be recommended to all serious students of modern cosmology. ☐

HIGH energy astrophysics is a rapidly growing field in which there have been many important discoveries, although graduate students or research workers may find it difficult to obtain a general introduction to the subject, with the possible exception of some lecture notes from summer schools. Now, however, several authors, assoc ated with Nasa's Goddard Space Flight Center, have produced a book which may overcome this problem as far as cosmic X and γ-ray astronomy are concerned. The authors are all well known researchers, each writing about his own specialty.

About one half of the book deals with cosmic rays. Experimental techniques, results concerning nuclear and electron components, and propaga-

tion effects in space are carefully reviewed. Not much is said about sources or about acceleration mechanisms.

The other half of the book deals with X-ray and γ-ray astronomy,

---

High Energy Particles and Quanta in Astrophysics. Edited by Frank B. McDonald and Carl E. Fichtel. Pp. xii+476. (MIT Press: Cambridge, Massachusetts and London, 1974.) $18.50; £9.25.

---

with an introductory chapter on radioastronomy. Little that is basically new has happened in X-ray astronomy over the last couple of years and these chapters can therefore be considered as a good reference. On the other hand, however,

γ-ray astronomy has recently led to the discoveries of bursts and of the SAS 2 results. Since the Goddard Center has been heavily involved in these developments, it is a pity that they were not included.

In a book of this kind a certain amount of bias is unavoidable in the choice and presentation of results. Readers curious about the more general aspects of high energy astrophysics will not find here a discussion of radiogalaxies, quasars and so on. Indeed, the authors never intended to provide an introduction to the whole field but only to those aspects indicated by the title. They have, however, certainly produced a useful collection of review articles which, largely, can be read independently.

F. Pacini

Aspects of lipid membranes . . .

Bilayer Lipid Membranes (BLM): Theory and Practice. By H. Ti Tien. Pp. ix + 655. (Marcel Dekker: New York, September 1974.) $39.50.

SINCE its rediscovery in 1962 by Tien and his colleagues, the bilayer lipid membrane (BLM) has been used successfully in the elucidation of previously intangible problems concerning the effects of a number of substances on natural membranes at the molecular level. The value of the isolated BLM as a membrane model lies in its simplicity of composition, structure and in its intrinsic inertness. These properties allow its accurate quantitative description as a system, which is essential for interpretation of the effects of extrinsic substances.

This book is, as the author states "a highly personal account" of research in this field. Its stated objectives are to summarise the current status of the research and to present practical methods for the formation of the BLM.

Within the book the principal successes of the past decade jostle with detailed descriptions of technique; though interesting, it will be perhaps confusing for the beginner, and of doubtful value to the experienced worker. And there are several exceptions notable by their absence: nowhere is there a mention of studies of the model unit conductance channel, possibly the most important recent development in the field, initiated by Haydon and his colleagues in Cambridge in 1970. Likewise, nowhere is there a mention of the use of step functions of current and voltage to distinguish between the effects of unstirred layers, diffusion polarisation and surface properties, studies initiated by Läuger and his colleagues in 1971.

In chapters 8–10, some 200 pages or so are devoted to electronic and photo-electric phenomena. The conditions under which some of the described experiments are carried out and the abbreviations used are not explained explicitly. As these are essential in the interpretation of the results it makes for unnecessarily difficult reading.

The content of chapter 11 ranges from detailed discussions of preparations of membrane forming chemical mixtures to a description of the apparatus for measurement of fluorescence; these are plentiful in detail but lacking in principle. The "simple experiments with BLM" included in the book belie the problems likely to be encountered in practice.

All this is not to say that there is not much useful information in this unique collection of typescript writings—there is, but its value must surely rank as a limited, expensive, and rapidly dating reference book. **Edward Lea**

. . . lipids in cancer cells

Lipids and Tumours. (*Progress in Biochemical Pharmacology*, vol. 10.) Edited by K. K. Carroll. Pp. x + 360. (Karger: Basel, London and New York, 1975.) SFr.148; £26.00; $67.50.

THE current surge of interest in the role of membranes in homeostasis and cancer ensured that a reappraisal of the role of their lipids would follow. In this area, the fluid mosaic model proposed by Singer for the structure of animal cell membranes has gained much favour and has stimulated a number of new ideas. The model considers membranes essentially as solutions of protein in a lipid environment, the fluidity of which determines the ease with which the protein components orientate in response to a number of external stimuli. Accordingly, this review on the subject of lipids and cancer comes at an opportune time and the book will attract readers from a wider spectrum of disciplines in cell biology than would have been the case a few years ago.

The contributors are well known in their fields and they have covered a comprehensive range of subjects including the glycerolipids, fatty acid metabolisms, proteolipids, lipids in cultured cells, fucolipids, control of lipid biosynthesis and the role of dietary fat in cancer. Unfortunately, the newer techniques of spin label and fluorescent probes are presumably too new to have been included.

The message that lipids in cancer cells are different from those in normal cells seems to be clear but the welter of changes described allows no coherent story to be formed. The use of rapidly growing 'laboratory' tumours carries with it many hazards of interpretation and since this material was used in most of the studies described it places severe limitations on conclusions about the relevance of the lipid changes to the tissue's behaviour as a cancer. Are the changes caused by the rapid growth of these cells? Which normal tissue provides the most appropriate control? Does the high proportion of necrotic tissue in some tumours affect the results? Lipidologists seem to have been slow to use the advantages of animal cell culture systems in which well controlled studies can be made with quiescent and growing normal cells, tumour cells, cells in different phases of the growth cycle, virus and chemically transformed cells and cells growing in medium containing delipidised serum with added lipids. In their chapter on lipids in normal and tumour cells in culture Howard and Howard point out the value of culture methods. An example of its application is the finding that the characteristic glycolipid change found in transformed cells in culture—the simplification of the carbohydrate moeity—is also found in rapidly growing normal cells. In the light of this result the degree to which this change is found in the range of Morris hepatomas can be interpreted as a function of their growth rate or, to put it another way, the time the cells spend in the phase of the cell cycle when the carbohydrate chain elongation is maximal—the quiescent or G_1 phase.

There is, however, much material in this book to prime the imagination of those working in the field of lipids and membranes. The format of the book and the layout of the chapter sections is pleasing. The texts read easily and most contributors have managed to avoid peppering them with references. It would have been helpful if the closing date for the literature survey for each chapter had been given and also if a short addendum with 'hot news' had been added to each section as late as possible before publication. The staggering price of this book (£26.00; $67.50) will ensure that it will not find its way into many private libraries. **I. A. Macpherson**

An Egyptian bas relief dating from 2540 BC showing cabinet makers at work (Mastaba of Tiye, Saqqara). The figure at the right is using a bow drill, perhaps the earliest forerunner of modern machine tools. From *Simple Working Models of Historic Machines.* Paper edition. By Aubrey F. Burstall. Pp. 79. (MIT Press: Cambridge, Massachusetts, and London, 1975.) n.p.

The Wild Canids: Their Systematics, Behavioral Ecology and Evolution. Edited by M. W. Fox. Pp. xvi+508. (Van Nostrand Reinhold: New York and London, March 1975.) £10.60.

UNTIL very recently no comprehensive review of the wild members of the dog family had been published since Mivart wrote his *Monograph of the Canidae* in 1890. Now two books on the subject have become available. The first, Lois E. Bueler's *Wild Dogs of the World* (Collins, London, 1974), is an excellent popular book; it is well complemented by the second, a more technical work entitled *The Wild Canids.* This latter volume is based on behavioural studies within a framework of five sections: taxonomy, behaviour, genetics, ecology, and the evolution of behaviour. Much of the work has been published before but this does not detract from the value of the book as a review.

The ethology and ecology of the northern races of the wolf, *Canis lupus*, have been studied in detail over the past decade and are well reviewed again here; and a new approach is used in a chapter on the Eskimo hunter's view of the wolf. There is still, however, a lack of any information on social structures in the Indian and Arabian races of the wolf and, as it is probable that these were the main progenitors of the domestic dog and the dingo, it would be most interesting to learn more about their social organisation (touched on by Lorenz in the foreword). Corbett and Newsome show that the dingo is not highly social and is a solitary hunter; whether this type of behaviour evolved since the dingo became feral in Australia, or whether it was inherent in their ancestors, provides a fascinating enigma to add to Macintosh's chapter on the origin of that animal.

Observations on the behaviour of the coyote, *Canis latrans*, and on some of the less well known canids, for example, the South American foxes and the Indian dhole, *Cuon alpinus*, are disappointingly slight. Lawrence and Bossert produce interesting evidence in support of hybridisation in the North American species of *Canis.* This work exemplifies an interesting aspect of canid behaviour that emerges in several parts of the book. This is the ability of certain species to have a close interaction with man (and with the domestic dog, with which the wolf, coyote, jackal, and dingo will all interbreed). Some species within the genera *Canis*, *Vulpes*, and *Dusicyon* are so flexible in their behaviour and ecological requirements that they can coexist with man and even take advantage of human disturbance to the environment.

The Wild Canids will be of great value to all students of animal behaviour. It has been well edited and the bibliography is comprehensive. As Michael Fox says in his conclusion, one of the aims of the book is to reduce man's alienation from nature. It should help.

Juliet Clutton-Brock

Dogs, frogs and fish

Xenopus: The South African Clawed Frog. By E. M. Deuchar. Pp. x+246. (Wiley-Interscience: London and New York, February 1975.) £10.25.

A GLANCE at the list of references within this volume will indicate to the reader how rapidly *Xenopus* has risen in popularity with research workers in the field of developmental biology.

Xenopus laevis is easy to keep because it is aquatic and thus not averse to life in aquaria, even when it is kept at temperatures much lower than those normally encountered in its African habitat. The male and female can conveniently be induced to mate by the injection of appropriate gonadotrophins which are used for human medication. Dr Deuchar suggests that the sperm may need to swim faster than the sperm of other species because the male and female cloacae are not as close as they are in other anurans during amplexus. But, while collecting freshly laid eggs, I have noticed that the male partner bends his back to bring the cloacae very close when the female is actively laying eggs, but not at other times.

Most research workers concentrate on studies of embryos and tadpoles that need not be as accurately timed as mine, but staging is all important and for this they find, as Dr Deuchar says, that the *Normal Table of* Xenopus laevis *Daudin* is invaluable. Even a group of tadpoles that have been reared together will display differences in their rates of development, though they are smaller than the differences between groups reared at different temperatures or on diverse food regimes. It is thus rather meaningless in research to refer to the ages of tadpoles alone instead of to stages which can be quite precisely used by all investigators.

Dr Deuchar has stressed the relative speed of *Xenopus* development which may be a pleasure to some but a disadvantage to others. The beautiful grace and transparency of the *Xenopus* tadpole is a delight to all.

She has read a great deal (more than 500 references) in order to produce such a comprehensive survey of the taxonomy, anatomy, physiology and development of *Xenopus.* Chapters devoted to the last of these subjects take up half of the book and provide an admirable review of present day research into many aspects of the pre-frog life of *Xenopus l. laevis.*

This book should be made available to all who work in this field. **Louie Hamilton**

The Early Life History of Fish. (The Proceedings of an International Symposium at Dunstaffnage Marine Research Laboratory, Oban, 1973.) Edited by J. H. S. Blaxter. Pp. x+765. (Springer: Berlin and New York, 1974.) DM98; $40.00.

THIS volume contains the collected contributions to a symposium on the early life history of fish held at the Dunstaffnage Marine Research Laboratory at Oban, Scotland, in 1973. Fifty four papers are published in their entirety, with two more in abstract form. The volume (like the symposium) is divided into seven categories (population studies, distribution, feeding and metabolism, physiological ecology, developmental events, behaviour, and taxonomy).

Most of the contributions fall under the heading of population studies, with discussions of egg and larval abundance in relation to fish population dynamics greatly outnumbering the other papers. High mortalities during early life have a potent effect on the recruitment of a year class to a fishery and several contributions are concerned with the causes of this: the interactions of starvation, predation, physical damage, loss to adverse current systems, and imperfections in development, are all discussed. Clearly, the causes are varied and rarely stem from any one factor.

The section on physiological ecology contains several valuable papers on environmental topics. The effects of cadmium on the development and survival of herring eggs, and the effects of thermal shock on larvae entrained in electricity generating station cooling systems, are two papers of particular relevance to fisheries in industrial regions. Another contribution discusses the effects of H_2S on the development and survival of larvae in freshwater fishes.

Under the heading 'Rearing', six papers cover techniques related to aquaculture. Variation in temperature and in photoperiod, hormone injection, selective hybridisation, and genetic manipulation all have an obvious relevance to rearing fish for food and are considered in various contributions.

These wide-ranging topics are typical of the broad spectrum of research into fish eggs and larvae that was presented at the symposium. The editing of this volume (and the organisation of the meeting) provides a lasting testimony to J. H. S. Blaxter's enthusiasm for this specialised field. **Alwyne Wheeler**

obituary

Maurice Freedman, a leading social anthropologist, died on July 14 at the age of 54.

Professor Freedman followed a distinguished career in London by becoming head of the Institute of Social Anthropology at Oxford and a Fellow of All Souls and at the time of his death was Professor of Social Anthropology at Oxford. He had entered the department of anthropology of the London School of Economics in 1946, his first work involving studies of racial and cultural relations in Malaya. Appointed to a lectureship in anthropology at the LSE in 1950, he became reader in anthropology in the University of London in 1957, and was elected to a personal chair of anthropology in 1965—moving in 1968 to an established post in this subject. But his main interests lay in the field of overseas Chinese society. In 1949–50 he spent nearly two years of field research among the Hokkien-speaking Chinese of Singapore, publishing as a result *Chinese Family and Marriage in Singapore* in 1957. For the next 25 years, he was to build on this framework to form a deep understanding of basic Chinese concepts and institutions. He clarified the structure of lineage and kinship in south-eastern Chinese society; the nature of ancestor worship; and the significance of geomancy—the art of relating a site, especially for burial, to the good fortune of men. Professor Freedman was also deeply concerned about the position of Jews in the social life of Britain.

Carl O. Sauer, who was emeritus professor of geography at the University of California at Berkeley, has died at the age of 85.

Sauer was for more than 30 years chairman of the geography department at Berkeley, retiring in 1957 as emeritus professor. He did much to establish Berkeley as a school of "cultural geography". He established the department's doctoral programme, and became a leading and widely published authority on desert studies, tropical areas, the human geography of Indian populations, and agriculture and native crops of the New World. He maintained that all geography is essentially historical. Written documents, archeological evidence, plant data, soil profiles—all provided him with clues for unravelling problems of the human global environment. His many awards included the Victoria Medal from the Royal Geographical Society, which he received recently, the Vega Medal from the Swedish Society for Anthropology and Geography in 1957, and the Charles P. Daly Medal from the American Geographical Society in 1940.

announcements

Awards

J. Bingham has been awarded the **Mullard Award** by the Royal Society for his contribution to agricultural productivity by breeding a series of winter wheat varieties.

The Potato Marketing Board has awarded a **James E. Rennie Award** to **D. N. Crowe** and **J. A. H. Taylor.**

Appointments

F. G. T. Holliday has been appointed a member of the Oil Development Council for Scotland.

The Nature Conservancy Council announce that **F. B. O'Connor** has been appointed deputy director.

International meetings

September 3–5, **Child language,** London (The Information Officer, School of Oriental and African Studies, Senate House, Malet Street, London WC1E 7HO, UK).

Person to Person

Bibliography on reconstruction from projections. Listings needed in computerised topography, radio astronomy map synthesis, multi-dimensional profile inversion, 3D electron microscopy, zeugmatography, inversion of Radon transform, and so on, all problems in reconstructing 2D and 3D images from data obtained by projection or line integration. To be published. (Richard Gordon, Image Processing Unit, National Cancer Institute, NIH 36/4D28, Bethesda, Maryland 20014).

There will be no charge for this service. Send items (not more than 60 words) to Holly Connell at the London office The section will include exchanges of accommodation, personal announcements and scientific queries. We reserve the right to decline material submitted. No commercial transactions.

September 9–10, **Morphology and biology of living and fossil reptiles,** London (The Executive Secretary,

The Linnean Society, Burlington House, Piccadilly, London W1V OLO, UK).

October 1–10, **High energy radiation dosimetry and protection,** Sicily, Italy (Dr A. Rindi, Building 72, Room 122, Lawrence Berkeley Laboratory, University of California, Berkeley, California 94720).

October 6–8, **Fertility and sterility,** Madrid, Spain (Professor E. V. Dominguez, Feneral Pardines 82-c-70 DCHA, Madrid, Spain).

Miscellaneous

Neuberger report. The British Nutrition Foundation has decided to institute an essay competition on 'Nutrition is an emerging subject; discuss in relation to the Neuberger report'. The competition (essay length up to 2,500 words) is open to young scientists and medical students under 25 and prizes of £100, £75 and £50 will be awarded. Entries (before December 31, 1975) to: Mr P. M. Victory, Secretary, British Nutrition Foundation, Alembic House, 93 Albert Embankment, London SE1 7TY, UK.

How companies benefit from the CERN connection

EVERYONE knows that the non-stick saucepan was a technological spin-off from the Apollo space programme, and everyone knows that you have to think quite hard if pressed to name a second product with which the ungrateful world of consumers has been accidentally endowed by high technology. But space exploration is not without its benefits of a sort. The vast technology-based industries that have sprung up to serve space and for that matter, military needs, can be seen as (if nothing else) a means of keeping large numbers of people in employment. Inevitably, however, one asks whether the development, say, of better space propulsion units by industry, when there is only one customer, serves any broader purpose, and almost equally inevitably one answers that it does not. The rapid break-up of many space-and-defence-based industries when the big client loses interest or runs out of money is testimony to the problems of industry capitalising on the push of technical demand when that push is on too narrow a front.

Not every major new project based on science and technology comes from aerospace, however. It is fascinating to ask whether anything rubs off on an industrial company which performs contract work in the construction of nuclear reactors, radiotelescopes, deep-sea drilling equipment or whatever: and a fascinating answer is given in a recent and highly readable report published by CERN (*A Study of Economic Utility resulting from CERN contracts*, H. Schmied, Report no. CERN 75–5). The diligent Dr Schmied conducted 110 interviews with CERN staff and ultimately identified 127 companies throughout Europe where there was a possibility that dealings with CERN had created 'utility' for the company beyond the contract itself. The utility could spring either from increases in added value in subsequent sales of products elsewhere or from cost savings in subsequent operations. Increases in added value might arise from the sales of new products originally developed for CERN, increased sales of existing products owing to the CERN connection, improvement of a product to meet a tough specification and subsequent sales of the improved product, or by other means. Cost savings could arise from the indirect use of CERN expertise in research, development and production, from savings on capital investment when CERN contracts had already partially covered costs and from savings in marketing from the use of CERN as a reference.

Companies were asked to make their estimates (using guidelines provided) of the utility of having worked on contract. Obviously, and Dr Schmied acknowledges as much, there is no foolproof way of identifying utility; some companies find it difficult to accept that anyone beyond their own four walls could possibly have contributed anything of significance, others might think a high value for utility would please CERN and perhaps land more contracts whilst yet others might think a high estimate could cause CERN to adopt a more hawkish attitude in its future letting of contracts. And the measurement of utility is itself bound to be a fairly hit-and-miss affair. Nonetheless there are some very striking conclusions.

If all 127 companies are taken together, their sales to CERN amounted to 394 million Swiss francs (MSF), but the utility generated came to 1,665 MSF: the CERN connection had borne fruit fourfold. There are obvious gradations. Manufacturers of standard electrical equipment such as cables have little to gain from working for CERN. At the other extreme manufacturers of computers and precision engineering reported an average of 17 and 32 respectively for the utility/sales ratio. And companies in the UK, Norway, Sweden and Denmark have done particularly well, undoubtedly because the CERN contract has opened up new geographical market horizons.

This study does not say that the world is economically a better place because of CERN, or that economic activity is created which would not have existed otherwise; it is entirely conceivable that a study of companies unfavoured by such contracts could identify losses to counteract the gains of the favoured companies. What it does say is that individual companies demonstrably profit in many ways from association with large-scale high technology. And this is particularly interesting in CERN's case, because none of the companies seems to have been exclusively dependent on CERN for its turnover, and a very large part of the utility achieved has necessarily to be outside the narrow realms of particle accelerators.

It would be wrong to take these figures as a good measure of the extent of technology transfer possible through major technological enterprises, as some of the utility has been gained by the simple process of stamping "as supplied to CERN" on the glossy brochures. But industrialists could well take note of the financial advantages of working with high technology. And governments involved in big projects should ponder whether the acquisition of large numbers of their own technical staff for specific jobs is the best way to take the broadest possible national advantage of the investment.

Net profits

C. E. Purdom and A. Preston of the Ministry of Agriculture, Fisheries and Food, Fisheries Laboratory, Lowestoft, write about the prospects for fish farming in the UK.

THE annual world production of farmed fish is approximately 4×10^6 tons which represents about 15% of supplies of fish for direct human consumption. In the UK, production at present is about 1,500 tons a year, or less than 0.2% of consumption. Precise statistics are not available, but a considerable proportion, perhaps half, of the production is for conservation or sport purposes.

The fish farming industry in the UK comprises a variety of small, mostly privately owned, farms and a few large companies. About 100 private farms exist, each producing between 5 and 200 tons per year with by far the greater proportion at the low end of the scale; in addition, about 30 farms under the control of Regional Water Authorities produce fish for re-stocking purposes. Small scale fish farming has a history going back about 100 years. It is traditionally associated with the production of trout for sport purposes, although current expansion also includes food production. Involvement by large companies is very recent and is still in an early developmental phase, with production primarily for food supplies. Output is still low and geared to the supply of luxury food in the form of trout and salmon, with research emphasis on the latter. So far there is little input into the mass retail industry and marketing methods remain traditional.

Apart from a very minor effort with cyprinid fish for re-stocking, fish farming in the UK is at present restricted to salmonids. The culture in fresh water of native brown trout (*Salmo trutta*) and North American rainbow trout (*S. gairdnerii*) is the dominant element, with sea-water culture of salmon (*S. salar*) restricted to large companies with production levels of only a few hundred tons per year at present.

Marine fish farming research in the UK was initiated by the Ministry of Agriculture, Fisheries and Food (MAFF) about 15 years ago but its origins go back much further than this and probably to the turn of the century when hatcheries were established for plaice (*Pleuronectes platessa*) and cod (*Gadus morhua*) to produce fry for liberation into the sea for conservation purposes. This ineffective measure was discontinued by about 1920, but the concept of farming marine fish seems to have grown out of the experience gained in the production and hatching of eggs of the plaice. Thus initial research was hatchery orientated and directed towards plaice farming. Hatchery techniques were successfully developed and large scale production of juvenile plaice became feasible by 1966. At this time the White Fish Authority (WFA) entered the field to develop the rearing techniques towards commercially viable levels and, especially, to study the growing-on phase from juvenile stages to marketable size. It was in this area that economic problems with plaice became apparent; their food bill exceeded the first-sale value. Attention was therefore switched to sole (*Solea solea*) and turbot (*Scophthalmus maximus*) for which better economic returns might arise. Sole has proved more intractable than plaice during on-growing but turbot has been shown to be very amenable during this part of its life cycle. A basic requirement in intensive fish farming is that food is taken rapidly and not wasted or allowed to decompose and pollute the environment. Turbot fulfil this requirement but sole, with present rearing techniques, do not, being slow, cautious feeders. Progress in turbot farming has been restricted, however, by serious difficulties encountered in the production of juvenile fish and present research on farming techniques depends, in part, on the collection of juveniles from wild stocks. For conservation reasons this sets a restrictive limit on possible total commercial production for this species of about 100 tonnes a year. The earliest attempt to rear turbot was made by Anthony in 1910 but the first hatchery reared juveniles were not produced until 1972 and then only in very small numbers. Improvements have been made in succeeding years, during which the development of turbot hatchery techniques has had considerable priority in government laboratories, but the methods still fall short of the level of achievement necessary for commercial exploitation, although one major food company is exploring the hatchery production of turbot with the assistance of MAFF.

Fish farming in the UK has grown slowly in the freshwater and marine salmonid field under commercial patronage, although some acceleration has occurred over the past 2 or 3 years; on the other hand, government research, largely under the auspices of MAFF, but with the later involvement of the WFA and the Natural Environmental Research Council (NERC), has been preoccupied with the development of methods for rearing marine flatfish. So far no major research work on salmonid farming has been undertaken by government agencies, and commercial interest in marine flatfish has been limited, largely to a joint project between the WFA and one major food company. This dichotomy is in marked contrast to the situation in other parts of the world, such as North America, Japan and Norway, where government and private concerns are mutually and extensively involved in a wide variety of fish farming projects.

With little prospect of increasing the direct yield from the sea of species of prime fish, and many indications that the reverse might occur, it has become necessary to examine the potential for an expansion in fish farming in the UK. In this context a review was commissioned with the object of drawing up a MAFF programme of research and development into marine and freshwater fish cultivation and assessing the facilities required to carry it out. This review, which took into account the existing scope of fish farming activities, formed the view that a viable industry needed to be broadly based and to cater for both the small farmer and major commercial interests. Some legislative adjustments may be necessary in this context but the primary objective should be to provide, through a well conceived research and development programme, a sound scientific basis for the expansion of fish farming into a broadly based national industry.

The question of which species of fish to cultivate is crucial to the development of a research and development programme of relevance to an expanding industry. Among the salmonids, rainbow trout and Atlantic salmon are obvious choices in view of their present commercial status; brown trout and sea trout may also be of value within the context of marine culture of salmonids. Among the marine flatfish, turbot alone seems to have potential at this time, although sole would have definite economic advantages if the feeding problems experienced in the growing-on phase could be solved. Other freshwater and marine species do not warrant attention at present but should be subject to periodic review in terms of their potential for cultivation

The research and development needs differ between species. The principal subjects areas for investigation are hatchery studies, nutritional requirements, water management studies, facility development, genetic manipulation and disease control. Of these, hatchery techniques, nutrition and disease control are well established for salmonids after more than a century of development. There is still room for much improvement, particularly at the nutritional level, and disease control and treatment require continuous study. The major constraint to a large scale expansion in trout farming in fresh water, however, lies in the nature of the water requirements. Rainbow

trout farms use about 30,000 gallons of high quality fresh water for each pound of fish produced and the availability of sites for expansion is very limited. Two methods for overcoming this constraint are the use of recycling systems and the culture of trout in sea water. The former can be regarded as a technological development based on present practices, whereas sea-water culture is a more radical change with many facets requiring investigation. Although no major research work on salmonid farming has been undertaken by MAFF or the Department of Agriculture and Fisheries for Scotland some facilities are available and plans for additional facilities are in hand: in these, special attention will be directed towards nutritional studies, cage systems in the sea, recirculation systems for fresh and salt water, and genetic studies aimed at producing improved strains. Disease research and monitoring is already covered both in England and Wales and in Scotland.

Flatfish farming research has not yet established a sufficiently reliable technology for full commercial development. The first priority for further work lies with turbot and especially with the need to overcome the problems of hatchery production of juveniles.

One major area of work of fundamental importance to any form of fish farming is the development of a genetic approach to produce improved strains, to avoid inbreeding depression and to conserve genetic uniformity and hence performance in domesticated lines of fish. A further useful field with genetic implications is the development of all-year-round spawning stocks and the control of sex itself. Genetic manipulation at the hatchery level is at present studied within the MAFF programme, but no facilities exist for extending this to the growing-on phase or for holding stocks of domesticated fish. For marine flatfish, the creation of domesticated lines has not yet begun. Similarly, Atlantic salmon stocks are basically of wild origin but rainbow trout exist in a wide variety of selected lines, particularly in North America. Although a proper evaluation of their merits, and the possibility of heterosis in F1 hybrids, seems not to have been attempted, this is an area of study which could have an immediate beneficial effect on farming practices in the UK.

In conclusion, there is an established and expanding industry for salmonid farming, principally in fresh water, and a growing interest on the part of large companies in marine flatfish culture. In view of the likely diminution of supplies of prime quality fish like sole and turbot from the sea it is desirable to encourage the continued expansion and development of this area of food production, on a broad basis and at all levels of commercial involvement, though this should not be construed as implying any substantial contribution to offset a short-fall in basic supplies. To this end the programmes of research and development in the fields of hatchery production, environmental control, nutritional innovation, genetic manipulation and disease identification and control within the species at present exploited or showing potential for exploitation require careful integration. The list of species at present includes rainbow trout, salmon and turbot with secondary consideration for brown trout, sea trout and sole. □

Funk therapy

THOMAS H. JUKES

The term "vitamin(e)" was coined by Casimir Funk in 1912. He was good at promoting its use, but he could never have foreseen the mind-expanding effect of this new word in the 1970s. Vitamins are coenzymes and other metabolic catalysts whose pathways of biochemical synthesis have been lost as a result of mutations during the evolution of animals Identification and synthesis of vitamins led to spectacular successes in preventive medicine; these became well known, and, as one result, popping vitamin pills is part of the American way of life, just like colour television in the family room. The idea is not so much that diets are deficient, but why not take vitamins "just to be safe"? Indeed, except for a half-hearted attempt some years ago by the US Food and Drug Administration (FDA) to throw cold water on it, the habit had few opponents and it was certainly better than smoking cigarettes.

There is, however, a basic pharmacological delusion of the layman that if a small dose of a medicine is good, a large dose must be even better, especially if it is not poisonous Many physicians have treated patients whose symptoms exceeded in severity their physical diagnosis, by prescribing "a good rest with lots of vitamins". This procedure is known as "placebo therapy"; the administration of a harmless nostrum for soothing the nerves of the apprehensive, and for convincing those who are open to suggestion that they are receiving "medical treatment". Vitamins can be sold without prescription, and the medical profession, by fostering the use of vitamin pills, made an opening for nonphysicians to practice medicine without a licence. The "health-food" industry responded, and its sales outlets stock pills containing vitamins and alleged vitamins. If health food is so "nutritious", why does it need supplementation with large doses of vitamins and minerals? The answer given in the health food literature is that such dosage will produce super-health, an effect not measurable in human beings or laboratory animals.

Vitamins go through periods of fashion. Thiamine was in the spotlight at one time and, more recently, ascorbic acid became the darling of the headlines. Vitamin B_{12} is popular, probably because it is often injected and is red. Vitamin B_6 is all the rage now, and vitamin E is a hardy perennial because it was lucky enough to be discovered by the fact that its deficiency causes infertility in rats. The same is true of vitamin A, of course, but E has ever since worn the halo of Aphrodite, and has collected many unearned credits.

"Megavitamin therapy" has its devotees, and publicity is currently given to "orthomolecular psychiatry", defined as the "achievement and preservation of good mental health by the provision of the optimum molecular environment for the mind, especially the optimum concentrations of substances normally present in the human body, such as the vitamins". Whether or not this actually works we shall probably never know, because the author (Linus Pauling) also says "the principles of medical ethics prevent orthomolecular psychiatrists from withholding from half of their patients a treatment that they consider to be valuable. Controlled tests can be carried out only by skeptics".

Efforts of the FDA to regulate megavitamin promotion, however, were set back by a court decision and by the passage last year of a bill in the US Senate that specifically prevents the FDA from classifying high-potency vitamin preparations as drugs.

international news

CAB move with the times

from a correspondent

THE Review Conference of the Commonwealth Agricultural Bureaux, which has just ended in London, could be a landmark in the history of the organisation. The CAB was set up in 1929 to provide an administrative centre for the group of bureaux, each of which acted as a clearing house for information in a different branch of agricultural research. Since then the group has expanded, and it now comprises nine bureaux, which function as originally intended, and four institutes, which have somewhat different functions. Although only an 'organisation', in the loosest sense, the bureaux have maintained, and justified, their reputation for providing the world's best and most comprehensive sources of information in the fields they cover. Nonetheless, and perhaps because of their very success, the bureaux have in recent years appeared to be somewhat conservative, even at times complacent, as regards their own functions and performance.

The CAB has three rather distinctive functions:
● A global documentation service covering virtually the whole field of agricultural and allied research in a series of abstracting journals.
● A taxonomic and identification service, provided by the three institutes dealing respectively with entomology, mycology and helminthology.
● An operational service provided by the Commonwealth Institute for Biological Control.

From these springs a fourth function, the operation of a 'mutual assistance' agency that provides Commonwealth countries with very much more in the way of information and services than they could obtain for themselves at anything like the same cost and effort.

The annual budget of the CAB totals slightly more than £3 million, of which about half comes from the subscriptions of member countries, and another £1·5 million from the sale of bureaux publications. Only about 30% of the output goes to Commonwealth countries, and because these can buy their information at a reduced rate, no less than 85% of the income from these services comes from outside the Commonwealth. The major 'foreign' clients are the United States, Japan, and one or two European countries such as the Netherlands and Germany. The question of the cost-effectiveness

of the bureaux operations was a principal subject of discussion.

Taking first the documentation services, it was felt that these could and should be more self-supporting than at present, particularly in view of the increasing cost of production and materials. So the CAB has been taking a hard look at some other internationally used abstracting services, such as International Retrievals (IRS), who are believed to make a profit, and INSPEC, which claims to break even, more or less. One result was a resolution that the bureaux should "seek to associate themselves with non-Commonwealth partners, national and international, as consortia". This is already done with Food Science and Technology Abstracts, providing an international food industry information service in consortium with the German company IDW.

One obvious development ought to be collaboration with the AGRIS system now being sponsored by the FAO from Rome. The CAB sees itself as complementary to, certainly not competing with, AGRIS, but the strong anti-national prejudice that at present surrounds all UN-oriented operations would probably make close collaboration impossible at present.

On the technical side, the CAB intends to make much more use of modern computerised production methods, including increased use of machine-readable material, which the bureaux have been noticeably slow to adopt.

The situation as regards the work of the three institutes is very different from that of the bureaux, Their services have always been given free, only the Commonwealth Mycological Institute having a small income from the sale of cultures of fungi. A small step is now being taken, whereby a charge of £10 an item will be levied for all identifications done for non-contributing governments or com-

mercial clients The case of the Commonwealth Institute for Biological Control (CIBC) is different again. A suggestion that its headquarters might be moved from Trinidad back to the UK was resisted by the representatives of the less developed Commonwealth countries. But there was general agreement that the institute should in future concentrate on fewer, bigger projects rather than providing a 'fire service' to deal *ad hoc* with any problem that might arise within its terms of reference.

In line with efforts to streamline the services of the CAB, the CIBC's outstations will also be reduced to four in number, strategically situated in accordance with a new, more closely regional policy. They will be sited in Trinidad, in Delemont, Switzerland (for forest pests mainly in North America) in Kumasi, Ghana and in Bangalore. Smaller outstations will be run down and, in future, work not done at the four main centres will be on an *ad hoc* project basis.

Finally, there are to be changes and expansion in the central management of the CAB. The present small secretariat, with only four senior officers, will be reinforced by the appointment of a marketing manager (although in deference to the inhibitions of some of the older bureaux staff, his official brief will be "circulation and services") two editorial managers and a scientific coordinator. More problematic will be the question of regrading and even redundancy in certain staff categories. This may well have to wait until some of the more conservative among the present Directors of Bureaux have retired. The fact is that these have hitherto traditionally been senior scientists with great experience in the discipline for which their bureaux are responsible. But under modern conditions, what is probably needed is a group of highly expert information scientists, ready to take advantage of every new aid to quicker, more efficient production of the Abstracts, more prepared to enter into agreements with other organisations and perhaps less inclined to feel that if the CAB doesn't do it, it isn't worth doing. Many of the changes that must come will have to be made anyway, and in most instances the sooner the bureaux can meet changing circumstances half way. the better for everyone. ☐

Dr Gerald Stanhill has recently come to the conclusion that his Biblical and post-Biblical ancestors showed remarkable powers of scientific observation and analysis. Dr Stanhill, who heads the Division of Agricultural Meteorology in Israel's Agricultural Research Organisation, points out that the traditional Jewish prayers for rain, codified almost two thousand years ago, are most frequent and most intensive at precisely those times of year when additional moisture will do most to raise wheat yields in the Holy Land.

Scientific studies carried out over the past 20 years indicate that above average rainfall in the early winter immediately after sowing increases yields, as does bountiful precipitation after the wheat has flowered. In contrast, rainfall at the beginning of the season (before sowing has taken place) and in midwinter (between tillering and booting) depresses yields. And, indeed, prayers for rain become most frequent and high pitched just after sowing (which took place in Biblical times, and takes place now, in November). If rain does not fall in spite of the prayers, a series of fasts is prescribed: at first only for the sages, then for the entire public from dawn to dusk and finally, if the dry spell continues, 24 hour fasts are to take place twice each week.

Both religious practices and archaeological digs indicate that Jewish farmers of the Biblical period were growing wheat primarily in the southern part of the country (where rainfall is both scarce and uncertain) or in the hilly regions (where the soil is thin and does not absorb a great deal of moisture at one time). Today's most prosperous agricultural areas, where rain can be counted upon, were not cultivated for the most part by the Israelites. Interior lowlands, like the Huleh and Jezre'el Valleys, were soggy swamps, and remained so until they were drained a few decades ago.

● While the draining of the swamps increased the supply of fertile farmland and contributed to the elimination of malaria, it has not always proved an unmixed blessing. As a result of the elimination of the Huleh Swamp, for example, the Sea of Galilee is facing a pollution threat.

The peat of the former swampland is heavily impregnated with nitrogen, and when water flows through the Huleh and into the Sea of Galilee, some 15 km to the south, it carries with it large quantities of nitrogen. This influx, many scientists believe, increases the growth of aquatic vegetation in the water, thus contributing to the pollution of Israel's central fresh water reservoir.

A number of researchers have suggested that the problem be solved by planting crops in the Huleh Valley which would consume the excess nitrogen. Dr Avraham Hartzook of the Agricultural Research Organisation, for example, has in mind a plant known as Kenaf (*Habiscus cannabinnus*), which would not only deal with the nitrogen question, but might also reduce the country's dependence

Letter from Israel

from Nechemia Meyers

on increasingly expensive and scarce wood pulp for the production of paper.

Some time ago Hartzook helped to introduce Kenaf to Tazania, where he spent two years as an Israeli agricultural expert. Now a successful cash crop in that country, its fibres primarily serve as a substitute for jute, but they have also been used, albeit on a small scale, as a substitute for wood pulp by the paper industry. Dr Hartzook sees a considerable potential for Kenaf in Israel, which has little wood of its own and might therefore be ready to exploit the plant earlier than other, more richly endowed countries.

● Pollution problems in the Gulf of Eilat are, if anything, more serious than those in the Sea of Galilee according to Professor Ralph Mitchell, now on a working visit to the Weizmann Institute from Harvard University.

Mitchell, who has done extensive studies of the Gulf under the sponsorship of the United States Office of Naval Research, says that if pollution, particularly oil seepage, continues unchecked, the beautiful coral reefs of the area will be eaten away in 25 years.

Mitchell has also done studies on how oil affects the biological behaviour of inter-tidal snails. Some stop bunching together (to keep from being washed away), and others simply stop eating.

Oil likewise affects the ability of bacteria to detect their food, thus interfering with their vital role as marine self-purifying agents. Following the discovery that motile marine bacteria are chemotactic to many of their food sources, Mitchell demonstrated that sub-lethal concentrations of oil inhibit this chemotactic process so that the rate of substrate decay is retarded.

Mitchell is concerned not only by oil seepage, but also by the possibility of a major oil spill from one of the big tankers that wend their way to Eilat.

● Israel's mathematics teachers have established their own emergency group to fight a Ministry of Education ruling that mathematics will no longer be a compulsory matriculation subject for secondary school students.

Cutting the teaching of mathematics, they argue with great vehemence, would undermine secondary schools and hamstring universities, forcing the latter to disregard matriculation certificates and devise a battery of entrance examinations. Even worse, according to the teachers, the Army would find itself short of men with the kind of mathematical background required to handle increasingly sophisticated modern weapons.

The controversy can only be understood against the background of Israel's educational system, which differs considerably, for example, from that in the UK. Students are not given an 11-plus examination, and when they finish elementary school, a great majority continue on to a secondary modern school.

The last two years of secondary school do bring a measure of specialisation similar to that at A-level in Britain. But, even so, students concentrating on mathematics and science have thus far had to pass courses in history and literature, while those interested in the humanities have had to prove their abilities in science and mathematics in order to obtain a matriculation certificate.

Though there had long been complaints about the burden these requirements imposed on students, demands for a change only came to a head several years ago when the Education Ministry revealed that 40% of the humanities students were failing matriculation mathematics.

As an interim measure, the examination was made easier, thus allowing a much larger percentage of examinees to slip under the wire, but this only disguised the problem without solving it. So the ministry decided on more drastic action: students in the last two years of secondary school, it announced, could choose to study maths at various levels (the higher the level, the more points towards a matriculation certificate), or not study maths at all.

Wheatstone's wheezes on show

by John Hall

IT comes hard to be told that Sir Charles Wheatstone actually didn't invent the bridge of the same name, but such was the range of that scientist's inventiveness and imagination that one feels he must, on balance, be forgiven what amounts to a fairly minor omission. Bridges apart, he made fundamental contributions to the study of electrical measurement in the 1830s and 1840s, and in the process he happened across principles of transmitting electrical impulses which formed the basis of modern telecommunications systems. As if that were not enough, he spent his twenties experimenting with musical instruments, and managed as the *pièce de resistance* of this period an invention which was to become the fisherman's friend. Letters patent granted by George IV in 1829 described his creation as "a certain improvement or improvements in the construction of wind instruments"; it was the concertina, successor to earlier brainchildren like the 32-key Wheatstone symphonium (pocket-sized and powered by breath). and precursor of mighty wheezers like the 81-key Wheatstone duet, with the range of a piano. The inventor's nail fiddle, a poor ·relative of the African thumb piano, made of nails to be scraped with a violin bow, was less of a raging success.

But Wheatstone of Wheatstone's Music Shop, Islington. clearly had a novel turn of mind, as the scientific community discovered when he was appointed Professor of Physics at King's College, London. His interest in the transmission of sound vibrations led him to experiment with the transmission of electrical impulses, and to measure their speeds along wires. His success in sending information by this means led to the needle telegraph on which the developing railway system came to depend for its signalling, the ABC telegraph, an automatic Morse transmitter, a punched-tape Morse transmitter and Wheatstone's printing telegraph, which in operation was akin to a Telex printer. For the record, Wheatstone's contribution to the measurement of voltage, current and resistance was that he produced an accurate calibrated variable resistance to replace the unreliable galvanometric instruments available at the time. Later prophets will also be sad to learn that the linear motor was invented by Wheatstone in 1842: given a larger current, it might have proved his brightest wheeze.
He was also responsible for the introduction of the Royal Institution's practice of locking lecturers in a room immediately before they are due to lecture; apparently, on one occasion when he was about to give a public discourse, Wheatstone's nerve went at the last minute, and he disappeared from the scene, leaving Faraday to *ad lib* the evening away.

Wheatstone is one of two eminent Victorian members of King's College to be honoured by an exhibition there this summer. The other is Sir Charles Lyell, an equally prominent and worthy man in his field of geology, but affording rather less tangible tokens of his life's work than does Wheatstone. Lyell established the main principles of geology, and amazed the learned of his day by showing that the Earth was about 4,000 million years old when you would have sworn it wasn't half that age. This scale managed to accommodate the Darwinian theory of evolution, and also gave cosmological theories a realistic time perspective, but doesn't sit conveniently in an ex-hibition display cabinet. By way of compensation there are some nice photographs of the Lyell family seat, a moderately accomplished watercolour by the man himself, and a body of evidence which testifies to the meticulous nature which the documentation of his theories must have demanded. Even as a child he collected shells and bones for his private museum, and when he wrote home to Papa it was in Latin. But he was not such a scholar that he closed his eyes to the exigencies of the world outside his books: after a page and a half of Latin, written from Midhurst Grammar School in 1814, he blurts out in the mother tongue: "If I write any more in Latin I shall miss the post."

The exhibition, at King's College, Strand, London, continues until September 10.

The picture shows the shining lights of Victorian science (left to right): Michael Faraday, Professor T. H. Huxley, Sir Charles Wheatstone, Sir David Brewster and Professor John Tyndall. □

THE British government is to draw up codes of practice for some experiments involving the genetic manipulation of microorganisms which could pose a potential hazard to workers and the general public. Mr Fred Mulley, Secretary of State for Education and Science, in answer to a parliamentary question, announced the setting up of a working party, which would

● draft a central code of practice and make recommendations for the establishment of a central advisory service for laboratories using the techniques available for such genetic manipulation, and for the provision of necessary training facilities

● consider the practical aspects of applying in appropriate cases the controls advocated by the Working Party on the Laboratory Use of Dangerous Pathogens, chaired by Lord Godber, which reported earlier this year.

Mr Mulley also asked the Research Councils and others concerned not to proceed with work already identified as involving a potentially serious hazard, pending advice from the working party.

The question of potential hazards inherent in the new techniques which allow DNA of different bacteria and viruses to be linked together and introduced into other bacteria was con-

Government codes for gene manipulation

by Eleanor Lawrence

sidered by the Working Party on the Experimental Manipulation of the Genetic Composition of Microorganisms, set up by the Advisory Board for the Research Councils and chaired by Lord Ashby. This committee, which reported in January of this year, came to the conclusion that such experiments should be permitted but only with certain safeguards.

These conditions include the use of experimental microorganisms which have been rendered relatively innocuous by specific mutations, and that certain types of experiment should be carried out under conditions of the strictest bacteriological security, in laboratories where the risk of escape to the outside or contamination of workers is minimised.

The definitive code of practice approved by the government, which the new working party should provide, will be welcome since it should end a period of delay and uncertainty which started a year ago with a call for a moratorium on a range of experiments by a committee of the National Academy of Sciences in the United States. At the same time the working party will be concerned with the practical aspects of implementing the findings of the Godber Committee which considered the use of proven pathogenic bacteria and viruses in laboratories throughout the UK. This committee drew up a list of organisms which could only be worked within conditions of strict security, which in the UK would confine such work to the few existing laboratories with suitable facilities. □

Shutting the GATE

by John Gribbin

THE World Meteorological Organisation (WMO) has been stirred into issuing a formal denial that the GARP Atlantic Tropical Experiment (GATE), conducted last year by ten nations and probably the largest and most complex international scientific experiment ever undertaken, was an experiment in hurricane control which adversely affected weather conditions in some countries.

The need for this denial stems, according to the WMO, from a statement made by "a professor of the

University of Mexico", and the WMO says that "it would indeed be regrettable if such unjustified statements were to detract from the acknowledged success of this international scientific research venture". Since the purpose of GATE was to monitor natural changes in the atmosphere and oceans, including large scale tropical disturbances, it would have been rather stupid of the investigators to attempt to alter the natural state of affairs, and most meteorologists are well aware of the need to understand natural changes in atmospheric processes before trying to induce changes by artificial means.

Perhaps the professor was confused by the inclusion of the word "experiment" in GATE's name which, al-

though in the acronymic tradition of the WMO, is perhaps a slightly misleading title for an entirely observational project. But since Mexico was one of the participating countries, it should not have been too difficult for the critic to check his facts before issuing a public statement. The lesson to be drawn, perhaps, is that research into weather and climate is such a sensitive area that bodies such as the WMO should expect to be subject to the same intensive scrutiny as agencies responsible for nuclear research, or laboratories involved in genetic engineering.

In that case, perhaps GARP Atlantic Tropical Study might have been a happier choice of name. □

correspondence

PAC report: a failure of communication

THE Indian Public Accounts Committee report "Foreign Participation or Collaboration in Research Projects in India" (discussed in a leading article on July 31) was critical of the Bombay Natural History Society, as well of the Research Unit for Genetic Control of Mosquitoes. In this letter, Dr A. N. D. Nanavati, Secretary of the Bombay Natural History Society, considers some implications of the report.

THE Public Accounts Committee (PAC) has expressed grave doubts about a number of research programmes carried out with foreign collaboration in India. Much of their alarm stems from the fact that the knowledge obtained from such researches can have applications in chemical and biological warfare (CBW) and that the administrators examined by them did not seem to be fully aware of the fact. Based on this finding the committee has formed an opinion implied, though not explicitly stated, that those concerned in these

projects were dupes, sometimes maybe even willing tools (in view of the relatively high salaries they received) in the hands of foreign organisations who wished to use India as an experimental arena for such studies.

I do not propose to go into the details or to try to refute the numerous misunderstandings and errors in the evidence on which these opinions were based. The facts of which I have personal knowledge, namely those connected with the Bombay Natural History Society (BNHS)—Migratory

Animal Pathological Survey (MAPS) Bird Migration Study, have already been stated in your columns (November 29 1974) and, I believe, adequately answer every criticism voiced against the study originally by Dr Jayaraman, and later endorsed by the committee.

I need not repeat these arguments here except to point out that Dr Salim Ali's *cri de coeur* to Dr T. Ramachandra Rao, then the Director of the Virus Research Centre (VRC), Poona, requesting assistance for the studies on ectoparasites and blood smears of ringed birds has been completely misinterpreted At the outset of the programme between the WHO and the BNHS, studies on this aspect were made by the VRC, Poona, and details of their findings were published from year to year in the Annual Reports of the VRC. When the WHO withdrew from the study, the VRC also withdrew, as it had no staff to spare for this work. Apart from occasional seasonal trips by the Institute of Natural Foci of Infectious Disease (NFID), Omsk for collection of such material (reports published in Russian), no other organisation came forward and this material remained unstudied until the MAPS organisation came on the scene. After the first year, they also requested that no more blood smears be sent as they were not in a position to study them. It was this lack of interest, and not any secret removal of data, which occasioned Dr Salim Ali's appeal to Dr Rao (who also found himself unable to help). These "orphan" blood smears are still with the society, awaiting a godfather to take an interest in them. There are several other misconceptions in the report, for example, the importance attached to Dr Theiler's suggested hypothesis on Yellow Fever epidemiology. This remains no more than a hypothesis, because it fails to explain all the observed phenomena. But these misconceptions are not of primary importance. What is important is that the PAC did not examine any scientist directly working on the projects, except Dr T. Ramachandra Rao, the officer on special duty, whose position was rather peculiar and is further discussed later. Had they examined the scientists, rather than the administrators and administrative scientists, who were only nominally concerned with the actual work on the projects, they might have revealed a completely different picture. In the case of the BNHS study, an examination of the facts will readily show that every working scientist was aware of the possible implications and repercussions, that the programme of work was formulated by the Indian Chief Investigator, and that adequate safeguards against secrecy were in force.

This brings us to the question of how far the administrator should be aware of the different facets and possibilities of any research study he is required to sanction. He must obviously rely on the opinions of his experts. Is it then incumbent on the experts concerned to appraise the administrator of all the various possibilities inherent in a proposed research study, and is such a procedure really necessary or relevant or even possible? When a project is being prepared with a particular object in mind, it is necessary to establish how far that the object will be met by the study. The expert has to advise on (a) the importance of the problem (so that it may be judged in proper perspective in the national contest), (b) the type of information which needs to be obtained to solve the problem and (c) the extent to which the proposed study can be expected to yield the required information. This is all the administrator needs to know to enable him to assess the project correctly and to judge its requirement in men and materials and its anticipated benefits relative to the many other demands which may be made on his resources. Anything else is irrelevant. Considerations like possible misuse of the knowledge gained, the safeguards necessary, and so on, must be the responsibility of the experts on the job. For example, a few years ago a study was made on the spread of cholera from village to village in West Bengal and the mechanisms by which the village wells got contaminated Every student of medicine and microbiology knows that the understanding of such process can be used either for countering the spread of cholera or for its enhancement, that is for biological warfare using cholera germs. Yet, had the administrators concerned been questioned about that project they would not have shown any greater awareness of such dangers than in the present case.

The committee's conclusions lose much of their significance because they were not, in fact, based on the evidence necessary for a correct appreciation, the evidence of the scientists concerned on the job. The only working scientist examined was Dr T. Ramachandra Rao, who made it clear that knowledge is neutral and the only safeguard against misuse of knowledge is its free publication.

The committee's criticisms and apprehensions about the detailed programme and sequence of studies made by the Research Unit for Genetic Control of Mosquitoes may or may not be correct. It is impossible to say without questioning the scientists concerned, which has not been done. Dr Rao could not say much about the formulation of the programme because he came on the scene after this work had been done. (It may be noted in pass-

ing that the remarks on the financial benefits supposed to have accrued to Dr Rao by joining the scheme are contradicted by the Indian Council of Medical Research (ICMR) letter, laying down the terms of Dr Rao's appointment.)

In spite of such errors and misconceptions, we must take due note of the fact that an independent body of men, representing all shades of opinion, has enquired into these projects and has found reasons for apprehension. Although some of these apprehensions may be exaggerated or based on incorrect evidence, there are others, not so prominently emphasised by the committee, which call for attention.

If we accept the proposition that the details of work, the implications of the study, and the safeguards against possible dangers are the responsibility of the expert concerned, it is also incumbent on the authorities to appoint proper and competent experts. Was this done? The committee has rightly pointed out that neither of the two individuals who occupied the office of the Director General of the ICMR (Indian counterpart of the Project Director) was qualified to judge the intricacies of entomological research. This was a serious lapse and though it was soon remedied, by the appointment of an eminent entomologist, Dr T. R. Rao, as an officer on special duty, such an appointment should have been made before any programmes were decided on. This delay may, as the Press Trust of India correspondent claimed, have involved us in programmes of dubious value. Whether this was or was not the case could not be ascertained from the evidence available. But that such a possibility existed is indicative of our failure to maintain adequate vigilance; this is the real danger which needs to be highlighted.

Unfortunately, the defect is a part of a larger malaise, and calls for examination of the defects in our methods of recruitment and appointment which leave a substantial proportion of our most brilliant men and women unemployed, so that they must seek opportunities for work in other countries. And what of our habit of vesting all authority in a top official irrespective of qualifications? But consideration of these points would not be strictly relevant to the issues raised in this report, however important they may be in creating such potentially dangerous situations

It is unfortunate that although the committee has made sincere efforts to examine the issues involved, its conclusions are invalid because of a lack of appreciation of the distinction between the role of the administrator and that of the scientist in research projects.   □

news and views

Hoyle on troubled waters

from John Faulkner

SIR Fred Hoyle (Cockley Moor, Cal-tech, Cornell . . .), the angry young man of British astronomy, turned a surprising 60 recently, and some seventy-five astronomers and astrophysicists met to celebrate the event on July 15–17 at a conference in his honour, "The Frontiers of Astronomy in 1975".

Isola San Giorgio, Venice was the apparently curious but in fact inspired choice of site for a meeting in which past achievements and the at times pessimistic future were surveyed. An attempt to ensure coverage of most areas in which Hoyle had contributed significantly meant that an unusually wide variety of topics were discussed.

In the popular mind, Hoyle is mainly known for his part in cosmological and other arguments. To the professional astrophysicist, however, his most important and enduring achievement must surely be his seminal contributions, going back three decades, to the theory of nucleosynthesis—the production of the elements—in both stellar and cosmological environments. It is worth stressing this point because Hoyle's ideas and their consequences have become such an accepted part of the "obvious" background for present studies that his role has to some extent suffered that curious extinction and obscuration which occurs when "everybody knows that". I have found that not a few professional astronomers are unaware of the 1946 (yes!) paper on the equilibrium process in supernovae and the abundances of the iron peak nuclei. Perhaps they can be forgiven—even Margaret Burbidge (University of California, San Diego) confessed that its importance only hit her six years later. Again, in the early fifties, Hoyle pondered the difficulty of producing the observed abundances of carbon and oxygen in reasonable stellar environments and was led, following Salpeter's identification of the normally unstable ^{8}Be nucleus as an intermediary, to propose the existence of a hitherto unsuspected energy level and its properties in the ^{12}C nucleus. Brilliantly confirmed by Whaling in Caltech's Kellogg Laboratory (despite the earlier scepticism of

his colleagues), this prediction had two important consequences: astronomy had been shown (again) to be a laboratory at large which could lead and stimulate, rather than merely follow, terrestrial physics; and it convinced Fowler (Caltech) to become a nuclear astrophysicist and ultimately led to the massive 1957 work of B^{2}FH. Some young astrophysicists are unaware of the way in which their subject changed from an arid preserve of applied mathematicians into a dynamic part of modern physics. They have Fred Hoyle to thank in large measure for that change.

Fowler discussed recent experimental and theoretical work at the Kellogg Laboratory on the properties of light to medium nuclei. He emphasised that there were many low-lying excited states likely to be important in supernova events, but essentially inaccessible in the laboratory. Work such as Woosley's on the systematics of the nuclei had been very important in this regard, and calculated and experimental charged particle reaction rates were good to factors of ~2 up to ~3 billion degrees. With uncharacteristic pessimism however, he concluded that this global approach to understanding was probably at an end. His colleague C. A. Barnes added to the gloom by remarking that the solar neutrino problem is still with us. The hoped-for escape route by way of a resonance state in ^{8}Be (preventing the ^{8}B neutrinos from being produced) seems to have been killed by no less than three groups working with different reactions (led by Dwarakanath and Kavenagh at Caltech and Parker at Yale). On a brighter note Barnes mentioned that work by Rolfs (University of Toronto) and his Caltech colleagues, measuring reduced widths of states near particle thresholds by direct capture studies, had opened the way for determining cross sections for a whole host of astrophysically important reactions. Gloom returned when he remarked that the trend in cross sections for important carbon and oxygen reactions ran counter to other heavy-ion reactions and were something of a puzzle.

A shaft of Texan sunlight illuminated

the scene when Clayton (Rice University) with customary evangelical enthusiasm presented evidence and arguments that refractory grains formed in supernova or nova ejecta may have survived heating in the early solar nebula (*Nature*, in the press). Concomitantly (*Astrophys. J.*, **199**, 765; 1975), extinct ^{129}I may have decayed in the grains rather than in meteorites, as currently supposed. This could require a major revision of the early evolution of the solar nebula.

In another interesting paper Woosley (Caltech) discussed the nucleosynthesis that can occur in portions of the Universe characterised by relatively high baryon densities (a possibility recently put forward by Hoyle). In contrast with earlier calculations, Woosley was able to produce large amounts of elements heavier than iron, up to $A \sim 100$; indeed, the amount in the range $60 \lesssim A \lesssim 80$ could be embarrassingly greater than in the Solar System. With an intermediate baryon density (as in the Rees "chaotic" models), abundances in this range are quite consistent with those observed in very metal deficient Population II stars, as discussed, among other abundance data, by Pagel (Royal Greenwich Observatory).

On the (possibly) cosmological front, Hazard (Cambridge University) pointed out that the apparent strong degree of density evolution exhibited by QSOs could lead to strong fluctuations in their volume density. An identification programme of Molonglo sources carried out with Murdoch (Sydney University) indeed shows large variations of QSO surface densities for a given redshift in different regions. While it was too early to fall in with the conference spirit and drew sweeping conclusions from grossly inadequate data, the recent discovery (on the same night!) of the two new $z \geqslant 3$ objects at Lick and Steward Observatories encouraged optimism that significant studies might some day prove possible. Ekers (Groningen) recalled Hoyle's 1959 suggestion of a minimum in the angular size–flux density relation in certain cosmological models. Several hundred weak Westerbork sources (down by ~100

on the weakest 3C sources) show such an effect, at last. But the results are not in quantitative agreement with the expectations of simple, non-evolving cosmologies.

In other areas, Wickramsinghe (Cardiff) recalled early work with Hoyle on the nature of interstellar grains. In addition to grains including graphite, a suggestion of a component consisting of silicates covered by crystalline organic polymers is supported by recent data on the melting temperatures of cometary dust. Steigman (Yale University), discussing the interstellar medium as studied through the Copernicus satellite observations, was critical of their earlier interpretation. With Strittmatter and Williams, he has shown that circumstellar HII regions can account for almost all the absorption features observed; hence the bulk of the observed material may be circumstellar rather than interstellar. Solomon (SUNY, Stony Brook) from studying CO emission at $\lambda \sim 2.66$ mm (resulting from $CO-H_2$ collisions) has concluded that most of the interstellar medium in the interior of the galaxy is molecular H_2.

Stellar structure, in which Hoyle also played a large role, was rather under-represented at the meeting. Demarque (Yale University) gave a largely histori-cal review. Faulkner (University of California, Santa Cruz) discussed Hoyle's stimulus on his own horizontal branch work, and recent developments in connection with the possible effects of gravitational radiation on close binary evolution. Arnett (University of Illinois) ruefully showed how six months work since the Dallas meeting (*Nature*, **253**, 231; 1975) had resulted in the calculations of supernova collapse and neutron star formation being pushed about a millisecond further.

Perhaps the most appreciated tribute to Hoyle was that in Rees' (Cambridge University) stimulating talk in which he announced that the main building at the Cambridge Institute of Astronomy would henceforth be known as the Hoyle building. "Being stimulating", said Rees, "can be more important than being right". When Hoyle concluded the meeting with a discussion of his most recent cosmological ideas (after expressing a hope that NASA and the NSF can survive the assaults of democracy) it was clear that many in the audience retained the right to be sceptical But that did not stop them from rising to applaud him for his achievements (as aptly put by the host, Professor Rostagni at the start of the meeting) during the first sixty years of his time on Earth.

electric vector is parallel to the field line, it can shake an electron it meets up and down the magnetic 'wire' and can, therefore, be scattered by it. If, however, its electric vector is perpendicular to the field, it cannot shake an electron as it passes and will emerge without being scattered. Such an aniso-tropic scattering process clearly produces polarisation of the emergent X rays, even if initially the X rays had no net polarisation. Observation that the X rays from the pulsed X-ray sources are strongly polarised would lend strong support to the accreting mag-netised neutron star models. In addition, observation of how such polarisation varies through the pulse cycle would give valuable information about the emission process itself.

A certain amount (though probably less than about 10%) of polarisation is to be expected in the X-ray flux from the non-pulsing sources as well. Material captured from the companion star is likely to have so much angular momentum that it cannot accrete directly on to the compact object. Instead it forms an accretion disk around it. Matter in the disk slowly spirals inward towards the central compact object, releasing energy in the form of X rays as it does so. If the compact object is a black hole, all the observed X rays come from the disk, but if it is a neutron star, about half of them come from a hot thin boundary layer where the disk grazes the stellar surface. In general, in the central region of the disks where the bulk of the X rays is produced, the disk is optically thick and the dominant opacity is due to scattering of the X rays by electrons. Suppose that we view such a disk from an angle, so that its apparent shape is an ellipse, and consider an X-ray photon emerging from the disk towards us. Before it was scattered out of the disk, the most probable direction in which it was travelling is upwards in the disk, that is, in a direction perpendicular to the plane of the disk. Since the electron which gave rise to this last scattering must have been shaken by the photon's electric field in a direction perpendicular to the photon's pre- and post-scattering paths, we see that the photon's electric vector must have been in the plane of the disk and perpendicular to our line of sight Thus photons leaving the disk are preferentially linearly polarised, and the position angle of the polarisation gives us information about the orientation of the disk in space.

In such close binary systems, a fraction (a few per cent) of the X rays emitted by the compact object strike the companion star. Of these, a large proportion is scattered off the stellar atmosphere, while the rest are absorbed and converted into optical and

X-Ray polarimetry in astronomy

from J. E. Pringle

MOST of the known X-ray stars in our Galaxy are believed to be members of close binary systems, in which material from an ordinary star is being accreted on to a compact, X-ray emitting companion. Our present evidence on the nature of these systems comes from studies of the variability and spectral shape of the X-ray continuum and from observations in other parts of the electromagnetic spectrum, in particular at optical and infrared wavelengths. In recent articles, Alan Lightman and Stuart Shapiro (*Astrophys. J.*, **198**, L73–L75; 1975) and Martin Rees (*Mon. Not. R. astr. Soc.*, **171**, 457–465; 1975) have stressed the importance of making observations of the polarisation of the X-radiation from these sources.

The two X-ray stars which display regular pulses, Hercules X-1 and Centaurus X-3, are thought to be rotating, magnetised neutron stars. The material being accreted on to them is funnelled by their strong (about 10^{12} Gauss) magnetic fields and falls on to the star at the magnetic poles. There the energy of infall is released as X rays, and so the poles act as two X ray emitting hot spots on the neutron star's surface. If the magnetic axis is not aligned with the star's rotation axis, then, as the star rotates, first one pole becomes visible and then the other, making the X-ray emission appear pulsed. Although the details of the X-ray emission process are not well understood, it is fairly certain that X-radiation produced in such a strong magnetic field should be strongly polarised. The cyclotron frequency for the electrons is in the X-ray range and the X-ray photons themselves are probably produced by emission at the cyclotron frequency or low harmonics thereof. Such cyclotron emission is itself highly polarised. The X-ray photons then have to find their way out from the emission region at the stellar surface through the column of accreting material which is falling down the magnetic field lines. In a strong magnetic field, the infalling electrons are essentially tied to the field lines like beads on a wire. Consider an X-ray photon travelling perpendicular to the field lines. If its

ultraviolet radiation. Such scattered photons are again likely to be highly linearly polarised. By arguments similar to those above it is clear that the net electric vector of the scattered photons would tend to be aligned with the rotation axis of the binary system. The amount of such polarised scattered X rays received would vary depending on how much of that part of the star that is illuminated by the X-ray source is visible—that is, it would vary with the orbital period. In addition, the smaller the angle between our line of sight and the rotation axis of the binary system, the greater the amount of time for which the illuminated part of the star is visible and hence the smaller the size of the variation. Thus, in principle, such an observation could tell us the inclination of the binary orbit to our line of sight. Because such a small fraction of the emitted X rays actually strikes the companion star, such an effect would, however, be difficult to detect.

X-ray polarimetry is at present in its infancy, but it seems likely to grow to maturity over the next few years. In the past, the best-known argument for X-ray polarimetry has been that it is often symptomatic of non-thermal synchrotron-type emission. Drs Lightman, Shapiro and Rees have drawn attention to other sources of X-ray polarisation and, more importantly, have shown how X-ray polarimetry can be used as a testing ground for theoretical models, and as a means of probing the structure, of the binary X-ray stars.

Ozone over Britain

from Peter D. Moore

IT is no longer possible for the British to be complacent about ozone pollution Though Los Angeles is still the worst hit area of the world, having occasional peaks of 70 p.p.h.m. of ozone in its air (Marx, *Science*, **187**, 731; 1975) and having at least once reached 99 p.p.h.m., the problem is far more widespread : even in Melbourne peaks of 28 p.p.h.m. have recently been recorded.

In the United States, ozone is regarded as by far the most damaging of air pollutants to plants. In New Jersey, Pell and Brennan (*Environ. Pollut.*, **8**, 23; 1975) consider that $128,000 worth of damage was caused to agricultural and ornamental plants in 1972, and estimated that losses of over $35,000,000 have been made for California. Ozone is not yet considered an economic threat to British agriculture.

In 1972, Atkins *et al.* (*Nature*, **235**,

372; 1972) demonstrated the production of atmospheric ozone over southern England and later Derwent and Stewart (*Nature*, **241**, 342; 1973) published data for central London in which they found daily peaks of 8–12 p.p.h.m. Recently Cox *et al.* (*Nature*, **255**, 118; 1975) have concluded that a proportion of southern England's ozone may have been transported considerable distances, of the order of 100–1,000 km. It seems clear, therefore, that Britain has an ozone pollution problem, though it is not entirely of her own making.

Bell and Cox (*Environ. Pollut.*, **8**, 163; 1975) have now published data, obtained in 1972, concerning plant damage by ozone in Britain. They exposed the ozone-sensitive variety of Bel-W3 of tobacco to the atmosphere in Ascot (32 km west of central London) and at the same time monitored the air for ozone. They observed the characteristic symptoms of ozone toxicity (necrotic spots on the leaf surface) and their atmospheric measurements showed that ozone levels had risen above 4 p.p.h.m. on 322 occasions between July 4 and September 15 and above 6 p p.h.m. on 83 occasions. On one occasion a level of 10 p.p.h m. was maintained for 5 h. (The United States air quality standard of the Environmental Protection Agency is 8 p.p.h.m. for one hour.) Bell and Cox confirmed that there was a strong positive correlation between the degree of leaf damage and the length of time for which each test plant had been exposed to ozone levels in excess of 4 p.p.h.m. More resistant tobacco varieties showed very low levels of damage and no significant correlation with ozone exposure; no correlation at all was demonstrable with sulphur dioxide concentration.

These results show that diurnal peaks in ozone, at levels which could be injurious to both man and plants, are not restricted to central London, but could be occurring over a much wider radius. No records have yet been reported of ozone damage to crops or to wild plants in Britain but, as Bell and Cox point out, growth may be suppressed without symptoms being visible.

Recent experiments on a number of herbaceous plants in America, however, by Harward and Treshow (*Environ. Cons.*, **2**, 17; 1975) suggest that visible symptoms and growth reduction are rare at levels of 5–7 p p h.m. ozone for about 2 h per day, but become apparent in some species when levels of 15 p.p.h.m. are used. In August 1973, levels as high as 17 p.p.h.m. were recorded at Harwell, 80 km west of London, so perhaps visible damage will soon make itself apparent and we can recognise that we do indeed have an ozone problem.

Agglutination of tumour cells

from Robert Shields

MUCH research effort has gone into investigations of why plant lectins often agglutinate tumour cells to a greater extent than their normal counterparts. As with all generalisations about tumour cells, enhanced agglutination is not an invariant property of transformation. It is, however, sufficiently widespread in the model systems used by cell biologists to have promoted intensive study

Using the lectin concanavalin A (Con A) it has been shown that agglutinability of some lines of cells is directly related to their tumorigenicity when injected into animals (Inbar *et al.*, *Nature new Biol.*, **236**, 3; 1972). Also, cells transformed with temperature-sensitive tumour viruses exhibit high agglutinability at the permissive temperature (where the transformed phenotype is expressed) and lowered agglutinability at the non-permissive temperature (Burger and Martin, *Nature new Biol.*, **237**, 9; 1972; Eckhart *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **68**, 283; 1971). The experiments show that high agglutinability is closely associated with oncogenic transformation This idea was considerably strengthened by experiments that used a variety of selective pressures to produce revertants of tumour cells with approximately normal behaviour. The revertants are less agglutinable and less tumorigenic than their transformed parents (Pollack, *In Vitro*, **6**, 58; 1970; Pollack *et al.*, *Proc. natn. Acad. Sci. U.S A.*, **60**, 126; 1968). One of the best pieces of evidence for the close linkage of agglutinability and transformation is from work carried out by two separate groups (Culp and Black, *J. Virol.*, **9**, 611; 1972; Ozanne and Sambrook, *Lepetit Colloq.*, **2**, 248; 1971) on revertants. They used the fact that agglutination of tumour cells with high doses of Con A leads to cell death. After treating transformed cells with high concentrations of the lectin and isolating surviving cells, they were able to establish cell lines with reduced agglutinability and a more normal phenotype.

It has recently been suggested that tumour cells are highly agglutinable because they have more microvilli on their surfaces and that the presence of these microvilli is regulated by cyclic AMP (Willingham and Pastan, *Proc. natn. Acad. Sci. U.S.A.*, **72**, 1263; 1975). These workers suggest that microvilli help agglutination by bringing larger areas of cells' surfaces into close apposition, allowing them to be cross-linked by lectins. They suggest that it is the low level of cyclic AMP

in tumour cells which allows formation of microvilli and hence agglutination.

Using dark field microscopy these workers found that the transformed cells examined had many hairlike microvilli on their surfaces, and normal cells (in this case 3T3 cells) had none. But when 3T3 cells rounded up in mitosis or were treated briefly with trypsin numerous microvilli could be seen. These are precisely the conditions where cyclic AMP levels are low and the cells agglutinate readily. The concept that cyclic AMP could regulate agglutinability through microvillus formation was tested directly by incubating transformed cells for extended periods with dibutyl cyclic AMP, then examining their surface for microvilli and measuring agglutinability. After 24 h treatment the cells had few microvilli and were far less agglutinable. But the decreased agglutination of tumour cells after prolonged incubation with dibutyl cyclic AMP may have more to do with expansion of the G2 phase of the cell cycle (Smets, *Nature new Biol.*, **239**, 123; 1972) where transformed cells are less agglutinable (Smets and deLey, *J. Cell Physiol.*, **84**, 343; 1974) than any genuine reversion to a more normal phenotype. Also dibutyl cyclic AMP has been reported to affect the syntheis of some cell surface components (Goggins *et al.*, *J. biol. Chem.*, **247**, 5759; 1972), and it is possible that it interferes with agglutination through its effect on these molecules rather than by any direct action on microvilli.

Better evidence for the direct role of cyclic AMP in agglutination comes from the use of prostaglandin E_1 or the phosphodiesterase inhibitor isobutyl methyl xanthine. Brief treatment of transformed cells (L929) with either compound leads to a rapid increase in cyclic AMP as well as a decrease in microvilli and a decrease in agglutination. When the cells are washed free of these componds cyclic AMP levels drop and microvilli and agglutinability return.

The idea that transformed cells are agglutinable because they have numerous microvilli is only the most recent of a long series of explanations, most of which have been oversimplified or erroneous. However, the theory does have the merit of being easy to test. It should be pointed out that not all tumour cells are more agglutinable than normal cells and not all cells that agglutinate have numerous microvilli. There is no reason to suppose that a single difference between cells is the reason for the difference in their agglutinability. It seems far more likely that agglutination is a very complex process involving factors such as microvilli, surface charge and density and mobility of lectin receptors and

only in a few model systems will one factor predominate. Perhaps only when agglutination is understood in simple cells such as the erythrocyte will factors that control agglutination in more complex cells be understood.

Around the world ballooning for dust

from David W. Hughes

BALLOONS have been used by scientists ever since the pioneering work of Etienne and Joseph Montgolfier in 1783, either to investigate the atmosphere or to lift apparatus above most of it. Modern plastic balloons provide an inexpensive vehicle that can lift thousands of kilograms above 99% of the atmosphere (to heights of ~33 km) or hundreds of kilograms above 99.9% (to ~50 km) and can carry the weight there for days.

One of the latest experiments, named Magellan, is jointly organised by Wlochowicz of the National Research Council of Canada, Ottawa and Hemenway, Hallgren and Tacketh of the Dudley Observatory, Albany, New York. Preliminary results were given at the IAU Colloquium no. 31 on Interplanetary Dust and Zodiacal Light recently held at Heidelberg. Magellan is designed to fly at an altitude of about 30 km and to collect relatively large solid particles, diameter 50–300 μm (mass 10^{-7}–5×10^{-5} g), as they fall through the atmosphere.

As the flux of particles is low the experiment must have a large collecting area exposed for a long time, but the particles must be concentrated in a much smaller area for easy counting, photography and chemical analysis. To do this the Magellan balloon payload has a vertical conical mylar funnel (like an umbrella) the wide end being uppermost and 50 m² in area. The funnel apex has an angle of 60° and particles falling into the funnel slide down the sides into a sampling pan at the bottom. The payload has three sampling pans which can be exposed for pre-set periods of time and then sealed. The funnel is hung from a 300 m nylon line below the balloon to minimise contamination. The payload weighs 385 kg and contains an electronics package for tracking and for activating the cut-down mechanism.

In two engineering flights from Australia using a 20 m diameter super-pressure balloon one payload went all the way round the world and was cut down and eventually recovered within 15 km of the launch site. The second payload was not so well behaved, circling the Southern Hemisphere twice and staying up for 210 days before

finally falling into the Pacific ocean. Two short-duration flights from the NCAR Balloon Flight Station at Palestine, Texas, showed that about nine particles per hour were collected by the system. These particles are now being analysed to give incident flux, mass distribution and composition.

As in all new techniques there are problems. First, the particles can have different origins. They could be micrometeoroids (particles which do not reach boiling point on atmospheric entry and are retarded and fall slowly to Earth); they could be fragments of much larger meteoroids which disintegrated on entering the atmosphere; or they could be terrestrial contaminants which have fallen off the balloon or been blown up to 30 km from lower down Only the micrometeoroid flux is known as this can be inferred from spacecraft data. The second problem is political. It is hoped that the work will not be hindered by nations reticent about balloons flying across their territory and that multinational cooperation will soon allow Northern Hemisphere flights to start.

Two-scale mantle convection

from Peter J. Smith

ALTHOUGH convection currents in the Earth's mantle have been the subject of extensive theoretical study and speculation, experimental investigations of convective models have been surprisingly few. Yet as Richter and Parsons (*J geophys Res.*, **80**, 2529; 1975) point out, laboratory studies have a crucial part to play in testing the stability of analytical and numerical models, especially of three-dimensional systems. In spite of previous work suggesting that the conditions for stable convection may be quite restrictive, the question of stability is all too frequently ignored—a situation which Richter and Parsons claim, somewhat wryly, "may in part be responsible for the proliferation of mantle convection models that bear little resemblance to one another".

Some years ago, for example, Busse (*J. Math Phys.*, **46**, 140; 1967) showed that two-dimensional convective rolls in a fluid layer between rigid stationary boundaries are only stable for Rayleigh numbers less than 13 times critical. At higher Rayleigh numbers, a second set of rolls develops at right angles to the original one, giving a rectangular pattern when viewed in plan (bimodal convection); and at Rayleigh numbers about 100 times critical, instability develops, giving a plan pattern which

resembles spokes radiating out of central upwellings or downwellings (multimodal convection). But in spite of this and other evidence, many workers have assumed stability for convective models of the upper mantle where the Rayleigh number is probably several hundred times critical. According to Richter and Parsons, for a model governed by nonlinear dynamics it is just not sufficient to find a solution satisfying the Rayleigh convection equations and the boundary conditions. The solution must also be shown to be physically possible; and only laboratory experiments can easily provide this critical information.

A good illustration of this point is provided by Richter's (*J. geophys. Res.,* **78**, 8735; 1973) own attempt to account for the pattern of oceanic heat flow. The high heat flow anomalies over active oceanic ridges can readily be explained in terms of large-scale convection. This is the well-known system in which mantle material rises at ridges, the seafloor spreads laterally and descends at oceanic trenches, and the cycle is completed by return fluid flow in the upper mantle. Much more difficult to understand, however, is the approximately constant and uniform heat flow through ocean floor older than a few tens of millions of years. Very little of the heat involved here can be produced in the oceanic crust itself which contains too few radioactive sources. Most of it (about 1 μcal $cm^{-2}s^{-1}$) must therefore come up from the mantle. But this raises the problem of how the mantle can transport so much heat. Calculations based on the available knowledge of upper mantle composition and physical properties show that neither conduction nor radiation is sufficient.

To overcome this difficulty, Richter proposed the existence of small-scale convection beneath the plates—convective cells having a horizontal scale comparable with the depth of the fluid flow region but smaller than the plate dimensions which characterise the horizontal segments of large-scale convection. In other words, he envisaged two coexisting horizontal scales of motion in the upper mantle (the vertical scales are the same)—one required by the moving plates and one by heat flow through old ocean floor. The principal result to emerge from analytical and numerical studies of such a system was that the large-scale convection suppresses small-scale convective rolls having axes perpendicular to the large-scale flow (transverse rolls) and, in time, replaces them with rolls having axes in the direction of large-scale flow (longitudinal rolls). Unfortunately, however, this analysis was strictly valid only for Rayleigh numbers slightly higher than critical. So does it, or does

Same species, different profiles
Malacoctenus triangulatus females. *a*, from Hog Island, Bahamas; *b*, from Trinidad; *c*, from Brazil. Drawn by J. R. Schroeder; from *Smithsonian Contributions to Zoology* no. 200 by Victor G. Springer and Martin F. Gomon; Smithsonian Institution, 1975.

it not, also apply to Rayleigh numbers more typical of the mantle?

This is where laboratory work is crucial; and the results of a series of experiments designed to study the interaction of small-scale and large-scale convection have now been reported by Richter and Parsons. Briefly, these are that irrespective of the initial stable state of small-scale convection (transverse rolls, bimodal convection or multimodal convection, depending on Rayleigh number over the range 3.0×10^3–6.8×10^5), the imposition of large-scale convection ultimately changes the form of the small-scale flow to longitudinal rolls. The experimental data thus both demonstrate the plausibility of two-scale convection and confirm that the earlier theoretical results also apply at high Rayleigh numbers.

They also enable a time scale to be applied to the development of the longitudinal rolls under different conditions. Assuming that the Rayleigh

number of the sub-oceanic upper mantle approaches 10^6 and that convection extends down to the 650-km seismic discontinuity (assumptions which Richter and Parsons attempt to justify in detail), the experiments suggest that where the plate velocity is 10 cm yr^{-1} the small-scale convection should become aligned as longitudinal rolls within 20–50 Myr. On the other hand, for a plate velocity of 2 cm yr^{-1} the time scale increases to several hundred million years. Taking into account typical lengths of time between major changes in plate motion, these results suggest that longitudinal rolls within the small-scale convection system should only develop where rates of plate motion are high.

Richter and Parsons have thus combined theory, experiment and some observation (for example, of heat flow) to produce an internally consistent two-scale convection model. But can these ideas be tested, or are they destined to remain unprovable hypotheses? The

problem here is the shortage of observational constraints that can be related directly to convection rather than just to the rigidity of the plates. Two possibilities suggested by Richter and Parsons, however, are free-air gravity anomalies and residual elevation anomalies (differences between measured ocean floor depths and the corresponding depths to be expected as the result of the cooling of the lithosphere as it moves away from the ridge). As far as the roll-like pattern of convection is concerned, the best place to look for such evidence would probably be the Pacific where the plate velocity is relatively high and where no significant change in spreading direction has apparently occurred for 40-45 million years. But the region in which anomalies have been most closely observed so far is the North Atlantic where the slower spreading rate makes roll-like features less likely to be observed (nor are they) and thus where the small-scale convection pattern is more likely to take the form of upwelling and downwelling spouts. This mismatch is unfortunate, but with luck only temporary.

Peanuts and cancer

from Arie J. Zuckerman

THE geographical pathology of primary cancer of the liver presents intriguing features. Liver cell cancer is rare in North America, Europe, the Soviet Union and Australia and it seems to be relatively infrequent in Central and South America. In contrast, hepatocellular carcinoma is common in many communities in Africa and South-East Asia and probably less so in Japan. In some parts of the tropics, liver cell cancer is the commonest type of cancer in adult males and it is often, though not always, found in patients with cirrhosis. Epidemiological and experimental evidence is accumulating to implicate natural hepatocarcinogens as contaminants in foodstuffs and hepatitis B virus in the aetiology of primary liver cancer.

The carcinogenic potential of a number of mycotoxins and pyrrolizidine alkaloids is now well established in experimental animals. The aflatoxins form a group of closely related substances produced by certain strains of moulds of *Aspergillus flavus-oryzae*. These substances have been shown to have marked toxic and carcinogenic effects on the liver and other tissues of experimental animals. The cytotoxicity of aflatoxins on human embryo liver cells in cultures has also been demonstrated; aflatoxin inhibited DNA, RNA and protein synthesis in such cultures (Zuckerman *et al., Br. J. exp.*

Path., **49**, 33; 1968). The order of toxicity of aflatoxin B_1 and G_1 in human liver cells was similar to the order of carcinogenicity in rats.

The mould *Aspergillus flavus* readily grows on groundnuts (peanuts) and grains when they are stored traditionally in the open, in hot, humid conditions. Indeed approximate relationships have been reported between aflatoxin contamination of market food samples and the incidence of primary liver cancer in Uganda, Swaziland and Thailand. Peers and Linsell (*Br. J. Cancer,* **27**, 473; 1973) found a significant correlation in the incidence of liver cell cancer and the amount of aflatoxin actually consumed in a study carried out in three different altitude areas in the Muranga district of Kenya. In the low altitude area, below 5,250 foot above sea level, the incidence of liver cancer was greater and the aflatoxin levels in the food samples were higher. Van Rensburg and colleagues (*S. Afric. J. Med.,* **48**, 250a; 1974) have also shown that aflatoxin consumption by Africans living in the Inhambane district of Mozambique was remarkably high, correlating well with the high prevalence of liver cancer in that area. Peanuts and, in some areas of Africa, maize form the staple diet of Africans and the consumption of food contaminated with fungal matabolic products is likely to be high. Yet it would be prudent to note that the quantity of aflatoxin that would need to be ingested by an individual in the form of contaminated peanuts, assuming that the dose is similar to that needed to cause experimental necrosis of the liver seen in animals, is in gross excess of that likely to be consumed, amounting to several kilograms per day (Higginson, *Tumours of the Liver,* Pack and Islami; Berlin, 1970).

The apparently high incidence of infection with hepatitis B virus in chronic liver disease and especially macronodular cirrhosis and primary liver cancer in many regions in Africa and South-East Asia also implies the possibility of some form of an aetiological association. That a strong correlation has been found in some studies cannot be denied, but there are also a number of conflicting reports from different regions. The most recent study by Bagshawe and her colleagues in Kenya (*Br. J. Cancer,* **31**, 581; 1975) revealed that in the Muranga district (see above) no significant differences were found in the prevalence of hepatitis B surface antigen (3.6%) between the low altitude areas, with a relatively high incidence of primary liver cancer, and the high altitude area (2.7%) with a low incidence of the tumour.

Liver cell cancer is probably the cumulative result of many factors, and the roles of viral and parasitic infec-

tion, chemical carcinogens, nutritional and other environmental factors remain to be determined.

QSOs still problematical

from R. F. Carswell

THE origin of absorption lines in some QSOs remains something of a puzzle. Perhaps the only thing that is clear is that there are absorbing clouds some distance from the QSO, which have redshifts which are usually less than that of the emitting object itself. The velocity differences are usually less than about one-tenth the speed of light, but in one well established case the velocity is about half the speed of light. Even so, the redshifts of the QSOs in which these absorptions are seen are so high that, even with these large velocities relative to the QSO, the clouds are still receding from us. Study of the absorption line regions is clearly important, since if they are intervening galaxies then they can give us some idea of the nature of galaxies during the early Universe, and if they are intrinsic to the QSOs then they must be telling us something about the properties of the QSOs themselves. There are a number of problems in interpreting the observational data however, which leave the situation unclear.

The first major problem is that of identifying the redshifts of the absorption clouds, given a spectrum which may contain anything up to 200-300 absorption lines. A single QSO may have many absorbing clouds, at many very different redshifts, each with differing excitation properties so that it is not always possible to say definitely what lines, or redshift systems, must be present. What is usually done in the case of a newly discovered absorption line QSO is to try all reasonable candidate lines at all possible redshifts, and see if any physically consistent, and statistically significant, absorption systems are present. Often this is done on a fairly subjective basis, but a computer program developed by Aaronson, McKee and Weisheit (*Astrophys. J.,* **198**, 13; 1975) may help bring a consistent approach to the subject. The authors have analysed all previously published data on absorption line QSOs looking for candidate absorption systems using a coherent set of atomic physics and ionisation equilibrium criteria, and checked the probability of finding such a system by chance. They show that the number of well-established systems is in fact much smaller than had previously been believed, notably in very absorp-

tion rich spectra such as PHL957 and 4C05.34 where there is a high probability of chance identifications This still leaves a large number of unidentified lines, which may be due to optically thin clouds with too few absorption lines to be sure of their reality in individual cases, but which together account for most of the features in the spectrum.

Aaronson *et al.* also examine the question as to whether or not the probable absorption redshifts they have are likely to have arisen from intervening galaxies or matter ejected from the QSO. Perhaps not surprisingly, with only eight absorption line QSOs for which good spectral material is available, it seems that the available data are consistent with either picture, though they suggest that the intrinsic hypothesis might be slightly favoured. To verify this we must await additional material on new absorption line QSOs

The question as to whether or not there are intervening galaxies between us and some QSOs depends to some extent on how distant the QSOs are, and this brings us to consideration of the nature of the redshift. It is generally believed that the high redshifts observed in QSOs are a result of nothing more than the general expansion of the Universe that seems well established from studies of normal galaxies at much lower redshifts. High redshifts are seen in QSOs only because they are intrinsically bright objects and can therefore be seen to much greater distances. But in spite of the wide acceptance of this view, some astronomers contend that there is really not sufficient evidence to say that there may not be some other explanation, for all or part of the high QSO redshifts, perhaps involving some physical principles of which we have no knowledge at present.

Given that we have no model of QSO behaviour under such circumstances, such a hypothesis is very difficult to test, but some headway can be made if we believe that some QSOs are physically associated with, for example, galaxies of much lower redshift. If this is true, then there could be an excess of QSOs near bright galaxies compared with the numbers we would expect on the basis of estimates of the number density of QSOs in the sky that have been made by Sandage and Luyten (*Astrophys. J.,* **155**, 913; 1968) and others A few years ago Burbidge, Burbidge, Solomon and Strittmatter (*Astrophys J.,* **170**, 233; 1971) found that in fact there were more QSOs identified from the 3C (third Cambridge) radio catalogue lying within 7' of bright galaxies than could be due to chance, and subsequently another 3C QSO was found close to such a galaxy. This was fairly

strong evidence, on the face of it, that QSOs had some intrinsic redshift. Subsequent studies of identifications from other radio catalogues did not show the same behaviour, though, and so after a while the result looked more as if it could have been due to chance apparent associations.

Recently, however, Arp, Baldwin and Wampler (*Astrophys. J.,* **198**, L3; 1975) have found two new radio-quiet QSOs near bright galaxies, and so now there are a total of four such known. On the basis of the estimate of the number of QSOs brighter than 19 mag the areas around several thousand galaxies would have to be searched to find four QSOs if they are randomly distributed, while the number of such searches made has been estimated by the authors to be about twelve. This suggests, then, either the estimates of numbers of radio-quiet QSOs are far too low or the associations are likely to be real. There are well-known dangers in drawing conclusions from statistics performed after the event, however carefully the work is done, so it is to be hoped that further searches in neighbourhoods of galaxies will be performed to see if the results are confirmed for a new sample.

Starting at the end
from R. Kamen

An EMBO-Inserm workshop on the *in vitro* transcription and translation of viral genomes was held on July 15–18 at Grignon, near Paris.

THE RNAs of picornaviruses such as polio and EMC have long been the paradigms for eukaryotic polycistronic messenger RNAs. These large RNAs encode a single nascent polyprotein which is cleaved to generate stable viral polypeptides, prompting the general hypothesis that eukaryotic mRNAs do not contain functional internal signals for the initiation of protein synthesis. The recent development of various plant and animal systems for *in vitro* protein synthesis and their successful application to the translation of a wide variety of viral messengers has provided a wealth of data generally supporting this hypothesis The picornaviruses, however, now appear as one special case of a more general mechanism involving mRNA as well as protein processing The results obtained in several laboratories, discussed at the Grignon workshop, fit a common pattern and experiments presented on the role of 5' terminal 'capping' (see *Nature,* **255**, 9; 1975) in translation may explain why eukaryotic ribosomes start at the ends of mRNA molecules.

The process common to many of the viral systems discussed is the following: the 5' terminal portion of a viral polycistronic mRNA functions efficiently in encoding a viral protein or polyprotein, whereas the 3' terminal region remains largely silent even though it contains the sequences which encode a further viral polypeptide. A smaller viral mRNA, comprising the 3' terminal cistron, must be generated (either by RNA cleavage or by selective transcription) to activate translation of the second protein. P. Kaesberg's (University of Wisconsin) results on brome mosaic virus (BMV) well illustrate this mechanism. BMV is a multicomponent plant virus comprising three distinct virions containing four different RNAs. RNAs 1 and 2 each have their own particles, while RNA 3 $(0.7 \times 10^6$ daltons) and RNA 4 $(0 3 \times 10^6$ daltons) share the third type of particle. When translated in the wheat germ system, RNAs 1 and 2 prove to be monocistronic messengers coding for large proteins of size consistent with their RNA molecular weights; thus the proximity of the initiation point to a 5' end is assured by the genome segmentation. RNA 3. however, includes at its 3' end all of the sequences of RNA 4 When translated *in vitro*, RNA 3 encodes one major polypeptide (called 3a) unrelated to the BMV coat protein, while RNA 4 is an efficient messenger for the coat protein. Thus RNA 3 contains one active 5' proximal start signal and a second largely inactive internal start signal which is unmasked in the generation of RNA 4. Competition studies showed that the second start in its

active state, has in fact higher affinity for ribosomes than the start at the 5′ end of RNA 3. Two alternative explanations for the dramatic alteration in efficiency of this initiation site between RNAs 3 and 4 were discussed: either the structure of RNA 3 blocks internal initiation, or a modification at the 5′ end of RNA 4 is involved in ribosome binding. Isolation and sequencing of a fragment of RNA 4 which specifically binds to ribosomes led Kaesberg to opt tentatively for the second alternative· the sequence is m⁷GpppGUAUUAA-UAAUG . . . followed by the codons for the first ten amino acids of the coat protein. A. J Shatkin (Roche, New Jersey) pointed out in discussion that the UAAU tetranucleotide of this sequence is complementary to the common 3′ end of eukaryotic 18S rRNA recently determined by Steitz, Shein and Delgano. Thus the mechanism of ribosome recognition may be in part similar to that used in prokaryotes. Results presented by M. N. Thang (Institut Biologie Physico-Chimique, Paris) and by L. van Vloten-Doting (State Universitv. Leiden). obtained with the small RNAs of the related alfalfa mosaic virus, although more preliminary, concurred with Kaesberg's conclusions on BMV.

T Hunt (University of Cambridge) discussed the *in vitro* translation of tobacco mosaic virus (TMV) RNA. He and his colleagues find that the 2.2 × 10⁶ dalton genomic RNA encodes overlapping 160,000 and 140.000 dalton proteins, but no coat protein. A small viral RNA (0.25×10⁶) found in infected leaves, comprising the 3′ end of the total RNA, is a very efficient messenger for TMV coat protein in several *in vitro* systems. Among the plus-stranded RNA animal viruses. two groups—I. Kennedy (University of Warwick), and L. Kääriäinen (University of Helsinki)—reported experiments with Semliki Forest virus consistent with the notion that the 42S genomic RNA encodes large nonstructural proteins while the 26S viral mRNA found in infected cells (comprising the 3′ terminal third of the 42S) is the mRNA encoding a different single polyprotein which is efficiently processed *in vitro* into the four viral structural proteins.

The mechanism also functions in DNA animal viruses. A. Smith (ICRF, London) and C. Prives (Weizmann Institute, Rehovot) agreed that the 19S late messenger either of SV40 or polyoma virus encodes the minor virion structural protein(s), but is an inefficient messenger for the major capsid protein (VP1). The 16S late messenger, which at least in the case of polyoma virus comprises the 3′ terminal half of the 19S mRNA, is the messenger for VP1 synthesis *in vitro*. Y.Aloni

recently reported at the European Tumour Virus Group meeting that the 19S SV40 mRNA is cleaved to 16S in the cytoplasm, and several groups have found that it has an m7G capped 5′ end.

Evidence implicating 5′ terminal methylation in ribosome recognition was presented for VSV RNA by H. P Ghosh (McMaster University, Ontario) and in detail for several messengers by Shatkin. The latter reiterated his published evidence that non-methylated reovirus or VSV mRNA functions poorly in wheat germ or mouse L cell *in vitro* systems, but can be stimulated by *in vitro* methylation in the presence of S-adenosylmethionine in either system. He also showed that chemical

removal of the terminal m7G from these viral messengers or from rabbit globin mRNA destroys messenger activity. Most interesting were direct experiments on messenger binding: the 7mG of reo messenger is required for binding to wheat germ ribosomes A 35-nucleotide long fragment of reo messenger containing the 7mG 5′ end, which rebinds to ribosomes, was isolated from sparsomycin initiation complexes after nuclease digestion. 7mG has also been found in the globin mRNA ribosome binding site. Finally, Shatkin described experiments in which the 7mGpppGᵐ 5′ terminal dinucleotide of Reo virus was extended with various mixed or homopolymers and assayed for ribosome binding. Only the

New blood parasites for old

from F. E. G. Cox

THE malaria parasites belong to the protozoan sub-order Haemosporina which also contains a number of other blood parasites. From the earliest days of parasitology these have received considerable attention and it comes as something of a surprise to discover that until recently a whole new family has existed unrecognised in South American lizards (Lainson *et al., Int. J. Parasit.*, **1,** 241; 1971; *Parasitology*, **68,** 117; 1974; *Parasitology*, **70,** 119; 1975). This family is the Garniidae and its importance has grown since its discovery in 1971 partly because it looks as if it is going to contain a large number of species and partly because of the implications of the various life cycles which its members undergo. The interpretation of these life cycles throw doubts on current ideas regarding the nature of reptilian malarias and on the evolution of the malaria parasites as a whole. So far, two genera have been described, *Garnia* with six species and *Fallisia* with four.

All the other members of the Haemosporina undergo asexual division, or schizogony, in fixed cells and the malaria parasites, in addition, multiply in circulating blood cells. In the Garniidae, however, schizogony occurs only in blood cells: in red cells in *Garnia* and white cells in *Fallisia*. Some species of *Fallisia* occur in neutrophils and thrombocytes, cells which have not been utilised by any other parasites. Since the discovery of the exoery-throcytic stages of the malaria parasites it has been widely accepted that schizogony in the blood evolved secondarily but this belief will now

have to be reassessed. In addition, all the descriptions of malaria parasites of lizards will have to be re-examined as Lainson and his colleagues have found that multiple infections with members of the Garniidae and with true pigmented malaria parasites are common and this may well have confused the original descriptions of different species. Telford (*Int. J. Parasit.*, **3,** 829; 1973) has claimed that some members of the Plasmodiidae, the malaria parasites, are not pigmented but the recent work indicates that there is no need to redefine this family in order to include non-pigmented forms.

While new blood parasites are being discovered in lizards it is likely that some widely accepted species (and even genera) in birds will have to disappear. Box (*J. Protozool*, **22,** 165; 1975) has found that infections with the intestinal eimerian *Isospora serini* in canaries results in the appearance of extra-intestinal stages in blood monocytes, something that does not happen with another species *I. canaria*. Box notes the similarities between these extra-intestinal stages of *Isospora* and *Lankesterella* spp. and other eimerian parasites which occur in blood cells. This is an extension of the discovery a few years ago that *Toxoplasma gondii* in many mammals is an aberrant *Isospora* sp. of cats.

The status of all non-pigmented blood parasites will have to be looked at critically in the light of the separate studies of Box and Lainson and his colleagues and the parasites of mammals cannot be allowed to escape the scrutiny.

m7GpppG™poly(A,U)   derivative, which should contain molecules with the . . . UAAU . . . sequence complementary to the 3′ end of 18S ribosomal RNA, showed significant interaction with 80S ribosomes.

Several observations must be mentioned which are in apparent conflict with the appealing idea that eukaryotic ribosomes only start at ends because they interact with 7mG Hunt mentioned evidence from TMV and M. Pranger (University of Utrecht) and Kääriäinen gave evidence from Semliki Forest virus, that there is more than one initiation site in the 5′ terminal portion of their respective mRNAs. R. Gesteland (Cold Spring Harbor), in discussing elegant experiments showing that yeast suppressor tRNAs work in mammalian cell-free systems, reconfirmed the observation that an internal cistron of bacteriophage Qβ RNA is translated accurately by eukaryotic ribosomes and initiation factors Moreover, to return finally to the picornaviruses, these RNAs can be translated in vitro although, as discussd by P Fellner (Searle, High Wycombe). 7mG cannot be detected at their 5′ ends.

Insectiverous grouse

from our Animal Ecology Correspondent

THE traditional management of heather moorland for red grouse production centres on regular burning of the vegetation so as to encourage sprouting of new green shoots. Such new growth is rich in nitrogen and phosphorus, elements now known to be correlated with performance of grouse populations (Moss, J. Anim. Ecol , 38, 103; 1969). The practice of burning seems right and proper since heather forms the bulk of the diet of adult grouse. But most species of animals are opportunist feeders—the grouse is no exception—and adherence to too rigid a management creed may deny some moors the extra grouse they could produce.

Different grouse moors do not have identical vegetation. About two-thirds of the total acreage in Britain is low lying and fairly dry. The remaining one-third lies at high altitude and the high annual rainfall it sustains keeps its deep peaty surface waterlogged almost the whole year through. Recent studies by Butterfield and Coulson on one such blanket bog moor reveal that adult grouse supplement their diet with quite considerable amounts of insect food (J. Anim. Ecol., 44, 601; 1975). The habitat is just right for craneflies, chiefly Tipula subnodicornis and Molophilus ater, and at the peak of emergence their densities may reach 15 m⁻²

and 400 m⁻² respectively. Adult male craneflies do not fly strongly and the females have no wings at all. They represent to the grouse an additional source of food almost as easy to harvest as the heather tips upon which they spend most of their adult lives. That adult grouse can develop a specific search image for craneflies is clear from the observation that one grouse shot in October 1970 had the remains of 495 adults of the rare T. gimmerthali in its stomach. This is more than the total number of individuals caught by British entomologists since the end of the nineteenth century.

Observations during May, June and July of fresh droppings taken from established grouse territories on damp moor revealed that the percentage containing insect material varied from 98% at the time of maximum emergence to 8% at the end of the hatching season. Most droppings contained plant material but in a small number the amount fell to less than a half of the total contents. Both species of cranefly were eaten by adult grouse, but chicks took considerably more of the small M. ater than they did of the larger T. subnodicornis For adult grouse the reverse was true. By contrast, droppings from a dry moor were almost totally devoid of insect remains.

What is of great interest is that weight for weight, T. subnodicornis contains nine times more nitrogen, seven times more phosphorus, six times more sodium and twice as much potassium as heather shoots. M. ater is richer, too, in these elements but less so than its larger relative. The importance of these elements in grouse nutrition is shown by the choice by breeding grouse of growing tips of heather which contain high levels of nitrogen and phosphorus (Moss, J. Anim. Ecol., 41, 411; 1972). Moss, Watson and Parr confirmed that maternal nutrition did affect breeding success but what was important was the length of time during which heather growth was possible prior to laying (J. Anim. Ecol., 44, 233; 1975). Management plans for grouse moors are aimed at creating conditions for maximum breeding success and standing crop of grouse. On wet moors craneflies are not available until after egg laying and so cannot directly influence pre-laying nutrition. Their peak in abundance comes shortly after clutches are completed when, it could be argued, female grouse are in a state of nutrient depletion. By offering an easily gathered, rich food source at this time, they could play a vital part in the maintenance of grouse populations. A full-scale investigation of the relationship between grouse and insects seems now to be overdue, for if these preliminary findings are generally sub-

stantiated the future management of the wet third of Britain's grouse habitat may well reflect the need to maintain suitable cranefly sites.

Tropomyosin in transition

from E. J. O'Brien

IN a resting muscle the level of Ca²⁺ is very low and interaction between the thick, myosin-containing and the thin, actin-containing filaments is inhibited. When the muscle is stimulated, Ca²⁺ is released from the sarcoplasmic reticulum so that its concentration around the filaments rises sharply. The inhibition is then removed and myosin and actin can interact, split ATP and produce contraction. The means by which inhibition and its removal are obtained has been extensively investigated, and, in the main, attention has been directed at the proteins troponin and tropomyosin which are combined with actin in the thin filaments of many types of muscle.

In the electron microscope actin resembles two strings of beads twisted slowly around each other. Much more difficult to see, because of its narrow width (2 nm), is tropomyosin, but from diffraction and other studies of the thin filament, it has been shown to lie end-to-end in each of the two grooves between the actin strings. Attached at intervals of about 40 nm along the actin–tropomyosin complex is troponin, which has three components: one, TN-T, which binds to tropomyosin, one, TN-C which binds Ca²⁺ and one, TN-I, which is responsible for inhibition.

With TN-C removed the thin filament is not Ca²⁺-sensitive and remains permanently 'switched off', as in a resting muscle. Without any of the troponin components the actin–tropomyosin complex is also not Ca²⁺-sensitive, but in this case it stimulates the splitting of ATP by myosin, that is, it is 'switched on'. Wakabayashi, Huxley, Amos and Klug (J. molec. Biol., 93, 477; 1975) have studied the nature of the structural change involved in the on–off transition. Since the required structural detail is at the limit of resolution provided by negatively stained material, their analysis has relied heavily on the use of sophisticated computer processing of electron micrographs. This involves densitometry of the micrographs to produce a digital scan, and from this, and a knowledge of actin's helical symmetry, three-dimensional reconstructions of the filaments can be obtained.

Wakabayashi et al. prepared fila-

ments of actin+tropomyosin and of actin + tropomyosin + TN–T + TN–I and formed them into paracrystals by the addition of Mg^{2+}. From the digital scans of micrographs of the paracrystals they selected one filament at a time and reconstructed it in three dimensions. From many such reconstructions the best averages were taken and the two types of filament compared. In the first type of filament the tropomyosin may be clearly distinguished running near the centre of each of the grooves between actin strands. When the TN–T and TN–I are added, however, the tropomyosin is displaced through about 1 nm and becomes much more closely integrated with each actin strand.

From observations of changes in the X-ray diffraction pattern of living muscle at rest and during contraction, several authors have proposed that tropomyosin moves in the actin grooves when the muscle is stimulated. This leads naturally to the proposal that inhibition is caused by blocking by tropomyosin of the sites of actin that interact with myosin. On stimulation of the muscle, increased Ca^{2+} concentration is thought to cause a conformational change in troponin with a consequent displacement of tropomyosin towards the centre of each actin groove and removal of the inhibition. Since the distribution of troponin is discrete along the thin filament (one troponin for every seven actin subunits), whereas that of tropomyosin is continuous, the function of the latter is both to mediate and to amplify the effect of the former.

Because only the amplitudes and not the phases of reflections in the X-ray diffraction patterns are recorded, the tropomyosin movement model cannot be substantiated from the whole-muscle studies alone. This is where the electron microscope work proves so useful. The direct determination by Wakabayashi *et al.* of a tropomyosin shift under the influence of TN–I is therefore an important advance in understanding thin filament control.

The simplicity of the steric blocking mechanism is appealing, but not necessarily convincing, and it may only be a part of a system which involves other subtler allosteric interactions. It has also still to be demonstrated that in the so-called inhibitory position, the tropomyosin does actually cover the actin site where myosin would attach. There is still work to be done then. Moreover, evidence has recently been accumulating for a Ca^{2+}-sensitive regulatory role in the thick as well as in the thin filaments of vertebrate muscles The full picture is bound to be complex and even the distinction between the process and regulation of contraction may become less clear-cut.

Interferon at Warwick

from Mike Clemens

Interferon seems to be a popular subject this summer. The most recent of several meetings on it was an EMBO Workshop held at the University of Warwick on July 29–31 in which much new information concerning the induction, purification and mechanism of action of this anti-viral protein was presented.

IT is well known that the synthesis of interferon can be induced in cells not only by intact viruses but also by synthetic double-stranded polynucleotides. But it is not at all clear whether the latter have to enter cells or act at the surface membrane. D. Hutchinson (University of Warwick) gave a critical account of the evidence in favour of the latter conclusion. In spite of the almost inevitable solubilisation of some double-stranded RNA which occurs when cells are incubated with this inducer covalently bound to inert supports, direct action at the cell surface seems likely. The immediately subsequent events are still a mystery but considerable progress has been made in identifying the messenger RNA for interferon in cells exposed to double-stranded RNA. P. Pitha (Johns Hopkins University) showed that poly(A)-containing RNA from induced human fibroblasts was translated both in mouse cell-free systems and in intact frog oocytes to give products with human interferon activity. No interferon mRNA could be detected in uninduced cells and it seems that regulation of interferon production may well occur at the transcriptional level. D. Burke (University of Warwick) presented evidence that the inhibitor of transcription camptothecin prevents induction of interferon by virus but not by double-stranded RNA, but it is not yet known whether a virus-directed or a host-directed transcriptional event is involved in this effect.

The most controversial area of interferon research concerns its mechanism of action. This has recently been studied by M. Revel (Yale University) using somatic cell hybrids containing a limited number of human chromosomes. The requirement for chromosome 21 for sensitivity of cells to human interferon is now thought to be because of a specific membrane receptor for interferon coded by this chromosome, rather than an intracellular 'anti-viral protein'. Studies with human fibroblasts monosomic or trisomic for chromosome 21 have confirmed this conclusion.

The events that occur between inter-

action of interferon with its receptor and inhibition of virus replication remain something of a mystery. There was general agreement that protein synthesis is a major target for interferon action but D. Metz (National Institute for Medical Research) produced convincing evidence that, in the case of monkey cells infected with SV40 virus, there is selective inhibition of viral RNA synthesis or enhanced nuclear turnover of viral transcripts after interferon treatment. The recently discovered process of methylation of the 5' ends of newly synthesised mRNA may also be a target for interferon action. P. Lengyel (Yale University) reported that the rate and extent of methylation of reovirus mRNAs in interferon-treated cell extracts was only half that seen in control extracts. However, A. Ball (University of Connecticut) stated that, in an interesting coupled transcription–translation system, methylation of newly synthesised vesicular stomatitis virus RNA is not impaired in the presence of extracts of interferon-treated chick embryo cells. In the same incubations translation of this RNA was severely inhibited compared to its translation in control cell extracts.

A possible clue to the mechanism of inhibition of translation came from the observation by I. M. Kerr's laboratory (NIMR) that interferon-treated L-cell extracts are more sensitive to inhibition by double-stranded RNA than control extracts. T. Hunt (University of Cambridge) described some recent experiments demonstrating that, in reticulocyte cell-free systems, double-stranded RNA causes the ATP-dependent phosphorylation of an initiation factor. However several groups have shown that polypeptide chain elongation as well as initiation is impaired by interferon treatment so that the situation is rather complex. Lengyel and Ball both stated that the established ability of tRNA to reverse the interferon-mediated inhibition of translation is not observed under certain conditions and the physiological relevance of this effect must therefore remain open to doubt. It would be a brave person who predicts, on the basis of present knowledge, just how interferon prevents viral replication within animal cells.

Correction

In the article by Donald Boulter "Breeding for Protein Yield and Quality" (*Nature*, **256**, 168; 1975) there occurred the phrase "the long-assumed negative relationship between protein yield and grain yield". The assumed negative relationship was in fact between protein content and grain yield.

review article

Analogies between embryonic (T/t) antigens and adult major histocompatibility (H-2) antigens

Karen Artzt* & Dorothea Bennett*

Progress has been made in defining cell surface components specified by the T/t locus in the mouse, both in their expression on sperm and, in the one case studied, on normal embryonic cells and teratocarcinoma. Some striking analogies between this putative embryonic cell recognition system and the adult major histocompatibility complex are presented.

IT is now generally accepted that cell surface structures have a critical role in cellular interactions during development and that they are genetically programmed. We are fortunate, therefore, to have available in the mouse an extensive set of mutations at the *T/t* locus that not only control specific points in embryonic development, but apparently operate through the specification of cell surface structures on embryonic cells and sperm. The serological identification and biochemical study of the products of *T/t* locus genes may offer some new insights into the genetic control and mechanism of development.

The *T/t* locus

The *T/t* complex is located on chromosome 17, fourteen crossover units to the left of *H-2*. It is marked by a class of semi-dominant *T* (Brachyury) mutations which, when heterozygous, cause a short tail and when homozygous are lethal[1,2]. But more important, *T* mutations interact with recessive alleles at this locus to produce a tailless (T/t) phenotype; this interaction makes possible the detection of recessive *t* alleles that would otherwise go unnoticed.

A large number of different *t* mutants have been detected; as homozygotes some are embryonic lethals, some are semilethal (some, but not all, homozygotes of this class die), and many are viable. Here we will consider mainly the lethal ones. These lethal mutations are not laboratory curiosities since they exist as natural polymorphisms in wild populations of mice the world over, where they are maintained by a distortion of their rate of transmission through males (but not females). Better than 90%, instead of the expected mendelian 50%, of the progeny of a heterozygous male (+/*t*) and a normal female (+/+) will carry the *t* allele[3]. Lethal *t* mutants also have the unique property of suppressing normal recombination, by some mechanism still obscure, along 14 units of chromosome between *T* and *H-2* (ref. 4, D.B., unpublished data and C. Hammerberg and J. Klein, personal communication). About one gamete in 10⁻³ does, however, carry a recombinant chromosome, as judged by the exchange of an outside marker. This kind of recombination event almost always generates a new and different *t* allele[5], usually viable. Observation of these transitions is facilitated because two different *t* mutants complement one another, so that *tˣ/tʸ* animals survive and are normal in all respects except male fertility (for reviews see refs 3, 6 and 7).

*Address: Department of Anatomy, Cornell University Medical College, New York, New York 10021.

The *T/t* locus clearly contains a set of genes of critical importance in early stages of embryonic development. We know that normal alleles are essential for normal development because homozygotes for any one of eleven different mutant alleles die at characteristic stages during embryogenesis, usually when a particular cell type proves incapable of maintaining itself or proceeding to the next step in differentiation. Morphological studies of affected homozygous embryos[6,8] provide a dramatic picture of failure of cell–cell interactions, and suggest strongly that the initial defect can be associated with the cell membrane[9,10].

These observations led in 1970 to a search for membrane structures specified by the *T/t* locus. Since sperm cells are also affected by *t* mutations[11] and since they were readily obtainable in quantity, whereas young embryos were not, sperm were used initially to define T/t cell surface structures. Immunisation of mice with mutant (*T/t*) sperm and appropriate absorption of the resulting antisera with + sperm yielded specific antibodies that were demonstrated in complement-mediated cytotoxicity tests to be directed against the products of *T* and several different recessive *t* mutations[12,13]. These initial studies and work in progress show: that codominantly specified T/t antigens exist on the sperm surface, that certain of the different *t* haplotypes produce unique specificities whereas others are cross reacting, that cross reacting antigens can in turn be resolved by absorption analysis into multiple specificites[14], and finally, that some of these specificities are separated from one another by the rare recombination events that generate a new *t* allele from a pre-existing one (unpublished results).

Once it was established that mutations in the *T/t* complex were in fact associated with serologically detectable alterations of the sperm surface, the task was to validate our hypothesis that these antigens also appeared on specific groups of embryonic cells at particular stages of development. It is technically difficult to test this assumption using mutant embryos. We therefore turned to the study of teratoma cell lines established and characterised in the laboratory of F. Jacob, to test the more general hypothesis that embryonic cells can be characterised by their display of genetically controlled cell- and stage-specific antigens.

Teratoma system

Teratomas are tumours that develop spontaneously from germ cells, or from experimentally manipulated embryos, and represent a form of disorganised parthenogenesis that gives rise to derivatives of all three germ layers: ectoderm, mesoderm

and endoderm[15]. Male mice of strain 129/Sv produce a high proportion of such tumours, and these tumours have been extensively studied both *in vivo* and *in vitro*[16]. An interesting and technically very helpful feature of teratoma cell culture lines is that different derivatives of the same tumour may form stable lines with different capacities for differentiation. For example, essentially pure cultures of the following types have been isolated. First, lines containing primitive teratocarcinoma (PTC) stem cells that are multipotential and capable of producing derivatives of all three germ layers. Second, lines containing differentiated teratocarcinoma (DTC) cells that are restricted to a particular pathway in development, and capable of producing only a limited array of differentiated cell types, for example yolk-sac carcinoma, or myoblasts. Third, lines containing PTC cells that have lost all capacity for differentiation and are nullipotential. Cultures of the last two kinds provide relatively homogeneous populations of embryonic cells that seem to be permanently trapped at specific developmental steps, and therefore can be used to attempt to identify cell- and stage-specific surface components.

The hypothesis was that cell surface structures concerned with early embryonic development appear and disappear long before immunological self tolerance, and therefore would behave as autoantigens[17]. (T/t antigens are on adult sperm but act as autoantigens to males because of their immunologically privileged location within the seminiferous tubules.)

The most simplified PTC cell line (F9) of the third category above was used to prepare syngeneic hyperimmune antisera against irradiated cells. This antiserum was assayed in complement-mediated cytotoxicity tests, and by absorption; it was found to react only with lines of teratoma which contained PTC cells, of either nullipotential or multipotential variety, but not with differentiated lines. The serum was also negative on all adult somatic cells tested, as well as a wide variety of tumour cells. Importantly, however, the anti-F9 serum reacted with sperm cells and normal cleavage stage embryos[18]; expression is low on one-celled embryos, increases to a maximum at about 8 cells, and then declines again (unpublished data). The exact timing of the disappearance of the antigen from the embryo is still under study, but it is not present on any differentiated cells that have been examined.

These results suggested that anti-F9 recognised a cell surface structure present on uncommitted cells and absent from differentiated cells. The antigen recognised was not a tumour antigen, and its normal tissue distribution was restricted to sperm and early embryos.

Relationship of F9 antigen to *T/t* locus

The general distribution of F9 parallels that postulated for T/t antigens. The parallel was quite precise with respect to a particular *t* lethal (t^{12}) as t^{12} homozygotes become abnormal and die at the morula stage. It seemed a promising possibility that the antigen detected on PTC-F9 cells, normal morulae and sperm, might be specified by the wild type allele of t^{12}, since of course, the genotype of the teratoma did not contain t^{12}, but rather (+) alleles at the *T/t* locus. Tests of this possibility were available, since the expression of T/t antigens on sperm is codominant[13]. Thus, if F9 were specified by the (+) allele of t^{12}, sperm from $+t^{12}$ males should carry only half as much F9 antigen as sperm from $+/+$ males.

The relationship of F9 to $+t^{12}$ was therefore tested by absorbing anti-F9 with known numbers of sperm from males heterozygous for t^{12}, and males that were either wild type or heterozygous for other *T/t* mutations. It was consistently found that sperm from males carrying t^{12} were only half as effective as all other types in removing anti-F9 activity[19]. The relative paucity of F9 antigen on sperm from t^{12} heterozygotes was confirmed with direct cytotoxicity tests of anti-F9 on sperm from various genotypes; T/t^{12} sperm were only half as susceptible to complement dependent lysis as were sperm from $T/+$ males or males carrying different later-acting *t* alleles (T/t^{0}, T/t^{w5}, T/t^{9}) (unpublished results). Thus, F9

antigen seems to be specified by the $+t^{12}$ gene.

To recapitulate, these experiments have been encouraging on three fronts: first, teratoma cells at a defined stage of differentiation have proved to be valid models for cells of the normal embryo; second, a genetically specified, stage-specific, embryonic cell-surface antigen (F9) has been defined; and third, the appearance of this antigen in the embryo has been shown to correlate temporally with the developmental function of the gene responsible for it. The functional role of this antigen in development is as yet unknown, but it may reasonably be speculated that it is concerned with cell–cell interactions.

Analogy between the *T/t* complex and MHC

Our own conceptual framework for some years has been that the *T/t* locus may represent an embryonic analogue of the adult major histocompatibility complex (MHC), and that both systems operate as mediators of cell–cell recognition; the former functioning in the embryo, the latter in the adult. The evidence in support of this hypothesis is as follows.

First, the *T/t* complex and the *H-2* complex of the mouse are linked on chromosome 17. Their linkage may not be entirely fortuitous. In the presence of most lethal and semi-lethal *t* alleles, recombination is suppressed between *t* and *H-2*, a distance of 14 cmorgans. This suppression is unexplained, but led Snell[20] as early as 1968 to propose that the two loci comprised a "super gene" acting as a functional unit for maintaining heterozygosity at *H-2* in feral populations of mice.

Second, each complex occupies a large region of chromosome. The *H-2* complex spans 0.4 cmorgans[21]; the *T* complex is not, as yet, measured because of the recombination suppression associated with *t* alleles; but this fact alone, and evidence that *t* mutation consists of several different functional elements separable by exceptional recombination, suggest that it also occupies a long region.

Third, both *T/t* and *H-2* specify codominant antigens on the cell surface which are complex and highly polymorphic. Each *H-2* haplotype of independent origin encodes on the average eight specificities[22]. Haplotypes of *t* mutants have three or four specificities; the total number currently defined is six, but this number rests on the analysis of only three cross reacting haplotypes[14]. Furthermore, since wild type specificities have not been taken into account at all, the six specificities so far defined probably represent only a fraction of the total.

Fourth, each complex locus has a minimum of two sero-logically detectable (SD) genes. The two SD regions of *H-2* are well documented[23]. The *t* lethals have long been known to consist of at least two functionally different regions separable by crossingover, namely a factor responsible for lethality and a factor responsible for phenotypic interaction with *T*. This is made obvious by the generation of viable alleles by recombination[24].

We have studied several of these recombinant haplotypes serologically, and in every case direct cytotoxicity tests demonstrate cross reactivity with the parental haplotype. In the one case analysed by absorption, when antiserum specific for the parental lethal is thoroughly absorbed with the recombinant *t* viable sperm, it retains activity for the parental lethal and for other cross reactive lethal haplotypes. On the other hand, the absorbed antiserum is negative on other viable haplotypes independently generated from the same parental lethal haplotype. The serological data are consistent with the functional criteria mentioned above and suggest that the crossover haplotype has lost the unique specificities associated with lethality but retained other mutant specificities (unpublished).

Fifth, the developmental expression of H-2 and T/t antigens seem to be reciprocal. H-2 is present on all adult cells, with the apparent exception of sperm[25], but absent from the early embryo[26] and analogous cells such as F9 (refs 25 and 27). T/t, on the other hand, is absent from all adult cells except germ cells[12], but is present on embryonic cells[19]. H-2 is first detectable in 7–9-d embryos[28], whereas T/t antigens associated

with lethal haplotypes are presumed to cease expression by 9 days of development. Furthermore, as *in vitro* populations of multipotential teratoma cells differentiate, detectable levels of F9 antigen fall, while H-2 shows a concomitant rise[29].

Sixth, both systems seem to have analogues in other species. MHC complexes like *H-2* have been found in all mammals studied, as well as birds[21]. Likewise, antigens cross reacting with F9 ($+t^{12}$) have been found on all mammalian sperm examined[30], including human sperm[31,32].

Finally, recent biochemical evidence suggests that the antigenic products of both *T/t* and *H-2* are structurally similar. Lactoperoxidase radioiodination of cell surface components of lymphocytes, sperm and F9 cells, and immunoprecipitation with appropriate antisera, show not only that the molecular weight and subunit structure of the D and K products of *H-2* and the F9 ($+t^{12}$) antigen are identical, but also that $+t^{12}$, like H-2, is associated with a B-2-microglobulin-like moiety in the membrane[25]. Similar results have been reported for the TL antigen[33,34] which is closely linked to *H-2D* and apparently has a reciprocal interaction with it in the plasma membrane. Amino acid sequencing of $+t^{12}$ is now under way and together with sequence data for H-2, will prove or disprove the homology strongly suggested by these data.

The considerations above suggest that the *T/t* complex may be an evolutionary precursor of the MHC, or that both complexes originated in a common ancestoral gene. An embryonic recognition mechanism of the type associated with *T/t* genes could have evolved with the metazoans at the stage when an immune system was not yet organised, indeed, not yet necessary. Later, with the advent of vertebrates and especially warm blooded animals, when protection from microorganisms became imperative, the duplication and specialisation of a complex genetic region already governing cell recognition may have been an economical way of providing genes for immuno-logical recognition.

Genetic control of cell size at cell division in yeast

Paul Nurse

Department of Zoology, West Mains Road, Edinburgh EH9 3JT, UK

A temperature-sensitive mutant strain of the fission yeast Schizosaccharomyces pombe *has been isolated which divides at half the size of the wild type. Study of this strain suggests that there is a cell size control over DNA synthesis and a second control acting on nuclear division.*

pombe has been isolated which divides at half the wild-type size. Study of this strain demonstrates that its cell cycle is also profoundly altered compared with wild type. The timing of DNA synthesis in the cell cycle, the size at which cells undergo DNA synthesis, and the size at which cells undergo nuclear division are all different from wild type growing with the same generation time. These observations may be understood in terms of models of cell cycle control that propose a cell size control over DNA synthesis and a second control acting on nuclear division.

GROWING cells tend to maintain a constant size at division[1-3]. This implies that there is coordination between cellular growth and cell division which results in a division occurring when the cell has grown to a particular size. The mechanism by which this is achieved remains obscure although there are various theoretical models which could account for the phenomenon[4]. A new approach to the problem would be the study of mutant strains in which the normal coordination between cellular growth and cell division is disrupted, resulting in the division of cells at different sizes. Such an approach in a simple eukaryote is described in this report.

A mutant strain of the fission yeast *Schizosaccharomyces*

Cell division cycle

The cell division cycle of fission yeast has been extensively studied[5,6]. Cell division is marked by the formation of a prominent cell plate across the middle of the cell, and separation of the two cells occurs a little later. The cell remains constant in diameter, growing only in length during the cell cycle. Cell length is therefore directly related to cell volume. As in higher eukaryotes the DNA–nuclear cycle can be divided into G1, S, G2 and M periods. The S period is very short and occurs at the beginning of the cell cycle

Table 1 Characteristics of wild type and mutant at 25 °C and 35 °C

Strain	Growth temperature (°C)	Generation time (min)	Cell volume at cell division (μm³)		Cell volume at nuclear division (μm³)		Macromolecular content per cell	
			Mean	s.d.	Mean	s.d.	Protein (pg per cell)	RNA (pg per cell)
Wild-type 972	25	228	129	9.1	121	8.4	12.4	2.54
	35	142	149	6 4	139	9 0	14.1	2.90
Mutant cdc9-50	25	232	109	8.8	98.0	7.9	9.66	2.26
	35	138	72.7	7.8	60.4	8.4	7.16	1.54

Cultures of the two strains were grown in a modified EMM 2 minimal medium[5], with the sodium acetate and sodium dihydrogen ortho-phosphate replaced by 15 mM potassium hydrogen phthallate and 10 mM disodium hydrogen orthophosphate. Photographs of cells grown at 25 °C and 5 h after shift to 35 °C were taken using a .× 16 objective in a Zeiss photomicroscope under dark field optics. The length and diameter of 200 cells with cell plates were measured and their volume calculated. Protein and RNA content per cell, and generation times were determined in exponentially growing cultures as described in ref. 12. Between 5 and 10 determinations were made for each estimate of macromolecular content per cell and in no case did the standard error exceed 4% of the mean. Cells with dividing nuclei were detected by staining with Giemsa[5]. The volume of 200 such cells was calculated after correction for cell shrinkage on fixation and staining

Fig. 1 Cell number. nuclei number, RNA, protein, and cell volume at division of wild-type 972 during the transition from exponential growth at 25 °C to 35 °C. A culture of 972 growing at 25 °C was shifted at 0 min to 35 °C, the culture reaching the higher temperature within 5 min of transfer The time of transfer is marked by the large open triangles. Experimental parameters were determined as described in Table 1. The real values of experimental parameters per ml, equivalent to one unit on the arbitrary log scale, is given in brackets in the symbol key. ■, No. of nuclei ml⁻¹ (1 ×10⁶); ▲, cell number ml⁻¹ (1 ×10⁶) ;○, protein ml⁻¹ (21 9 μg); □, RNA ml⁻¹ (5.46 μg), ●, cell volume at cell division.

simultaneously with cell separation. A long G2 period follows culminating in nuclear division about three-quarters of the way through the cell cycle. There is then a short G1 period ending with the start of the S period of the next cell cycle.

Characterisation of mutant strain

The mutant strain cdc9-50 was isolated from wild-type *S. pombe* (972h⁻ obtained from U. Leupold, Bern) after nitrosoguanidine mutagenesis (P. Nurse and B. Carter, unpublished). When grown at 35 °C, cells of strain cdc9-50 divide at about half the volume of wild-type cells at that temperature (Table 1). The mutant phenotype is temperature-enhanced since at 25 °C cdc9-50 divides at a cell volume only 15% smaller than wild type (Table 1). These differences are also reflected in the RNA and protein content per cell in exponentially growing cultures of the two strains at the two temperatures (Table 1). Thus cdc9-50 divides at both a lower cell colume and a reduced macro-molecular content compared with wild type. In spite of these differences cdc9-50 has a similar generation time to wild type at both 25 °C and 35 °C (Table 1).

The mutant phenotype of reduced cell size at division segregated 2 : 2 in all of 27 asci dissected from a wild-type 975 h⁺ × cdc9-50h⁻ cross (P Thuriaux, personal communication), demonstrating that it is caused by a mutation in a single nuclear gene

Size control over nuclear division

Use was made of the temperature sensitivity of the mutant phenotype to determine the stage in the cell division cycle at which the coupling of cellular growth to cell division takes place. Exponentially growing cultures of cdc9-50 and wild type at 25 °C were shifted to 35 °C. Cell number in the wild-type culture continued to increase for 50 min, stopped for about 30 min, and then gradually increased to the normal growth rate at 35 °C (Fig. 1). During the short plateau in cell numbers, RNA and protein continued to increase, consistent with the increase in cell volume at division that is observed at this time (Fig. 1). The temperature shift temporarily inhibits nuclear division, since for 25 min after the shift there is no further increase in the number of nuclei per ml of culture, and the normal rate of increase at 35 °C is only reached after a further 70 min (Fig. 1). Those cells in which nuclear division is temporarily inhibited are delayed from entering cell division, accounting for the observed short plateau and reduced rate of increase in cell number.

On shifting the culture of cdc9-50 from 25 °C to 35 °C, cell number continued to increase for 50 min and then almost stopped, similar to the behaviour observed in wild

type (Fig 2) Unlike wild type, however, the plateau in cell number was very short (10–15 min) and was followed by a rapid rise rather faster than the usual rate of increase at 35 °C (Fig. 2). This rapid rise in cell number was preceded by a dramatic drop in cell volume at division (Fig. 2). RNA and protein continued to rise as in wild type (Fig. 2) and thus the RNA and protein content per cell dropped to the reduced level observed in exponential culture at 35 °C (Table 1) For 20 min after the temperature shift there was no increase in the number of nuclei per ml of culture showing an inhibition of nuclear division similar to wild type (Fig. 2). Thereafter there was a very rapid rise for a period of 40–50 min (Fig. 2), much faster than the normal rate of increase at 35 °C This suggests that nuclear division is initiated in a large proportion of the population after a period of about 20 min at the higher temperature.

These data can be explained in terms of a size control over the initiation of nuclear division. In wild type at 25 °C the cell grows to a critical size and nuclear division is then initiated. On shift to 35 °C this control is modulated so that the cell grows to a larger size before nuclear division can take place. In cdc9–50 the size control is altered so that at 35 °C nuclear division occurs in cells of a smaller size than wild type On shift from 25 °C to 35 °C nuclear division is briefly inhibited by the same modulation that is observed in wild type. The mutant phenotype, however, rapidly expresses itself by reducing the cell size at which nuclear division is initiated. This results in nuclear division occurring immediately in that proportion of the cell population that were too small for initiation at 25 °C, but which were above the smaller critical size required at 35 °C Thus cells that were too small to divide at 25 °C would be accelerated through the cell division cycle and would divide at the smaller size characteristic of growth at 35 °C.

If cdc9–50 has an altered size control over the initiation of nuclear division, then nuclear division should occur in cells of a smaller size compared with wild type. When grown at 35 °C cells of cdc9–50 containing dividing nuclei were about half the volume of similar cells of wild type (Table 1). At 25 °C cells of cdc9–50 containing dividing nuclei were only about 20% smaller than wild type (Table 1) These relative differences are similar to the differences observed in cell volume at cell division for the two strains at the two temperatures. This would suggest that the size control over nuclear division determines cell size at cell division.

Timing of DNA synthesis during the cell cycle

The DNA content per cell in exponentially growing cultures is slightly reduced in cdc9–50 at 35 °C compared with wild type (Table 2) This suggests that a greater proportion of cells have the unreplicated 1C content of DNA in cdc9–50, and hence DNA synthesis occurs a little later in the cell cycle than in wild type. This was checked by

Fig. 2 Cell number, nuclei number, RNA, protein and cell volume at division of cdc9–50 during the transition from exponential growth at 25 °C to 35 °C. All experimental details as for Fig. 1. ■, No. of nuclei ml⁻¹ (1×10^6); ▲, cell number ml⁻¹ (1×10^6); O, protein ml⁻¹ (16 8 µg); □, RNA ml⁻¹ (4.58 µg); ●, cell volume at cell division.

measuring the increase in cell number in exponentially growing cultures after inhibiting DNA synthesis with hydroxyurea[2]. Under these conditions only those cells which have completed DNA synthesis can undergo cell division. The cell number increase for cdc9–50 was reduced compared with wild type (Table 2), again suggesting that DNA synthesis occurs later in the cell cycle in the mutant strain.

Table 2 Timing during the cell cycle and cell size at which DNA synthesis takes place in wild-type 972 and cdc9–50 growing at 35 °C

Strain	DNA content per cell in exponential culture (fg per cell)		Cell number increase after inhibition of DNA synthesis	Fraction of a cell division cycle at which midpoint of rise in DNA occurred	Macromolecular content per cell at midpoint of rise in DNA			
					Calculated		Measured	
	Mean	s e.			Protein (pg per cell)	RNA (pg per cell)	Protein (pg per cell)	RNA (pg per cell)
Wild type 972	34.6	1 4	× 2.04	0.00	10.2	2.09	12.0	2.61
Mutant cdc9–50	28.4	0.77	× 1.86	0.29	6.29	1.35	5 87	1.37

Strains were grown at 35 °C as described in Table 1; DNA, protein and RNA content per cell were determined as described in ref. 12. Inhibition of DNA synthesis was achieved by the addition of 11 mM hydroxyurea. Three synchronous cultures were prepared as described in Fig 3 and the mean fraction of the cell cycle at which the midpoint of rise in DNA occurred was determined (cell separation was taken as 0). The macromolecular content per cell at this time was measured, and was also calculated using the method described in ref. 8 and the data from Table 1.
Fig. 3 DNA and cell number during synchronous cultures at 35 °C of *cdc9–50* (*a*) and wild-type 972 (*b*). Strains were grown at 35 °C as described in Table 1. Small cells were selected from these cultures by sedimentation rate centrifugation through a lactose gradient in a zonal rotor[7]. The small cells were used as an innoculum for synchronous cultures and DNA and cell number determined, as described in ref. 12. A cell cycle map is given for both cultures starting at cell separation and showing the time of the midpoint of the rise in DNA. The real values of the experimental parameters per ml, equivalent to one unit on the arbitrary log scale, is given in brackets in the symbol key. *a*, ●, DNA ml⁻¹ (8.63 ng); ■, cell number ml⁻¹ (4×10⁶). *b*, ●, DNA ml⁻¹ (7.47 ng); ■, cell number ml⁻¹ (3×10⁶).

These observations were confirmed by synchronous cultures of *cdc9–50* and wild type at 35 °C. Synchronous cultures were prepared by selection of small cells from an exponentially growing asynchronous population using sedimentation rate centrifugation through a lactose density gradient[5,7]. In wild type the midpoint of the rise in DNA occurred at the beginning of the cell cycle simultaneously with cell separation (Fig. 3, Table 2). This timing is similar to that found in wild type at 32 °C (ref. 6). In *cdc9–50*, however, the midpoint of the rise in DNA occurred at 0.3 of a cell cycle, about 40 min later than cell separation (Fig. 3, Table 2). Thus in *cdc9–50* the G1 period is substantially lengthened at the expense of G2.

Knowledge of the timing of DNA synthesis during the cell cycle, and of the protein or RNA content per cell of an exponentially growing culture enables the protein or RNA content of cells undergoing DNA synthesis to be calculated[8]. Assuming protein and RNA to be accumulated exponentially during the cell cycle[9], the protein and RNA content

of cells undergoing DNA synthesis has been calculated for 972 and *cdc9–50* at 35 °C (Table 2). It can be seen that the macromolecular content of these cells is much reduced in *cdc9–50* compared with wild type. This was confirmed by measuring the actual protein and RNA content of cells at the midpoint of the rise in DNA in the synchronous cultures (Table 2).

These results demonstrate that the mutant strain shows several differences to wild type. The timing of DNA synthesis in the cell cycle, the size at which cells undergo DNA synthesis, and the size at which cells undergo nuclear division are all different from wild type growing under identical conditions with the same generation time. Thus the single genetic lesion in *cdc9–50* has profoundly altered the controls acting on a number of events occurring during the cell division cycle.

Model of cell cycle controls

To explain the pleiotropic behaviour of *cdc9–50* and the maintenance of a constant cell size at division, it is necessary to invoke controls that act at both nuclear division and DNA synthesis. One such model would be that a cell size control acts over the initiation of nuclear division, and a second separate size control acts over an event required for initiation of DNA synthesis. The latter size control refers more precisely to a critical mass per genome which in wild-type cells is attained in the cell cycle previous to that in which DNA synthesis actually occurs. This is because the size control over nuclear division produces daughter cells that are already larger than the threshold size required to initiate DNA synthesis. Since nuclear division is required before DNA synthesis can take place (ref. 10 and my unpublished results using temperature-sensitive mutants defective in nuclear division), DNA synthesis cannot occur early in the previous cell cycle at the threshold cell size, but will be delayed until after nuclear division. Therefore the size control over DNA synthesis would not be expressed. In *cdc9–50* the genetic lesion reduces the cell size at which nuclear division occurs, but does not alter the size control over the initiation event required for DNA synthesis. In this situation the size control over nuclear division produces daughter cells smaller than the threshold size required to initiate DNA synthesis. The cell then has to grow for a further 0.3 of a cell cycle before it is large enough for DNA synthesis to take place. In wild type the size control over DNA synthesis may be expressed only when the cell is growing in adverse conditions. For example, on approaching stationary phase, yeast cells tend to divide at a smaller size[5,11,12], and so the size control over DNA synthesis would be expressed. The operation of the size control would then prevent a new DNA synthesis–nuclear division cycle being started, accounting for the observed accumulation of stationary phase yeast cells in the G1 period of the cell cycle[11,12].

It should be noted that nuclear division could seem to be under a size control if there was a timing mechanism maintaining a constant period between the initiation event required for DNA synthesis and nuclear division. If the genetic lesion in *cdc9–50* resulted in a shortened period compared with wild type, then nuclear division would be initiated earlier when the cell had grown less, and hence cell division would take place at a smaller size. In this situation which is directly analogous to that proposed for the control of the cell cycle in bacteria[13], *cdc9–50* should be considered as altered in a timing mechanism rather than in a cell size sensing mechanism

Thus fission yeast seems to maintain coordination between growth and cell division with cell size controls over DNA synthesis and nuclear division. The latter size control could, however, also be the consequence of a constant timing period between DNA synthesis and nuclear division.

and encouragement, in particular B. L. A. Carter and J. Creanor for advice with the synchronous cultures and P. A. Fantes for first suggesting an altered timing mechanism The work was supported by a grant from the Science Research Council.

Infective transmission and characterisation of a C-type virus released by cultured human myeloid leukaemia cells

A C-type virus isolated from long term cultures of myeloid cells from a patient with acute myelogenous leukaemia is infectious for a wide variety of cells. The establishment of chronically infected cells enabled us to characterise the virus by biological, immunological, and biochemical tests. The virus is closely related to the simian sarcoma-associated virus isolated from a woolly monkey fibrosarcoma.

THE possibility that C-type RNA tumour viruses are involved in human neoplastic disease has been the subject of much experimentation and speculation recently. In particular, human leukaemia has come under close scrutiny because so many leukaemias from diverse species of animals such as chickens, cats, and mice, have a viral aetiology[1,2]. Although viraemia does not accompany human leukaemia, it is possible that a C-type virus exists in a latent state and some of the well-known 'footprints' of C-type viruses have been detected in a variety of leukaemic tissues. These include: (1) cellular nucleic acid sequences homologous to viral RNA[3-7]; (2) presence of RNA-directed DNA polymerase (reverse transcriptase) activity akin to the viral enzyme[3,8-14]; (3) presence of intracellular proteins that cross react in serological tests with antibodies to 'virus-specific proteins[15,16]; and infrequently (4) electron microscopic identification of virus-like particles[10,12,17,18]. In many of these reports the virus-like components in the fresh human leukaemic cells were shown to be most closely related to similar components from oncogenic primate RNA tumour viruses, especially woolly monkey (simian) sarcoma virus (SSV)[4,5,7,14-16].

Gallagher and Gallo[19] have reported the production and preliminary characterisation of C-type virus particles from long term cultures of myeloid cells from one patient, HL23, with acute myelogenous leukaemia (AML). The uncultured blood cells of this patient contained reverse transcriptase related to that of SSV (ref. 14). The virus released by HL23 cells is called HL23V-1. In addition, they have now reported the release of similar particles from cells derived from a bone marrow specimen from the same patient obtained 14 months after the original blood specimen[20]. This virus is called HL23V-5.

Here we show that these C-type particles are infectious. The virus may be propagated to high titre in several cell types and a quantitative bioassay is described. The production of substantial titres of virus has enabled us to characterise the virus in detail and to compare it with and show that it closely resembles the C-type SSV and its associated virus (SSAV) previously isolated from a fibrosarcoma of a woolly monkey[21].

Infective nature of virus particles

Supernatant fluids from the AML peripheral blood cell cultures containing virus-like reverse transcriptase activity were initially inoculated on to a wide variety of animal and human cells. After transient bursts of viral replication over a period of 3 months, four chronically infected cell lines were established in A204 cells (human rhabdomyosarcoma), WHE2 cells (fibroblastic strain from a whole human embryo), A7573 (canine thymus) cells, and NRK (normal rat kidney) cells. The establishment of chronically infected virus-producing cells was therefore neither a frequent nor a rapid event. A more rapid transmission of the virus to two cell lines (A204; and KNRK, a rat kidney cell line transformed by, but not producing, Kirsten murine sarcoma virus) was obtained, however, within 3 weeks of exposure of these cells to β-propiolactone-inactivated Sendai virus immediately before inoculation with supernatant fluids from the AML cell cultures. Table 1 shows the variety of cells infected with the AML culture fluids and the frequency of infectious transmission to new host cells. The viruses produced by these new host cells are referred to as 'secondary' viruses; the nature of the host producing each secondary virus is indicated in parentheses.

The secondary HL23V-1 viruses will infect a wider variety of cells than the primary virus (Table 2). This may be a result of the virus acquiring a genuinely wider host range or more likely the result of selection by infective transmission of higher titre virus stocks and higher infectivity to particle ratios. Electron microscopy of chronically infected cultures revealed abundant C-type virus particles (Fig. 1). In contrast to the host range of SSAV, most of the HL23V-1 isolates infected 1283 marmoset cells poorly and human cells well (Tables 1–3).

*Human acute myeloid leukaemic (AML) cells were passaged in tissue culture as previously described[19]. At passage 10, when the supernatant had more than a threefold higher incorporation of ^{3}H-TMP in the presence of poly(rA)·oligo(dT) compared with poly(dA)·oligo(dT) in a reverse transcriptase reaction[20], subconfluent cultures of the various cell types were infected with these fluids. 10^5 target cells were seeded in 5-ml flasks containing complete media and polybrene, 2 μg ml⁻¹. After 16 h the cells were washed and treated with 0.5 ml of cell-free supernatant from the AML cell culture (Strain I-1, ref. 20). The cultures were passaged at weekly intervals and supernatant fluids were periodically assayed for reverse transcriptase activity.

†+, ^{3}H-TMP incorporation with poly(rA)·oligo(dT) more than twofold higher than incorporation in response to poly(dA)·oligo(dT); —, less than twofold stimulation. ND, not done.

‡The test cells were exposed to 10^3 haemagglutination units of β-propiolactone-inactivated Sendai virus at 4 °C for 30 min. The cells were then washed and the AML cell culture supernatants were added in 0.2 ml volumes for 60 min at 37 °C; tissue culture medium was then added. Cell cultures were passaged at weekly intervals and assayed as mentioned above.

Quantitative plaque assay for HL23V-1

In addition to screening supernatant samples for reverse transcriptase activity, it is also possible to titrate the HL23V-1 virus isolates by an *in vitro* plaque assay test. The XC syncytial plaque assay technique[22], described and developed for the murine leukaemia viruses, is also suitable for titration of the non-human primate viruses[23], simian sarcoma associated virus (SSAV) and gibbon ape leukaemia virus (GALV)[24]. Utilising the standard technique[22], we have been able to make quantitative determinations of the HL23V-1 virus isolates on various cell types (Table 3). Although the human and rhesus monkey cells show the greatest susceptibility to infection by these viruses, a linear dose–response curve is obtained on all cell lines tested.

The availability of a plaque assay affords the opportunity to study the quantitative neutralisation patterns with sera from normal human subjects, leukaemic patients, and antisera prepared specifically against animal C-type viruses such as SSV. Recently Snyder *et al.*[25] have shown by radioimmunoassays that all human sera contain antibodies to the major proteins and glycoproteins of several C-type viruses, including SSV.

We are currently screening a variety of sera, by plaque neutralisation tests and by a radioimmunoprecipitation assay, for antibodies that cross react with the HL23V-1 isolates. Our tests so far indicate that antibodies that react with HL23V-1 are widely represented in the human population (R. Kurth, T. Oliver, R. W. and N. M. T., unpublished).

Formation and envelope specificity of murine sarcoma virus pseudotypes rescued by HL23V-1

Murine sarcoma virus (MSV) strains are defective for replication and require leukaemia viruses for propagation of infectious stocks. The leukaemia 'helper' virus provides envelope antigens, reverse transcriptase and perhaps other viral structural components for the MSV and the complemented, infectious MSV particles are called pseudotypes. 'Non-producer' cells transformed by MSV can be obtained by infection with high dilutions of MSV, and infectious MSV pseudotypes can be rescued on superinfection of the cells with helper virus. Leukaemia viruses of other species, such as feline leukaemia virus, GALV and SSAV will also rescue MSV pseudotypes on super-infection of susceptible non-producer cells. The KNRK cells

Table 2 Infectivity of secondarily-passaged HL23V-1 viruses as measured by reverse transcriptase activity

Cells of each cell type were seeded at 3.5×10^5 cells per flask (Falcon T30) and infected on the following day in medium containing 20 μg polybrene ml⁻¹. Medium was changed every 2 d and the fluids were collected on day 8 for assay of reverse transcriptase activity. Corrections for background c.p.m. have been subtracted.

used for the propagation of HL23V-1 are transformed, non-producer cells containing the genome of Kirsten-MSV. We therefore assayed the HL23V-1(KNRK) virus for focus-forming units (FFU) on NRK, 7605L, mink, and Japanese quail cells and found titres of up to 10^5 FFU ml^{-1} on all these cell types. The MSV(HL23V-1) pseudotype from infected KNRK cells plated with a linear dose response on NRK cells. The other HL23V-1 isolates, which were not propagated in MSV-containing cells, did not contain focus-forming virus in our assay, but could act as helper viruses. For example, when MSV-containing human cells (kindly provided by Dr P. Peebles) were super-infected with HL23V-1 (A7573), MSV pseudotypes were rescued at a titre of 2×10^4 FFU ml^{-1}.

The MSV pseudotype focus assay can be used as an alternative to the XC syncytial plaque assay in neutralisation tests with antisera. A 1% dilution of antiserum to SSV raised in a goat (kindly provided by Dr F. Deinhardt) which gave a 1,000-fold reduction in titre of MSV(SSAV) neutralised MSV(HL23V-1) to a similar degree. Serum from patient HL23, from whom the virus-producing myeloid cell line was originally derived, did not significantly neutralise MSV(HL23V-1) or MSV(SSAV) pseudotypes. Preliminary tests, however, indicate that weak neutralising activity (approximately 10-fold reduction of FFU using 10^{-1} dilutions of serum) is evident in the sera of some normal individuals and patients in remission stages of myelogenous leukaemia.

The MSV pseudotypes were also used in a virus interference test. 7605L foetal human lung fibroblasts cells were infected with HL23V-1(A7573) or GALV and were challenged after three passages with MSV(HL23V-1) and MSV(SSAV) propagated in KNRK cells. Both leukaemia viruses reduced the plating efficiency of the two MSV pseudotypes to less than 1% that on uninfected 7605L cells. This indicates relatedness among cell receptor sites for SSAV, GALV and HL23V-1. The combined results from neutralisation and interference assays suggest that the envelope proteins of the three groups of viruses are genetically related.

Immunological characterisation of proteins of the HL23V-1 isolates

Biochemical and immunological characterisation of the HL23V-1 virus strains was carried out to evaluate the relationship of the secondary virus isolates to (1) the parental virus isolate, (2) the other secondary virus isolates, and (3) the non-human primate viruses, SSV and GALV.

Antibodies to the reverse transcriptase enzymes from the different C-type viruses have become valuable tools for studying immunological relatedness among these viruses. A quantitative assay for neutralisation of reverse transcriptase activity used antisera prepared specifically against the purified viral enzymes [11,13,19]. We used this technique to analyse the serological specificity of the enzyme activity in supernatant fluids from the myeloid cells producing the primary virus and the cells producing the secondary virus isolates (Table 4).

The viruses produced by the AML cells in culture, HL23V-1

Fig. 1 C-type particles in HL23V-1-infected KNRK cells ($\times 18,600$).

(ref. 19) and HL23V-5 (ref. 20) from peripheral blood and bone marrow, respectively, obtained from the patient several months apart, show nearly identical patterns in these assays of inhibition of reverse transcriptase activity. They are most strongly inhibited by antiserum prepared against the SSV enzyme, less strongly inhibited by anti-GALV enzyme and inhibited least by antiserum to RD114 enzyme (Table 4). This last neutralisation pattern is also seen when purified SSV and GALV enzymes are treated with the RD114 antiserum. By these criteria, the HL23V isolates are most closely related to SSV and GALV.

The specificity of the reverse transcriptases of the secondarily propagated viruses gave much the same pattern as the primary isolates. One interesting anomaly is the HL23V-1 virus grown in A204 cells which may contain two C-type viruses. As with the protein analysis (see below) and the low XC plaque titres, this virus isolate shows a larger cross reaction to RD114 than the other isolates. Also noteworthy is the shift in this pattern with continued passage (compare experiments 1 and 2) which could represent the selection of the SSV-like component over the RD114-like component. Further studies are in progress to elucidate the basis of this phenomenon.

Other tests (not shown) using antisera prepared against the enzymes of feline leukaemia virus, Rauscher murine leukaemia virus, Mason–Pfizer virus, avian myeloblastosis virus, and human cellular polymerase α show little or no inhibition of the HL23V-1 viral reverse transcriptase.

The secondary cells infected by HL23V-1 contained proteins that bound antibodies prepared against p30 protein [26] of SSV and GALV but not with antisera prepared against p30 of mouse or rat leukaemia viruses (R. Gilden, personal communication). In addition, secondarily-infected A204 and A7573 cells contained a protein that reacted with antisera prepared against p30 of baboon endogenous virus and, to a lesser extent, RD114. The p30 proteins of GALV and SSV are not distinguishable by immunological cross-reaction assays [27]; therefore the relatedness of p30 from HL23V-1 to p30 of SSV and GALV indicates that

Table 3 XC syncytial plaque assay of HL23V-1 isolates

Cells	Plaque-forming units per ml of virus

1283	5.0×10^1	5.5×10^4	5.0×10^2	1.0×10^2	2.0×10^4
NRK	1.5×10^2	7.7×10^5	1.7×10^5	$< 5.0 \times 10^3$	3.5×10^5
SIRC	$< 5.3 \times 10^3$	7.5×10^4	5.5×10^4	$< 5.0 \times 10^3$	5.0×10^3

Cells were seeded at 2×10^5 per 35-mm diameter plates (Linbro) and infected on the following day with 0.1-ml volumes of serially 10-fold diluted virus stocks in the presence of 20 μg ml^{-1} polybrene. Assays were done according to the standard XC plaque method. Reverse transcriptase assays on the various input virus inocula were determined; ^{3}H-TMP incorporated per ml of undiluted virus in a 30 min reaction with poly(rA)·oligo(dT): 6.9×10^6 c.p.m. for HL23V-1 (A204); 1.2×10^7 c.p.m. for HL23V-1 (KNRK); 2.5×10^6 c.p.m. for HL23V-1 (A7573); and 5.8×10^5 c.p.m. for HL23V-1 (WHE2). Cells not mentioned previously: 7605L, foetal human lung fibroblasts (kindly provided by Dr E. H. Macintyre) and FRhL-1, foetal rhesus monkey lung cells (US Division of Biological Standards).

% Inhibition of reverse transcriptase activity by

Antisera reactions and reagents are described elsewhere[19]. Inhibition represents the reduction in DNA polymerase activity, using the primer–template poly(rA)·oligo(dT) and ^{3}H-TTP, with an immune serum compared to that with non-immune serum. DNA polymerase activity did not significantly differ when non-immune serum was replaced by 0.1 M Tris, pH 8.0. Values represent the average of duplicate determinations in assays with a minimum of 15,000 c.p.m. above background in the absence of immune serum.

*Antiserum to reverse transcriptase of RD114, an endogenous virus of domestic cats[28-31], which also selectively inhibits the reverse transcriptase of an endogenous primate virus isolated from normal baboon tissues[32,33]. Antiserum kindly provided by Dr R. Gilden.

†Antisera to reverse transcriptases of the two primate C-type viruses. Preparation of antisera in rabbits and rats has been described previously[19].

‡HL23V-1, C-type virus produced by cultured myelogenous leukaemia cells from peripheral blood of patient HL23. HL23V-5, C-type virus from cultured myelogenous leukaemia cells from a bone marrow specimen of the same patient.

§Mean values from determinations achieved with different collections of media in January 1975 (expt 1) and in March 1975 (expt 2) after further passage of the same cultures.

¶Ranges from multiple assays.

all three viruses are members of the same family, not that they are identical.

In a competitive radioimmune assay for p12 viral protein, secondary cells infected by HL23V-1 contain a protein that is indistinguishable from p12 protein of SSV but unrelated to p12 from GALV (Tronick, Stephenson, and Aaronson, personal communication).

Nucleic acid hybridisation

For molecular hybridisation studies using viral RNA, the supernatant fluids of infected cells were clarified, centrifuged through sucrose gradients, and the poly(A)-containing 70S RNA was extracted. All of the HL23V-1 secondary viruses had characteristic 70S RNA and these purified RNAs were then subsequently used for hybridisation reactions.

The viral RNAs were hybridised with cellular DNA of uninfected NRK or KNRK cells or SSV-infected KNRK cells to analyse the genetic relatedness of the HL23V-1 isolates to SSV (Table 5). All the HL23V-1 RNAs show more hybridisation to DNA from those cells infected by SSV than to DNA from uninfected cells. Therefore a qualitative relationship exists

between the nucleic acid of SSV and those of the HL23V-1 isolates. Further studies to determine the degree of homology between the different viral RNAs, by hybridisation between the viral RNAs and their complementary DNA transcripts, are in progress. It is interesting to note the low degree of hybridisation seen between the viral RNAs and DNA from normal human cells; this would indicate that viral genetic material related to HL23V-1 is not maintained as an endogenous genetic component in humans, at least not in all cells.

To elucidate further the genetic relatedness between HL23V-1 and SSV, hybrids formed between SSV 70S RNA and infected and uninfected cellular DNA were subjected to an analysis of thermal stability (Fig. 2). From such profiles, the t_m values (the temperature at which 50% of the hybrid is dissociated) indicate the extent to which the hybrids are well matched in base pairing. The t_m curves are rather broad, indicating heterogeneity in provirus DNA and/or in virus RNA. As can be expected, however, the hybrids formed between SSV RNA and DNA from cells from two different species infected with SSV have a high t_m and therefore better matching of base pair sequences than do the hybrids with normal gibbon ape DNA, cells infected with GALV, or cells infected with one of the HL23V-1 viruses.

% Hybridisation of viral RNAs

Virus-producing cells were labelled for 48 h with 100 µCi ml⁻¹ ^{3}H-uridine. Media was freed of cells by centrifugation at 1,000g for 10 min, adjusted to a final concentration of 1% SDS, 0.1% polyvinylsulphate, and 0.3 M NaCl, and passed over an 0.2 ml bed volume column of oligo-(dT)-cellulose at 25 °C and 1 ml min⁻¹. Poly(A)-containing RNA was eluted with 10 mM Tris, pH 7.4 and centrifuged for 2 h at 22 °C in 5–20% sucrose gradients containing 0.5% SDS, 0.01 M Tris,, pH 7.4, 0.1 M NaCl and 0.001 M EDTA. The 70S RNA was used in hybridisation experiments. Hybridisation mixtures of 0.1 ml consisted of 300 c.p.m. of ^{3}H-RNA (0.3–1 ng), 1 mg of DNA, and 0.3 M PO₄, pH 6.8. The mixtures were flame-sealed in capillary tubes, boiled for 5 min, and then incubated at 60 °C for 7 d (C_0t = 20,000 uncorrected for ionic strength). The contents of the capillary tubes were expelled into 0.8 ml of 2×SSC (0.3 M NaCl, 0.03 M Na citrate, pH 7.0). A 0.2 ml aliquot was precipitated with 10% trichloroacetic acid (TCA); the remaining 0.6 ml aliquot was incubated with 20 µg ml⁻¹ of RNase for 2 h at 37 °C, then precipitated with TCA. The precipitates were collected on nitrocellulose membrane filters, incubated for 1 h at 60 °C with 1 ml of 0.2 M NaOH mixed with 1 ml 50% acetic acid, and counted in 10 ml of Aquasol after incubating 24–36 h at 5 °C in the dark. No TCA-precipitable radioactivity was lost during hybridisation at 60 °C. Percentage RNA hybridised = (c.p.m. in RNase-treated aliquot) (c.p.m. in 0.2 ml aliquot × 3)⁻¹ × 100.

*SSV grown in NRK rat cells or in 71AP1 marmoset cells.

†KNRK cells infected with SSV.
Fig. 2 Thermal stability profiles of hybrids formed between SSV 70S RNA and infected cellular DNAs. [125]I-70S RNA isolated from simian sarcoma virus (SSV) produced by 71AP1 marmoset cells (15,000 c.p.m.; 5×10^7 c.p.m.μg^{-1}) was hybridised at 60 °C in 0.4 M PO_4 to 1,000 μg of DNA isolated from the indicated cells. Hybridisation was carried out to a $C_0 t$ of 20,000 with respect to DNA concentration and uncorrected for (Na⁺). Hybrid solutions were expelled into a 100-fold volume excess of 0.15 M Na⁺, divided into 0.5 ml aliquots, and held at the indicated temperature for 5 min. The solution was brought to final concentrations of 0.45 M Na⁺ and 20 μg ml^{-1} RNase, and the sample was incubated for 2 h at 37 °C. Acid-insoluble material was collected on nitrocellulose membrane filters. ○, HF marmoset cells infected by and producing SSV; □, rat cells infected by and producing SSV; ●, human rhabdomyosarcoma cells infected by and producing HL23V-1; ×, human lymphoblastoid cells infected by and producing gibbon ape leukaemia virus; ■, fresh brain tissue from an apparently normal gibbon ape. The percentage SSV RNA hybridised was 9 % with normal gibbon DNA and 25–50 % with DNA from virus-infected cells.

Although the hybridisation and immunological assays of genetic similarity show that the nucleic acids and proteins of HL23V-1 and SSV are closely related, the t_m experiment suggests that genomic differences do exist between HL23V-1(A204) and SSV. More complete analysis will be presented elsewhere.

Possible implications

It is not surpising to find a C-type virus associated with acute myelogenous leukaemia; viral-related proteins and nucleic acid sequences have been detected in a variety of leukaemias and sarcomas in humans. We have shown here, however, that such virus-related markers can be associated with an infectious virus particle. Freshly isolated leukaemia cells do not release readily detectable C-type virus and the capacity to maintain and propagate the myeloid leukaemic cells in culture for extended periods of time may have allowed production of transmissable virus in this case. Myeloid cell cultures established from an independent, later biopsy of the same patient also release virus particles as measured by reverse transcriptase activity[20]. We have found that this virus, designated HL23V-5, is also infectious for human cells and can be titrated by the XC syncytial plaque assay.

The clear resemblance of the HL23V-1 viruses from human AML cells to the SSAV isolated from a fibrosarcoma of a woolly monkey is striking. The viruses are markedly similar by biological, immunological and molecular criteria. But our data on the relative plating efficiencies on human and 1283 marmoset cells, the inhibition of reverse transcriptase activity

by specific antisera, and the nucleic acid hybridisation studies suggest that, though closely related, the HL23V-1 virus and SSV are not identical. Many precautions were taken to ensure against the possibility of a laboratory contamination[19]; there was no SSAV grown or handled in the biohazard facility in which the myeloid cells or chronically infected cells were maintained. Should we then be surprised by the relatedness of the simian and human viruses? One interesting fact is that the SSV(SSAV) viruses were obtained from a woolly monkey that had been a pet[14] and was therefore in close contact with a human population. We do not know of any C-type viruses isolated from other woolly monkeys. If the HL23V-1 virus and SSAV do indeed have a common origin, it is plausible that the monkey was infected by the human virus. Preliminary serological studies indicate that antibodies to the virus are widespread in the human population. Moreover, a closely related virus has been isolated several times from normal human embryo cells by Panem et al.[34], and Nooter et al. describe elsewhere in this issue the isolation of an SSV-related virus from human leukaemic cells[35]. We should bear in mind, however that isolation of the virus from leukaemic cells does not necessarily mean that the virus is aetiologically related to the leukaemia. Tests are currently in progress to determine whether the virus has oncogenic potential in animals.

Our characterisation of the infectious nature of this virus may be useful in detection and propagation of similar viruses from freshly-isolated leukaemic and solid tumour tissues.

Multiple steps in DNA recognition by restriction endonuclease from *E. coli* K

Robert Yuan, Thomas A. Bickle, Walter Ebbers & Christine Brack

Department of Microbiology, Biozentrum of the University of Basel, Basel, Switzerland.

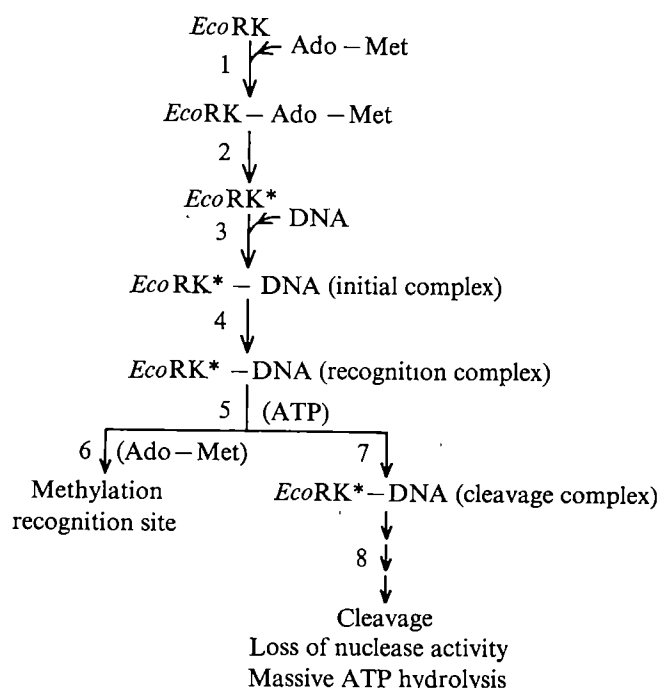
The process of DNA recognition by the activated form of the restriction endonuclease from E. coli *K involves three enzyme–DNA complexes which can be differentiated experimentally. These are: an initial complex formed at a nonspecific site; a recognition complex involving the host specificity site; and a cleavage complex dependent on the presence of ATP.*

THE restriction endonuclease from *Escherichia coli* K, *Eco*RK, is a complex multifunctional protein which cleaves unmodified DNA in the presence of S-adenosylmethionine (Ado–Met), ATP and Mg^{2+} (ref. 1). A powerful ATPase activity appears during the course of this restriction reaction[2] and the same protein is also able to methylate unmodified DNA, rendering it insensitive to its own restriction activity[3].

The way in which the enzyme recognises the host specificity sequence on the DNA, and the factors that determine whether it will act as an endonuclease, or as a methylase, are two aspects of the mechanism which go beyond the immediate area of restriction and modification. The first of these, recognition of nucleotide sequences, is common to most proteins that react with nucleic acids. The second is that the interaction involved in the recognition of the nucleotide sequence directs the protein towards either of two opposed modes of action, restriction or modification. In other words, a specific nucleotide sequence may not only be recognised by a protein, but also act as a signal for the mode of action of a multifunctional enzyme.

In a certain perverse way, it is the very complexity of this protein and the reactions that it carries out that enables us to distinguish experimentally four major stages in the *in vitro* reaction (Fig. 1). These are: Enzyme activation: *Eco*RK binds Ado–Met rapidly, and in a slow second step, an allosteric transition to an activated form (*Eco*RK*) takes place. DNA recognition: *Eco*RK* interacts with DNA, first, at a nonspecific site (initial complex), and then at the unmodified recognition site (recognition complex). The recognition site is the host specificity site on the DNA that confers susceptibility to a given restriction and modification system (the sites for the K system are called sK). Enzyme action: in the absence of methyl groups at the recognition site, the DNA will be either cleaved or methylated. Methylation occurs at the recognition site while DNA scission takes place elsewhere. Loss of nuclease activity: the enzyme is altered following DNA cleavage, and is unable to cleave again. This phenomenon is probably related to the appearance of a vigorous and sustained ATP hydrolysis which begins at the time of DNA cleavage, but continues long after the DNA digest has reached its limit.

This paper deals with the process of DNA recognition. *Eco*RK* can form three distinct complexes with DNA in its restriction mode. It first forms an initial complex at a nonspecific site which is transformed to a more stable recognition complex if an unmodified host specificity site is present on the DNA. Neither of these complexes can be trapped on membrane filters. If ATP is added to the recognition complex, a rapid transition to a third complex which can be trapped on filters, takes place. This presumably occurs at the cleavage site.

Fig. 1 Reaction mechanism of endonuclease *Eco*RK.


Enzyme forms a specific complex with unmodified DNA that is retained on filters

*Eco*RK has previously been shown to form a specific complex with unmodified λ.0 DNA that can be stabilised with EDTA and detected by binding to nitrocellulose filters. (λ bacteriophage grown on a non-modifying host is designated λ.0; phage grown on a host that confers K-specific modification to the DNA is called λ.K.) The formation of this complex requires the presence of Ado–Met, ATP and Mg^{2+} (ref. 4). No filter-binding complex can be detected with modified λ.K DNA or with DNA that contains no recognition sites for the enzyme. Complex formation reaches its maximum after 2 min at 30 °C, and then decays at a rate consistent with its dissociation after DNA cleavage.

That this complex was not the result of binding to sK sites on the DNA was suggested by experiments with a purified restriction endonuclease from a mutant strain of *E. coli* K12 (ref. 5). This strain is unable to restrict, but can modify normally. As expected, the restriction enzyme purified from it can methylate (but cannot cleave) unmodified DNA *in vitro*. It does not form the filter binding complex. Therefore, *Eco*RK can recognise and methylate λ.0 DNA without forming a filter binding complex. The conclusion then is that the filter-binding complex must be associated with the cleavage reaction, and not DNA recognition proper.

Activated enzyme is stabilised by interaction with DNA

EcoRK* forms two different types of complex with DNA: a nonspecific initial complex and a specific recognition complex. These two complexes can be readily differentiated by observing the effect of λ.K, λ.0 and mutant λ DNAs on the stability of EcoRK*.

The slow allosteric activation to EcoRK* follows the rapid binding of Ado-Met to EcoRK[6]. On dilution to remove free Ado-Met, EcoRK* decays with a half life of 130 s. The effect of DNA on the stability of EcoRK* was determined by adding modified λ.K or λsK$_1$[0]sK$_2$[0].0 DNAs to the dilution buffer. The latter DNA is from a λ–Φ80 hybrid in which all of the sK sites have been eliminated[7]. Clearly both λ.K and λsK$_1$[0]sK$_2$[0].0 DNAs stabilise EcoRK* (Fig. 2a) and thus interact with it, although neither of them is a substrate for the enzyme. Similar stabilisation was observed with λ.0 and T4 DNAs. We define this kind of interaction as initial complex formation.

To detect differences in the interaction between EcoRK* and the various DNAs, the enzyme was activated in the presence of λ.0,λ.K or λsK$_1$[0]sK$_2$[0].0 DNAs and the stability of the complexes formed in these conditions was measured over a period of 60 min following dilution into prewarmed buffer (compared with 6 min in the previous experiment). Figure 2b shows that, although all of the DNAs protect EcoRK* from decay, substrate λ.0 DNA is more efficient than the others. The half life of the activated enzyme goes from 130 s for the enzyme alone to 6 min in the presence of the non-substrate λ.K and λsK$_1$[0]sK$_2$[0].0 DNAs and 22.5 min with substrate λ.0 DNA. This enables us to postulate an initial complex formed by EcoRK* with any DNA, and a more stable recognition complex formed with a DNA that contains the unmodified sK sequence.

Recognition complex is a precursor of the filter-binding complex

The complex formed by activating the enzyme in the presence of λ.0 DNA (that is, the recognition complex) does not bind to nitrocellulose filters, but the addition of ATP converts it to the filter-binding form. The rate at which this occurs seems to follow first-order kinetics with a half time for the reaction of 6.5 s. This is more than 10 times faster than the result obtained when EcoRK* is added to λ.0 ^{32}P-DNA and ATP (Fig. 3a), also a first-order reaction with a half time of about 80 s. Given these rapid binding kinetics, it cannot be ruled out that the recognition complex is, in fact, formed at the cleavage site after interaction with the sK site. Also in this figure are the kinetics of filter binding complex formation when a standard assay was initiated by the addition of non-activated enzyme, and when EcoRK* was diluted into λ.0 ^{32}P-DNA, and ATP was added 2 min later. In the latter case, no DNA binding was observed. Therefore, the rate at which the recognition complex was formed could not be measured directly.

The rate of activation of the enzyme in the presence of un-modified DNA is first or pseudo-first order (Fig. 3b) and is faster than activation of the enzyme alone[6] (respective half lives of 36s as against 54s). Therefore, interaction of the enzyme with DNA displaces the equilibrium towards complex formation and prevents the decay of EcoRK*.

The reaction of the recognition complex with ATP should be second order; therefore some subsequent rate-limiting change in the structure of the enzyme-DNA complex which generates the filter-binding form may explain the apparent first-order kinetics. The recognition complex formed in the absence of ATP was shown to be an intermediate in the restriction pathway. On dilution into ATP, the DNA was rapidly cleaved. The initial complex formed between EcoRK* and λ.K DNA (on dilution into λ.0 ^{32}P-DNA and ATP) produced filter-binding kinetics that were faster than the standard reaction rate and similar to
Fig. 2 Effect of DNA on the stability of EcoRK*. a, Stability of EcoRK* in presence or absence of DNA. b, Comparison of effect of different DNAs. a, λ.K and λ.0 ^{32}P-DNA were prepared as described previously[1]. λsK$_1$[0]sK$_2$[0].0 DNA was prepared from phage after heat induction of 803 (h[80]attλsK$_2$[0]cI$_{857}$S$_7$sK$_1$[0]), obtained from Dr N. Murray. EcoRK was purified to homogeneity after modifying the procedure published elsewhere[1]. All reaction mixtures for this and subsequent experiments contained 6 mM MgCl$_2$, 0.26 mM EDTA, 12 mM 2-mercaptoethanol and 100 mM either Tris–HCl or HEPES–OH, pH 8.0. Other additions are detailed in Figure legends. An aliquot (70 µl) of reaction mixture containing 0.13 nmol Ado-Met was mixed with 50 µl (50 µg) of EcoRK, incubated for 5 min at 30 °C, chilled and kept on ice. Aliquots (3 µl) were then diluted into 300 µl pre-warmed reaction buffer containing either no DNA, 0.3 µg of λ.K DNA, or 0.3 µg λsK$_1$[0]sK$_2$[0].0 DNA. After incubation for varying periods, 5 µl of the mixture containing 80 nmol ATP and 0.1 µg λ.0 ^{32}P-DNA (16,700 c.p.m.) were added and the incubation continued for a further 2 min. The reaction was terminated by the addition of 50 µl 0.5 M EDTA and filtered through a nitrocellulose filter. The filters were washed, dried and counted as described previously[4]. b, Three reaction mixtures of 100 µl containing 0.13 nmol Ado-Met each and either 2.4 µg λ.0 ^{32}P-DNA (380,000 c.p.m.), 2 2 µg λ.K DNA or 2.4 µg λsK$_1$[0]sK$_2$[0].0 DNA were prepared. They were incubated at 30 °C for 2 min with 30 µl (6 µg) EcoRK and then rapidly diluted with 11.5 ml prewarmed reaction buffer. Aliquots (500 µl) were removed at various intervals and mixed with either 20 µl ATP mixture (incubation containing λ.0 ^{32}P-DNA) or 20 µl ATP–DNA mixture (the other two incubations). ATP mixture contained 0 2 nmol ATP per 20 µl and ATP–DNA contained 0.2 nmol ATP and 96 ng λ.0[32]P -DNA per 20 µl (15,200 c.p.m.). After addition of the ATP mixture, further incubation was for 1 min, whereas after adding the DNA–ATP mixture the incubation was for 2 min. All reactions were terminated by the addition of 0.5 ml 0.1 M EDTA, filtered and counted as above ●, No DNA; △, λ.0 DNA; ×,λ.K DNA; ○, λsK$_1$[0]sK$_2$[0].0 DNA.

the rate when EcoRK* is added to λ.0 ³²P-DNA and ATP. Dissociation of the enzyme from such initial complexes must therefore be a relatively rapid process and the activated enzyme must interact with many different DNA molecules during protection by non-substrate DNA (compare the half life for protection of 6.5 min with the rapid release detected above).

Recognition complex is insensitive to heparin

The polyanionic glycan, heparin, is an inhibitor of both the DNA binding and cleavage reactions (R. Y., T. A. B., W. E., and C. B., unpublished). This inhibition has been used to study the interactions between the enzyme and substrate DNA. Table 1 shows the results of one such series of experiments. The addition of

Fig. 3 Kinetics of enzyme–DNA interactions. *a*, Kinetics of DNA binding to filters after ATP addition. *b*, Kinetics of enzyme activation in presence of DNA. *a*, Standard reaction kinetics were followed by adding 9 μl EcoRK (1 8 μg) to a prewarmed reaction mixture containing in 4.5 ml: 1.6 μg λ.0 ³²P-DNA (2.16 × 10⁵ c.p.m.), 1.8 μmol ATP and 120 nmol Ado–Met. Aliquots (250 μl) were removed into 25 μl 0 5 M EDTA after different times of incubation at 30 °C and the samples were then assayed on filters. EcoRK* was formed by adding 18 μl EcoRK (3 6 μg) to 190 μl reaction mixture containing 1 nmol Ado–Met and incubating for 3 min at 30 °C. This was chilled in ice and 5 μl aliquots were added to 250 μl reaction mixture containing 0.09 μg λ.0 ³²P-DNA (1.2 × 10⁴ c.p m) and 0 1 μmol ATP. Incubation was carried out for varying time intervals, the reaction was stopped with EDTA and the samples were filtered. In a separate set of incubations, 5 μl of the same EcoRK* was added to 250 μl of a similar mixture, but without ATP, the incubation continued for 3 min and 0.1 μmol ATP was then added After further incubation at 30 °C for varying time intervals, the reactions were terminated with EDTA and filtered. In the last set of reactions, the EcoRK*–λ.0 DNA recognition complex was formed by adding 9 μl (1.8 μg) EcoRK to 90 μl reaction mixture containing 2.4 nmol Ado–Met and 1.6 μg λ.0 ³²P-DNA (2 16 × 10⁵ c.p.m.) and incubating for 3 min at 30 °C. The mixture was chilled in ice and 5 μl aliquots were added to 250 μl reaction mixture containing 0.1 μmol ATP. The samples were incubated for different time intervals at 30 °C, stopped with EDTA and filtered. *b*, Reaction mixture (60 μl) containing 2.75 μg λ.0 ³²P-DNA (2.2 × 10⁵ c.p.m.), 0.13 nmol Ado–Met and 1 μl (0.2 μg) EcoRK was incubated at 30 °C, and at different times 3 μl aliquots were removed and mixed with 200 μl prewarmed buffer containing 0.1 μmol ATP. Each sample was then incubated for a further 2 min, 50 μl 0.5 M EDTA was added and the samples were filtered and counted as before. ●, Standard reaction kinetics; △, kinetics with EcoRK*; ×, incubation of EcoRK* with DNA in absence of ATP; ○, kinetics of filter binding with preformed recognition complex.

Fig. 4 EcoRK*–DNA complexes on glycerol gradients. *a*, Composite showing the positions of EcoRK* and λ DNA. *b*, EcoRK*–λ.0 DNA complex. *c*, EcoRK*–λ.K DNA complex. Four reaction mixtures of 100 μl containing: *a*, 0.45 μg λ.0 ³²P-DNA (63,000 c p.m) *a*, 6.7 nmol Ado–Met and 5 μl (1 μg) EcoRK; *b*, 0 45 μg λ.0 ³²P-DNA (63,000 c p.m.), 6.7 nmol Ado–Met and 5 μl (1 μg) EcoRK; *c*, 0.57 μg λ.K ³H-DNA (132,000 c.p.m), 6.7 nmol Ado–Met and 5 μl (1 μg) EcoRK All reactions were incubated at 30 °C for 3 min, chilled in ice and layered on 4 ml 10–30 % glycerol gradients containing 20 mM potassium phosphate, pH 7.0, 5 mM 2-mercaptoethanol and 0.2 mM EDTA. These were centrifuged at 55,000 r.p.m. for 100 min at 4 °C in an international SB 405 rotor. Twenty fractions were collected from each gradient and 50 μl aliquots were removed from each fraction from *a*, *b* and *c* for counting. Aliquots (50 μl) of *a′* and *c* were assayed by the standard procedure except that Ado–Met was omitted from the incubation Aliquots from *b* were assayed similarly except that both Ado–Met and additional λ.0 ³²P-DNA were omitted.

Table 1 Inhibition by heparin of DNA binding to filters by EcoRK

First incubation	Second incubation	λ.0 ³²P-DNA bound (c.p.m.)	% Maximum
Set 1

		1,913	100
8 EcoRK+Ado–Met+λ.0 DNA +heparin	ATP	36	1.9
		24	1.3
9 EcoRK+Ado–Met+λ.0 DNA	ATP+heparin	800	41.8
		1,131	59.1

Set 1, Each reaction mixture of 250 μl contained 0.13 μg λ.0 ³²P-DNA (14,650 c.p.m.), 6 7 nmol Ado–Met and 0.1 μmol ATP. Sample 2 also contained 0.25 μg heparin. EcoRK (0.1 μg, 0.5 μl) was added to the samples indicated and incubation at 30 °C was carried out for 2 min. The reaction was stopped by the addition of 50 μl 0.5 M EDTA and filtered.

Set 2, Each reaction mixture of 5 μl contains 27 pmol Ado–Met. In sample 5, 0.25 μg heparin was also present. EcoRK (0.5 μl, 0.15 μg) was added, the samples were incubated at 30 °C for 3 min and diluted with 250 μl of a reaction mixture containing 0.1 μmol ATP and 0.13 μg λ.0 ³²P-DNA (14,650 c p.m.) per 250 μl or a similar mixture containing in addition 0.25 μg heparin. After a further 2 min incubation the reaction was stopped with EDTA and the samples filtered.

Set 3, Procedure as for set 2 except that the λ.0 ³²P-DNA was incubated with the 5 μl enzyme activation mixture rather than added later during the dilution step.

heparin to a standard reaction mixture abolishes the binding of DNA to filters (Table 1, set 1). Heparin also inhibits the activated enzyme, both when it is added to the activation mixture, and when it is added to a dilution buffer containing DNA and ATP (Table 1, set 2). If, however, the enzyme is activated in the presence of λ.0 DNA and then diluted into buffer containing ATP and heparin, little inhibition is observed (Table 1, set 3). If heparin is added to a recognition complex, and ATP is added later, the same lack of inhibition is observed. Therefore, once the recognition complex has formed, the enzyme is no longer sensitive to inhibition by heparin. Normal DNA cleavage is observed when ATP and heparin are added to such a complex.

Both the initial and recognition complexes can be isolated on glycerol gradients

Direct evidence for the various enzyme–DNA complexes was obtained by glycerol gradient centrifugation. Sedimentation through glycerol gradients readily resolves DNA from the free enzyme (Fig. 4a, a composite of two different gradients). To detect the recognition complex, EcoRK was incubated with λ.0³²P-DNA, Ado–Met and Mg²⁺ at 30 °C, chilled and sedimented through a glycerol gradient. Aliquots from each fraction were counted to determine the position of the DNA and further aliquots were assayed for the recognition complex (Fig. 4b). To detect the initial complex, the experiment was repeated with λ.K ³HDNA in place of λ.0 DNA, and the gradient was assayed after addition of ATP and λ.0 ³²P-DNA to an aliquot from each fraction (Fig. 4c). In both cases, the activated enzyme comigrated with the DNA. Surprisingly, a control incubation of enzyme with λ.0 ³²P-DNA showed that the endonuclease was also bound to the DNA in spite of the fact that it had not been activated with Ado–Met (data not shown). This particular complex, however, does not seem to be an intermediate in the restriction reaction as the binding kinetics of this complex after ATP and Ado–Met addition are those of a standard reaction initiated by addition of EcoRK to λ.0 DNA and cofactors. As in the latter case, the reaction is inhibited by heparin.

An enzyme mechanism

Steps 1 and 2 of the reaction mechanism (Fig. 1) have been described in detail elsewhere[6], and involve the fast binding of Ado–Met by the enzyme followed by a slow transition to an activated form.

Here, we are primarily concerned with the phenomenon of DNA recognition which we show involves the sequential formation of at least three different types of enzyme–DNA complex. To understand this process, we must briefly describe the relationship between the sites on the DNA for host specificity, methylation and cleavage. The recognition sites are those sites on the DNA that confer susceptibility to the endonucleolytic action of the enzyme. They are relatively few in number for a given DNA and may be lost by mutation to yield a DNA molecule that cannot be cleaved, in vitro or in vivo, by the enzyme[8]. The methylation site seems to be a specific sequence of bases at the recognition site, since phage mutants that have lost their recognition sites also lose (again, both in vivo and in vitro) the ability to be methylated[9,10]. Furthermore, Horiuchi et al. have isolated small, specific DNA fragments from modified f1 DNA and found that of these fragments, only the two that contain the genetically mapped sB sites were methylated[11]. The situation concerning the cleavage sites is less clear. The enzyme does not cleave the DNA at the recognition sites and the number of possible cleavage sites is larger than the number of recognition sites[12]. Mapping studies with PM2 DNA have shown that the K cleavage sites are related to the readily denaturable regions of the genome (R.Y., T.A.B., W.E., and C.B., unpublished).

The interaction of EcoRK* with the host specificity site presents one of the most interesting aspects of the reaction mechanism because it is this interaction which will determine whether the enzyme will methylate or cleave the DNA. The site can exist in three possible forms: fully modified, fully unmodified or heteroduplex (one strand modified, the other not). We have previously shown that such heteroduplex DNA is not a substrate for restriction[1], and Vovis et al.[13] have shown that it is the best substrate for modification and that Ado–Met, ATP and

Mg^{2+} are required for optimal reaction. It is thus the recognition site that determines whether the enzyme will restrict or modify. If the site is unmodified, it will trigger the enzyme to its restricting mode, the enzyme will proceed to a cleavage site and restrict the DNA. If it is modified on one strand, the enzyme will be altered to its modifying form, and methylate the other strand. If it is fully modified, the enzyme will not recognise it, and will continue to scan other DNA molecules. The interactions of the enzyme with heteroduplex DNA are currently the object of extensive study in our laboratory. Both the recognition and cleavage complexes protect a small segment of DNA from DNase digestion. Sequencing of these fragments is currently in progress, and should clarify the location on the DNA of the recognition and cleavage complexes.

The restriction enzyme first breaks one strand followed some time later by a break on the opposite strand[1]. At this point, it no longer behaves as an enzyme, since having cleaved once, it does not do so again. Simultaneously with DNA cleavage, a vigorous ATP hydrolysis occurs, which continues for a long period of time[2]. Both observations can be readily reconciled if the restriction enzyme dissociated during cleavage to yield a species that would remain bound to the DNA. This complex would catalyse the ATP hydrolysis. Three observations lend support to this view: detection of a stable protein–DNA complex that hydrolyses ATP[14]; the lack of turnover (measured by both DNA binding and cleavage); and the complementation of a limit digest by either of two mutant restriction enzymes[5] to give a new round of endonuclease activity.

In conclusion, it is clear that the mechanism of *EcoRK* is highly complex. What is not readily apparent is the reason for such an elaborate machinery to carry out reactions that are carried out in a much simpler manner by other restriction and modification systems. It cannot be ruled out that the complexity may be related to its involvement in other reactions such as DNA replication or recombination.

letters to nature

Chemistry of the solar neutrino problem

ELECTRON neutrinos with energies of about 1–10 MeV are generally presumed to be produced by thermonuclear reactions in the Sun's core. Since 1967 an experiment has been under way on Earth to detect a subset of these neutrinos: argon atoms from the reaction

$$\nu_e + {}^{37}Cl \rightarrow {}^{37}Ar^+ + e^- \qquad (1)$$
are chemically isolated, and the Auger electrons characterising their electron-capture decay are counted.[1] A sizeable discrepancy—the solar neutrino problem[2,3]—has appeared. The most recent observational results[4] imply an upper limit (1σ) of 1 SNU ($= 10^{-36}$ solar neutrino captures per target ${}^{37}Cl$ nucleus s^{-1}), whereas the latest theoretical expectation based on standard models[5] is 5.6 SNU.

Something is definitely awry in our understanding of solar structure theory, nuclear physics, neutrino physics, or the detection chemistry. A solution to the solar neutrino problem has been extensively sought in the first three of these areas[6,7] (see also refs 2 and 3), but these efforts have recently encountered severe constraints[8-10]. The last area—the chemistry of the detection experiment—is one of the more neglected aspects of the problem; here I shall attempt to rectify this imbalance.

In the solar neutrino experiment a tank of liquid tetrachloroethylene (C_2Cl_4) provides the target ${}^{37}Cl$ nuclei of equation (1). The number of ${}^{37}Ar$ nuclei in the tank, $N(t)$, is governed by the equation

$$dN/dt = R + b - (N/\tau) \qquad (2)$$

where R and b are the respective production rates resulting from solar neutrinos and background processes, and where τ ($=50.6$ d) is the electron-capture-decay lifetime of ${}^{37}Ar$. For $t \gg \tau$, the solution to equation (2) asymptotically approaches the limiting value, $N(\infty) = (R + b)\tau$. The detector parameters[1] yield $R\tau = 9.6$ ${}^{37}Ar$ nuclei per SNU; the cosmic-ray-induced background for the water-shielded tank is estimated[11] to be $b = 0.09$ ${}^{37}Ar$ nuclei d^{-1}. Therefore

$$N(\infty) = 9.6(SNU) + 4.5 \qquad (3)$$

where (SNU) denotes the actual capture rate of solar neutrinos in the tank of C_2Cl_4.

Standard theory[5] implies that (SNU) $\simeq 5.6$, so the anticipated steady-state population from equation (3) is $N(\infty) \simeq 58$ ${}^{37}Ar$ nuclei. The experimenters are attempting to extract fewer than 100 ${}^{37}Ar$ atoms from 390,000 l of tetrachloroethylene, to count them, and to determine the number produced by solar neutrinos in comparison with that arising from background processes. The complexity and marginal nature of the experiment lead me to put forward the hypothesis that the solar neutrino problem is solely an artefact of the chemistry of the detection technique. A direct corollary is that ${}^{37}Ar$ nuclei are, in fact, being produced by solar neutrinos in the tank at the rate of 5.6 SNU, so that $N(\infty) = 58$ ${}^{37}Ar$ nuclei. The experimental upper limit of 1 SNU then implies that only a small fraction of the ${}^{37}Ar$ in the tank is revealed in the output pulses of the Auger counter. (I shall use the loose terminology, 'chemical trapping', to indicate the fate of the undetected ${}^{37}Ar$ nuclei.)

Five experiments constrain this chemical hypothesis. First[1], a known volume of pure ${}^{36}Ar$ gas was dissolved in the tank

tetrachloroethylene, extracted by helium purging, and measured volumetrically; a 22-h extraction recovered 95% of the ^{36}Ar. Second (R. Davis, Jr, and J. C. Evans, Jr, unpublished), 612 ± 20 atoms of ^{37}Ar were mixed into the tank, the helium purge operated for three days, and the extracted ^{37}Ar detected in the Auger counter; it was inferred that the tank had contained 650 ± 50 (1σ) ^{37}Ar atoms.

These two experiments alone imply that neutral atoms of argon are not 'trapped' in Davis' system, even at the level of about 10^2 atoms. I note, however, that the product of reaction (1) is the cation ^{37}Ar$^+$ and not neutral ^{37}Ar. The remaining three experiments probe the possible 'chemical trapping' of this charged ^{37}Ar$^+$.

In the third experiment (see ref. 1), *in situ* irradiation of the tank liquid with fast neutrons produced ^{37}Ar$^+$ by the reaction

$$[n^0(\text{Ra–Be}) + {}^{35}\text{Cl} \to {}^{35}\text{S} + \text{p}^+ \text{ (fast)}$$
$$\downarrow$$
$$\to + {}^{37}\text{Cl} \to {}^{37}\text{Ar}^+ + n^0 \quad (4)$$
Positive identification of ^{37}Ar at the Auger counter showed the helium-purge recovery of ^{37}Ar atoms to be proportional to that of the carrier ^{36}Ar, and the production rate was inferred to be 7.5×10^{-7} ^{37}Ar nuclei per incoming neutron. This determination was not, however, absolute; most of the ^{37}Ar nuclei could well have remained 'chemically trapped' in the tank.

The fourth 'experiment' (see ref. 11) was the calibration of cosmic-ray-induced ^{37}Ar in Davis' tank. The standard chemical procedure indicated that the equilibrium ^{37}Ar activity of small tanks of C_2Cl_4 at six different depths in the Homestake gold mine scaled with depth as expected theoretically; extrapolation to Davis' main tank implied a background rate of $b = 0.09 \pm 0.03$ ^{37}Ar nuclei d^{-1}. These results are, however, also not absolute, since the theoretical curve was normalised to the data at a depth of 25 hg cm^{-2} (standard rock). Should 'chemical trapping' prove important, then the canonical background rate will become highly suspect.

Ion–molecule reactions leading to the bound species ArC$_n$Cl$_m$$^+$ were tested in the fifth experiment[12], in which a gas-phase mixture of ^{40}Ar and G_2Cl_4 (at 1 mmHg pressure) was ionised with 40–eV electrons and the products were detected with a quadrupole mass analyser. No ArC$_n$Cl$_m$$^+$ was found, and the results were completely dominated by charge transfer (neutralisation of ^{40}Ar$^+$ by electron pickup). To extrapolate these gas-phase findings to a liquid C_2Cl_4 environment ($\simeq 10^6$ times denser), however, is totally unwarranted.

From this investigation of experimental constraints I conclude that the chemical hypothesis remains a viable solution to the solar neutrino problem only if the ^{37}Ar$^+$ is 'chemically trapped' in Davis' system before neutralising to free ^{37}Ar atoms. This final loophole may be closed by another experiment now being performed by Davis (unpublished): a known number of $C_2Cl_3{}^{36}Cl$ molecules is put in his tank, the β-decay of ^{36}Cl produces a determinate number of ^{36}Ar$^+$, and the amount of ^{36}Ar recovered is measured

The evidence supporting my chemical hypothesis is purely circumstantial, but deserves mention. The clear signature of 58 ± 20 ^{37}Ar atoms in the tank at the end of run 27 was provided by the Auger counter[4,13]; equation (3) then implies that (SNU) = 5 6 ± 2.0. Contamination, cosmic-ray background variations, and statistical fluctuations are considered extremely unlikely causes[4,14], so the result of run 27 is generally attributed to a large ν_e burst from a galactic 'collapsing star' (see refs 4 and 14; also R. Davis, Jr, and J. C. Evans, Jr, unpublished). On January 4, 1974 (during run 32), however, a strong $\bar{\nu}_e$ burst was apparently detected in an independent experiment in the Homestake gold mine[15]. If this burst signalled a 'collapsar', then a large accompanying $\bar{\nu}_e$ flux can be expected[16], so it becomes difficult to understand the data of run 32 which implied only 9 ± 9 ^{37}Ar atoms in Davis' tank[4]. These observations can, however, be accommodated by my chemical hypothesis.

By what mechanisms may ^{37}Ar$^+$ become 'chemically trapped' in Davis' system? Tetrachloroethylene is an unsaturated molecule, and short-chain polymerisation of liquid C_2Cl_4 has been achieved[17] using MeV-γ-radiation; the ^{37}Ar$^+$ may induce polymerisation and trap itself within a solid polymer analogous to Teflon. The rare-gas atoms, krypton and xenon, occur in stable molecules[18] (for example, XeF$_6$), apparently partially because of electron-d-orbital interactions; since Ar$^+$ is isoelectronic to neutral chlorine there are 3d orbitals available which may permit 'back-binding', as in ClO$_4^-$ and in the 'π-d-complex intermediates'[19]. The existence of stable molecules containing argon has been suggested[20]. Finally, the stabilisation of ion–molecules involving Ar$^+$ and C_2Cl_4 (in bound excited states?) should be promoted by the strong inductive effects of Ar$^+$ and by cooperative relaxation processes in the liquid tetrachloroethylene environment. Chemical experiments to investigate some of these possibilities are currently underway.

Ultraviolet laser sounding of the troposphere and lower stratosphere

WE report here measurements made with a ground-based, ultraviolet laser operating in the wavelength range 297–308 nm, which relate to the question of the atmospheric transmission between ground level and about 20 km, and particularly to the contributions of absorption by minor constituents There has been considerable concern in recent years about the biological effects of increased solar ultraviolet radiation at ground level associated with a reduction in the concentration of atmospheric ozone[1]. It seems that wavelengths between about 300 and 310 nm are most likely to produce erythema (sun burn) and skin cancer[2]. The effects of aerosols, clouds, non-absorbing haze or fog and other absorbing atmospheric gases need to be considered in addition to the effects of ozone and of Rayleigh scattering when examining the penetration of these radiations to the Earth's surface[3,4]. Except for the Junge layer[5] of aerosols which extends from about 12 to 22 km, and cirrus clouds,

these scattering and absorbing agencies are probably located in the lower troposphere, below about 5 km.

Our observations were made at Winkfield (60 m above sea level and 40 km west of central London) with a laser radar system (Table 1). The transmitter consisted of a flash-lamp-pumped dye laser, tuned with Fabry–Perot etalons, frequency-doubled by an ammonium dihydrogen phosphate (ADP) crystal orientated for critical phase-matching. The receiver used a 1–m aluminised mirror, various interference filters and a bialkali-cathode photomultiplier The absence

Table 1 Parameters of the ultraviolet laser radar system

Transmitter	
Wavelength range	297–308 nm
Linewidth	0.2 nm
Energy per pulse	approximately 0.2 mJ
Beam divergence	0.2 mrad × 2 mrad
Pulse duration	5 µs
Pulse repetition rate	1 s^{-1}
Receiver	
Mirror area	0.6 m^2
Beamwidth	2 mrad
Separation from transmitter	4 m

of spurious signals from any photomultiplier overloading or signal-induced noise[6] was confirmed from soundings of cloud observed in the 5–10 km height range, above which no signal was detected. Rotation of the ADP crystal from the index-matching angle showed that the blocking of the receiver filters was sufficient to reject radiations scattered from the fundamental beam.

Figure 1 shows the results obtained on five nights when the laser was tuned to 308 nm. Measurements were restricted to periods when the sky was apparently clear, and the number of laser firings each night varied between about 100 and 1,000. The signal observed in each height channel was compared with that expected for Rayleigh scattering from the standard atmosphere for midlatitude winter conditions[7], the resulting relative signal being normalised at 5.5 km. Attenuation of the beam because of Rayleigh scattering was allowed for in the calculation of the expected signal. The results obtained on different nights show height variations which are either consistent with Rayleigh scattering (February 24, 1975; Fig. 1e), show decreases with increasing height by up to a factor of 4 (January 12, January 31 and February 1, 1975; Fig. 1b, c, and d, respectively), or show small enhancements (December 30, 1974; Fig. 1a). Changes in the total molecular density cannot account for the night-to-night variability, so the results indicate either appreciable scattering and absorption by aerosols in the heightrange 5–20 km, or absorption of the radiation by a minor molecular constituent. This would probably be ozone, as the concentrations of sulphur dioxide, hydroxyl and other absorbing constituents above 5 km are expected to be too low to give detectable attenuation.

In an attempt to measure the height distribution of ozone, observations were also carried out using two wavelengths· 308.0 nm and 303.5 nm. These correspond to a ratio of 1 : 1.7 in the ozone absorption cross section[8,9] and are close to minima in the sulphur dioxide cross section[10]. As the scattering and absorption characteristics of aerosols are not expected to vary significantly over this wavelength range, the difference in attenuation would arise from absorption by ozone. The results obtained are shown in Fig. 2 where the points for each wavelength have been separated horizontally for ease of presentation. For heights between 5 and 15 km, the two sets of results are each consistent with a straight line variation on the logarithmic scale. The ratio of slopes of these lines is closer to unity than would be

expected for absorption by ozone alone, but the difference in slope is found to correspond to ozone concentration of about 4×10^{17} m^{-3}, a height-independent which is within the range of measurements by other methods[11].

Signals received from heights below about 5 km could not be interpreted, mainly because of uncertainty in the overlap of the transmitting and receiving beams. An estimate of the transmission coefficient below 5 km after allowing for Rayleigh scattering can, however, be obtained by comparing the observed signal from 5–6 km with that calculated from a knowledge of the ultraviolet pulse energy and overall receiver efficiency. A comparison of the results obtained for different wavelengths is relatively free from the uncertainties associated with the transmission coefficient obtained for each separately. From measurements carried out with a greater range of wavelengths on February 24, it was found that the two-way transmission coefficient below 5 km at 297 nm was lower by a factor of 10 than that at 308 nm. This cannot be explained by the attenuation effects of aerosols alone and absorption by molecular oxygen is negligible as the cross section is less than 10^{-29} m^2 (ref. 12). If the ratio of transmission at 297 and 308 nm is attributed to absorption by sulphur dioxide in the 0–1 km height range, a concentration of 4×10^{19} m^{-3} is implied (1 p.p.m.), which is very unlikely. If absorption by ozone in the height range 0–5 km were responsible, an average concentration of about 5×10^{18} m^{-3} would be required. This is an order of magnitude greater than that deduced for the 5–15 km height range, and is about five times larger than the mean background concentrations observed near the ground in north-western Europe during summer and is approached only during periods of photochemical air pollution[13,14]. The

Fig. 1 Observed signals at 308 nm on five nights between December 1974 and February 1975, relative to those expected for Rayleigh scattering: a, December 30; b, January 12; c, January 31; d, February 1, e, February 24. Error bars indicate the standard deviations corresponding to the photon count for each height channel
Fig. 2 Observed signals at 303 5 nm (●) and 308.0 nm (○) for February 27, 1975, relative to those expected for Rayleigh scattering Error bars indicate the standard deviations corresponding to the photon count for each height channel.

results can be better interpreted in terms of absorption by water vapour in the height range 0–5 km; a difference in absorption cross section of about 10^{-27} m^2 between 297 and 308 nm would be required for that to occur, but no accurate measurments of cross section are available for this range of wavelengths.

There is considerable scope for the further development of this technique of ultraviolet laser sounding of the atmosphere. With the production of new frequency-doubling materials suitable for 90° phase-matching[15], it should become possible to increase substantially the available ultraviolet pulse energies. The accuracy and height resolution of the present type of measurement should thereby be improved, and the height range extended. In addition, measurements of the concentrations of certain constituents by resonance scattering or fluorescence should become possible.

Petroporphyrins as indicators of geothermal maturation

WE report here two new sets of data which provide evidence of the occurrence of the postulated conversion of deoxyphylloerythroetioporphyrin (DPEP) to etioporphyrin. Simulated geothermal maturation in the laboratory demonstrates that DPEP–etio conversion occurs proportionally to the severity of the treatment, and an analysis of petroporphyrins from a suite of genetically related petroleums and their source rocks reveal that the DPEP:etio ratio is inversely proportional to the presumed severity of the geothermal history of the sample.

Alkyl petroporphyrins occur in a wide range of geological materials[1,2] where they are usually present as two major homologous series of the deoxyphylloerythroetioporphyrin (DPEP) and etio type. Initially, the DPEP compounds containing the isocyclic ring were thought to be representative of, and derived from, chlorophylls, whereas the etio homologues, with no isocyclic ring, were considered to be remnants of the haem type pigments[3]. But though chlorophyll pigments exist in far greater abundance than haem pigments in the biosphere[4], DPEP and etio porphyrins[5] frequently occur in similar amounts in geological samples, and Corwin suggested[4] that the conversion of

Fig. 1 Relative abundance of metallopetroporphyrins (VO) from thermally altered (210 °C for 0 (*a*), 50 (*b*), 100 (*c*), 150 (*d*) and 385 (*e*) h) La Luna (Mara) extract obtained by mass spectrometric dermination of M$^+$ at the following masses: DPEP (solid line) = $(457+n14)$ a.m.u ; etio (dashed line) = $(459+n14)$ a.m.u,; where $n = 1$ to 13 (C_{27} to C_{39}). The mass spectra were collected by computer controlled gas chromatography–mass spectrometry; because of instrument background low abundance ions are occasionally not recorded (for example, C_{37}, C_{38}, and C_{39} in the 50-h (*b*) and 100-h (*c*) heating experiments)
Table 1 Characteristics of petroporphyrins and source rocks from the Maracaibo Basin

| Sample | | Current geological setting | | | | Petroporphyrins | | |
| | | | | | | Carbon no. of most abundant molecular ion | | |
	Type	Age*	Depth (m)	Temperature (°C)	Content‡ (p.p.m.)	DPEP	etio	DPEP/etio

c La Paz (P187-Z)	Petroleum	Jurassic fracture	3,300–3,450	95	628	31	30	0.56
d La Luna (36E-2)	Source rock	Cretaceous	4,410–4,550	135	2,730	31	30	0.56

*The two oils are believed to have originated in the La Luna Formation (Cretaceous) but are currently found in the host formations indicated[13].
†No information concerning maximum depths of burial or temperature history is available but low reflectivity ($R_{av} = 0.19$) of vitrinite suggests a mild geothermal history. (We thank Dr M. Jones, Organic Geochemistry Unit, University of Newcastle, for this measurement.)
‡Metalloporphyrin content (p.p.m.) in oil or organic extract.

DPEP to etio homologues must occur in the geological environment. Indirect evidence of the conversion of DPEP to etio has been obtained from a comparison between petroporphyrins recovered from a retorted shale oil and those from the original shale[6]. The retorted oil contained a large proportion of etio type homologues, suggesting that conversion did occur during the retorting. The drastic temperatures required for the retorting process are, however, significantly higher than those (about 50–180 °C) normally experienced in deeply buried sediments, which effect the geothermal maturation of entrapped or dissolved petroporphyrins and other organic materials. Evidence of the conversion has also been provided by the thermal alteration, in the laboratory, of a crude petroleum containing metallopetroporphyrin to which etioporphyrin III had been added as an internal reference compound[7]. Other studies which have simulated geothermal maturation[8-11] have been restricted to porphyrins of the etio skeleton; they could not, therefore, provide information about the fate of the isocyclic ring of DPEP homologues or about the occurrence of the DPEP to etio conversion.

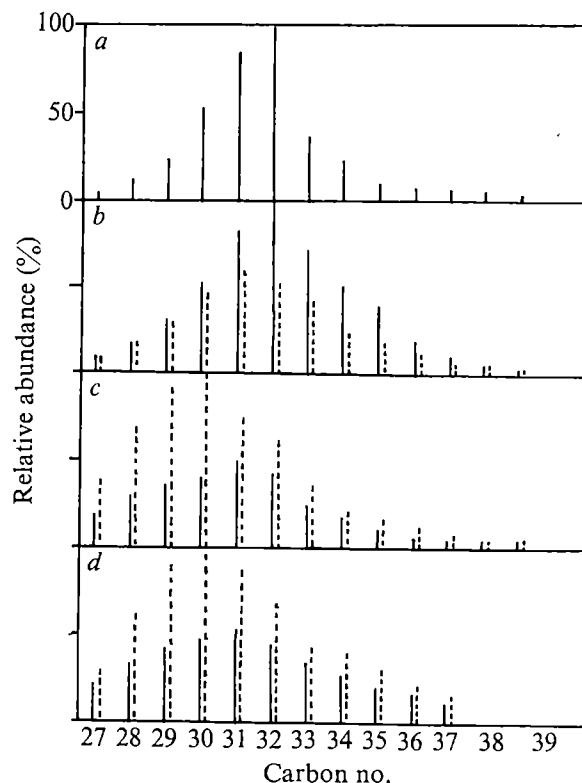
The geological materials used (Table 1) in this study are from, or are genetically related to, the Cretaceous La Luna formation of the Maracaibo Basin in western Venezuela. This formation is extensive and source beds in it are believed to have generated the major part of the oil produced in the Maracaibo area[12]. One of the most remarkable characteristics of these shaly limestones is the high porphyrin content (up to 55,000 p.p.m. of the organic extract); it has, in fact, been used to establish source rock–crude oil relationships for the oils from the Maracaibo Basin[13].

The simulated geothermal maturation was performed on the total organic extract of the least mature shale (Table 1*a*). The toluene–methanol (3:1) extract was deposited on prewashed (redistilled hexane B.D.H.) and vacuum-dried bentonite to give a concentration of about 2,790 p.p.m. of metallopetroporphyrin (98% vanadyl). Bentonite, a montmorillonitic clay mineral was chosen as the organic free matrix for thermal alteration experiments. Results obtained using this material rather than limestone should be more generally applicable to the geothermal fate of porphyrins in argillaceous sediments.

Aliquots of coated bentonite were placed in heavy-walled glass tubes (15 × 150 mm), flushed with oxygen-free nitrogen and sealed under vacuum. The sealed tubes were stored in the dark at 210 °C; individual tubes were removed at successively longer time intervals from 0 to 385 h. After cooling, the bentonite was extracted with toluene–methanol (3:1) and the metallopetroporphyrins were isolated, and purified using thin-layer chromatography (silica gel H, 0.5 mm, toluene–methylene chloride 1:1). Recoveries of total metallopetroporphyrins after thermal treatment varied from 81% (0 h) to 19% (385 h experiment). The thermal degradation of metallopetroporphyrins was found to be first order ($t_\frac{1}{2} = 166$ h). The extracts were examined using mass spectrometry: a computerised data handling system[14] monitored and collected the spectra in real time.

Bar diagrams (Fig. 1) show the relative abundance of the molecular ions of metallopetroporphyrins isolated after various times of thermal treatment. The zero-time extract exhibits a single homologous DPEP series of carbon number C_{27}–C_{39}, maximising at C_{32}. After 50 h an etio series could just be detected, after 100 h this was prominent and after 385 h the abundance of this series exceeded that of the now much-diminished DPEP compounds. Thus, the DPEP series seems to have undergone extensive thermal conversion to the etio series. The most abundant DPEP homologue remaining was then C_{31}, indicating that a second maturational process involves loss of alkyl groups. Dealkylation is a well known feature of geothermal maturation of other geolipids[15] and has been recorded following the laboratory thermal alteration of etioporphyrins[8-11].

In the second part of this study petroporphyrins from two crude oils and from the toluene–methanol (3:1) extracts of two

Fig. 2 Relative abundance of petroporphyrins isolated from geological samples described in Table 1. Mass spectrometric determination of M⁺ occurring at the following masses: DPEP (Solid line) = (392+*n*14) a.m.u.; etio = (394+*n*14) a.m.u.; where *n* = 1–13 (C_{27}–C_{39}). *a*, La Luna (Mara), *b*, Boscan BN4, *c*, La Paz P187-Z; *d*, La Luna 36E-2.


different samples of their presumed source rock (Table 1) were isolated using demetallation-extraction with methanesulphonic acid (4 h at 110 °C) and were analysed using mass spectrometry[16]. Figure 2 presents the relative abundances of the petroporphyrins of these samples; the samples increasing in maturity (based on geological information) from top to bottom of the diagram. As the geothermal maturity increases there is an increase in the relative abundance of the etioporphyrins and a shift to the lower carbon number of the most abundant petroporphyrin observed (Table 1). The decrease in the DPEP : etio ratio would suggest that during geothermal maturation DPEP species are converted into etio homologues. A general trend observed[17] within a group of non-genetically related geological materials suggests that the DPEP : etio ratio decreases with the depth of burial.

The DPEP–etio conversion suggested for the Maracaibo Basin samples parallels the conversion observed in the thermal alteration experiment. In each case the maxima of the two homologous series occur either at the same carbon number or with the abundance of etio homologues maximising one carbon atom lower than the DPEP homologues. Similar distributions have been observed in a wide range of naturally occurring petroporphyrins[1]. The thermally induced conversion of DPEP to etio porphyrins may be widespread in the geological environment and could account for the abundance of etio homologues in crude oils and sedimentary rocks. The decrease in the DPEP: etio ratio with increasing maturation could be a useful measure of the extent of maturation of genetically related geological materials.

We thank the Empresa Nacional del Petroleo (Chile), the Ford Foundation, the University of Riyadh and the Nuffield Foundation for financial support. The geological samples were provided by the late Dr J. A. Gransch (Shell, Holland) and by Mr E. E. Hagan (Chevron Oil Company of Venezuela).

Effect of climate on the magnetic susceptibility of soils

The magnetic susceptibility of soils derived from sedimentary rocks is normally significantly higher than that of the parent rock. Le Borgne[1,2] has suggested that this enhanced susceptibility of the soil is due to the *in situ* conversion of the iron oxides from an antiferromagnetic form such as haematite (α Fe_2O_3)

or goethite (α FeOOH) to the ferrimagnetic form, maghaemite (γ Fe_2O_3). He also proposed two possible mechanisms involving a reduction process followed by reoxidation to maghaemite. In the first (fermentation mechanism), the reduction occurs as a result of the decay of organic matter in the soil in anaerobic conditions achieved during wet periods, and reoxidation to maghaemite occurs in the aerobic conditions prevailing during subsequent dry periods. In the second (heating mechanism) the burning of organic material produces the temperature increase and reducing atmosphere necessary for the reduction to magnetite (Fe_3O_4) in a thin layer of soil underlying the fire and reoxidation occurs during the cooling down of the fires when air enters the system.

On the basis of the heating mechanism, the percentage of the iron oxide in the soil which has been converted *in situ* to maghaemite (that is, the percentage conversion) is given by the ratio of the observed magnetic susceptibility (χ_O) to the susceptibility (χ_N) after heating the soil in a laboratory furnace at 550 °C in an atmosphere of nitrogen followed by air[3]. Although pure maghaemite converts to haematite at temperatures above 350 °C, maghaemite doped with, for example, sodium, aluminium or magnesium is stable up to very much higher temperatures[4]. Therefore, since the iron oxides in soils are in a finely divided form and in intimate contact with the clay minerals, it is assumed that the laboratory heating converts the iron oxides to a thermally stable, impure maghaemite. Support for this hypothesis has been provided by Le Borgne[1] who has shown that soils with a high magnetic susceptibility exhibit an exothermic DTA peak, characteristic of maghaemite, at about 700 °C. Furthermore, X-ray diffraction measurements on the laboratory heated soils have established that either maghaemite or magnetite is present, and in view of the final oxidising stage in the heating, the latter alternative is unlikely.

Magnetic susceptibility measurements (Table 1) were undertaken, using an a.c. bridge system[5] operating at 1 kHz, on soils (0–20 cm; A horizon) derived from a wide range of sedimentary rock deposits (Triassic–Miocene) in England and Italy, as well as on a small selection of soils from other parts of the Mediterranean zone and from various tropical regions.

Table 1 Magnetic susceptibility ranges for soils

Region	Geology	Magnetic susceptibility ($\times 10^{-8}$ kg^{-1})	
		Observed (χ_O)	After heating (χ_N)
England	Limestone	15–90	1,000–5,000
England	Sandstone, clay	10–180	600–8,000
Italy	Marly limestone, marl	10–80	600–3,000
Italy	Sandstone, clay	5–30	600–2,000
Italy	Limestone	30–500	200–4,000
Mediterranean	Limestone	150–600	1,500–3,000
Mediterranean	Calcareous alluvium	30–400	500–6,000
Tropics (wet and dry)		15–500	200–8,000
Tropics (rainy)		5–15	700–1,000

The percentage conversions (that is, $100\chi_O/\chi_N$) observed for the English soils were normally less than 5%, irrespective of the type of sedimentary rock from which they were derived (Fig. 1*a*). In contrast, the percentage conversions observed for the Italian soils differed widely depending on the associated rock-type. Soils developed on marly limestones, marls, sandstones and clays, again normally exhibited percentage conversions of less than 5% (Fig. 1*b*) whereas those developed on hard, as opposed to marly, limestones exhibited significantly higher percentage conversions extending up to 50% (Fig. 1*c*). These differences in percentage conversion cannot be satisfactorily explained in terms of the heating mechanism as it is extremely unlikely that the limestone soils from Italy have been consistently subjected to more extensive burning than either the other

Italian soils or the English soils. Instead, it seems probable that the higher percentage conversions associated with the limestone soils from Italy arise because the fermentation mechanism is more extensively activated as a result of the combined effect of the prevailing Mediterranean climate and the high permeability of the limestone substratum. Anaerobic (reducing) conditions are achieved during the humid winters and the necessary aerobic (oxidising) conditions are achieved during the subsequent hot dry summers in the case of the well-drained soils which are developed on limestones.

Further evidence for the role of climate is provided by the fact that the limestone soils from Apulia, the Orbetello region and the southern Apennines, which are mainly of the red Mediterranean type[6] (that is, terra rossa) exhibit higher percentage conversions than those from the central Apennines which are mainly rendzinas (Fig. 1c). Again, it seems probable that this difference is because more sustained aerobic conditions are achieved during the summer months in the former areas as a result of lower rainfall and higher temperatures.

The percentage conversion data for soils developed on limestones and for calcareous alluvia from Greece, Crete and Turkey (Fig. 1d) confirm that high values for this parameter are not peculiar to Italy but seem to be generally characteristic of well-drained soils in the Mediterranean climatic zone. Similarly, the data for tropical soils from Nigeria, Gambia, Zambia, British Honduras and North Borneo provides further evidence for the role of climate in determining the percentage conversions achieved in soils (Fig. 1e). The majority of the soils from those regions in which a pronounced dry period occurs (that is, the

Fig. 1 Histograms showing the distribution of values for the percentage conversion for: a, English soils derived from limestones (shaded), and sandstones and clays (blank); b, Italian soils derived from marly limestones and marls (shaded), and sandstones and clays (blank); c, Italian soils derived from limestones in Apulia, the Orbetello region and the southern Apennines (shaded), and the central Apennines (blank); d, Mediterranean soils derived from limestones (shaded) and calcareous alluvia (blank); e, soils from wet and dry tropics (shaded) and rainy tropics (blank).

wet and dry tropics) again exhibit percentage conversions in excess of 5%, the characteristic red tropical soils being predominant in this group. In contrast, the soils from those regions in which no definite dry period occurs (that is, the rainy tropics) exhibited percentage conversions of less than 2%.

These results suggest that there is a high percentage conversion of iron oxide to the ferrimagnetic form, and a concomitant high magnetic susceptibility (Table 1) in well-drained soils developed in regions with a climate that includes a pronounced, hot, dry period. It is, therefore, possible that magnetic susceptibility measurements could be used to identify those palaeosols in, for example, England which were formed in warmer dryer climatic conditions than exist at the present time. In interpreting the magnetic susceptibility of soils it must, however, always be remembered that high percentage conversions can also be produced by burning associated either with the clearance of land for agriculture or with human habitation. For example, in England, although normal soils exhibit low percentage conversions (Fig. 1a), soils from archaeological sites (that is, topsoils, pit and ditch fillings) exhibit significantly higher percentage conversions in the range 4–20% (ref. 7).

We thank Dr C. Mullins, Mr J. A. Varley and Dr C. Vita-Finzi for providing soil samples. This work was supported in part by a grant from the Italian Ministry of Foreign Affairs.

New interpretation of dielectric loss peaks

ALTHOUGH the dielectric loss peaks in many materials are known to show a frequency dependence which departs radically from the ideal Debye shape, the interpretation of their temperature dependence is carried out implicitly within the framework of the Debye mechanism. This cannot produce a good physical insight into the situation and here I look at it from a new standpoint.

The frequncy dependence of loss, χ'' (ω), in many dipolar materials may be expressed by the empirical formula[1,2]:

$$1/\chi''(\omega) = (\omega/\omega_2)^{-m} + (\omega/\omega_1)^{1-n} \qquad (1)$$

where ω_1 and ω_2 are generally, thermally activated parameters, and the exponents m and $(1 - n)$ are both smaller than unity and decrease with decreasing temperature. This law of reciprocal addition gives a loss peak at a frequency ω_p, which increases with temperature. In many dielectric materials in which the polarisation is caused by hopping charges rather than by dipoles the peak is not readily observable because of the onset of direct current conduction, but the loss is still given by the second term in equation (1). I shall refer to this as the 'universal law of the dielectric behaviour'.

This law implies that the ratio of the imaginary to the real parts of the susceptibility is independent of frequency

$$\chi''(\omega)/\chi'(\omega) = \cot(n\pi/2) \qquad (2)$$
Fig. 1*a* Frequency-dependence of loss; *b*, time-dependence of current under step-function electric field excitation. Both correspond to equation (4), with $n = 0.7$ and values of $k = 1.2$, 1 3 and 1.5. The χ' (ω) and χ'' (ω) curves are Fourier-transformed numerically from equation (4) and show the parallel slope on the high-frequency side of the peak and the effect of the exponent on the positive slope and on the half-width of the peak. The pure Debye characteristics are shown on the same frequency scale in *a* and the exponential response on the same time scale in *b*. The vertical scales in *a* and *b* are scaled by arbitrary factors.

and leads to the physical interpretation that the ratio of energy lost per cycle to energy stored per cycle is constant, in marked contrast to the Debye mechanism for which it is equal to $\omega\tau$, where τ is the appropriate relaxation time. Any model satisfying this energy criterion must necessarily follow the universal law as a consequence of the Kramer–Kronig relationship. A physical mechanism which has the required properties and which should

be very widely applicable to both dipolar and hopping charge systems requires two assumptions: first, that charges or dipoles do not move smoothly but in discontinuous hops or jumps between preferred positions or orientations; second, that interactions with other charges of dipoles give rise to partial screening which can only follow the abrupt transitions with a finite delay.

The second term in equation (1) has, therefore, a simple interpretation in the frequency domain. The physical significance of the first term is less clear but I have suggested[3] that the gradual decrease of loss as $\omega \to 0$ arises because the perturbation of the system from its thermal equilibrium condition becomes progressively slower.

In the accepted interpretation of the temperature dependence of ω_p, the loss peak is treated as though it were a simple Debye peak[4]. The fact that its width at half-height may be two to eight times that of a Debye peak is left out of consideration, even though it may be acknowledged that the shape, and therefore the position of the peak, is determined by some distribution function, $g(\tau)$, of Debye relaxation times.

The concept of $g(\tau)$ is superficially very plausible—there is no doubt that physical systems must contain distributions of parameters rather than show strictly discrete values, especially in disordered materials and where stochastic processes govern the behaviour. In certain simple systems—for example, those involving multiple allowed orientations of molecular dipoles[5] or systems in which localised electrons execute multiple hops (V. Halpern, private communication)—it is possible to calculate exactly the distributions involved. Very complicated situations may arise for such cases as polar sidegroups on folded polymeric chains, but no rigorous analysis is possible in those cases[6].

What seems to have happened with the passage of time, however, is that the otherwise plausible, if restricted, concept of $g(\tau)$ became the universal explanation of all phenomena which did not fit into the idealised pattern, thus acquiring gradually the status of an unquestionable truth. The first point I challenge, therefore, is the scientific justification of the concept of the distribution of relaxation times in its application to the interpretation of dielectric data.

My argument is based on the universality of the observed behaviour[1,2] covering materials from plastics, through glasses, metal oxides, organic long-chain molecules and on to sand aggregates—seemingly regardless of their physical structure, chemical combination and bondage, or of the nature of the prevailing charged species responsible for polarisation (for example dipolar, electronic or ionic). It is completely implausible that the distribution of relaxation times in all of those diverse systems should happen accidentally to be such as to give the observed behaviour provided by the second term in equation (1). Having proposed a physical mechanism for the interpretation of this part of the spectrum[1], I turn here to the physical mechanism governing the region of the loss peak and below.

The precise form of the first term in equation (1) is of little significance here and the essence of my argument is not affected by it.

I propose that a more direct insight into the physical nature of the loss peaks may be obtained from an analysis of the time-domain response, $i(t)$, of a dielectric to step function electric field excitation. For an ideal Debye system:

$$i(t) \propto \exp(-t/\tau) \tag{3}$$

and the response corresponding to the empirical law is:

$$i(t) \propto [(t\omega_p)^n + (t\omega_p)^k]^{-1} \tag{4}$$

where the exponent, n, is the same as in equation (1) and $k > 1$.

Figure 1 shows a set of corresponding ω-domain and t-domain responses for an ideal Debye system and for the empirical behaviour, with $n = 0.7$ and with three values of k: 1.2, 1.3 and 1.5, respectively. In the latter case, ω_p corresponds to the time at which the slope of the log χ'' — log ω graph changes from a
Fig. 2 Schematic representation of the effect of a rise in temperature: a, on $\chi''\omega$, and b, on the corresponding $i(t)$ The slopes m and $(1-n)$ in a reflect qualitatively the observed behaviour. Solid lines, lower temperature. dashed lines, higher temperature.

value of less than unity to one of more than unity; that is, at the 'kink' in the response curve. Similarly, for the Debye mechanism the peak frequency is associated with the time, $t = \tau$, at which the slope goes through -1. But whereas the Debye exponential relationship (equation (3)) gives a smoothly varying slope corresponding to a single physical process in which the polarisation $P(t)$ tends exponentially to the limiting steady-state value, P_0, the empirical relationship is clearly seen to correspond to distinct physical processes. This implies that the polarisation process occurs in two separate stages with transition at a time $t = 1/\omega_p$.

I suggest the following physical significance of these two stages in terms of the mechanism characterised by the two points already mentioned. At time $t < 1/\omega_p$ after the application of the step function field the response $i(t) \propto t^{-n}$ is determined by a 'primary' adjustment of dipoles or hopping charges to the prevailing field, accompanied by the corresponding delayed screening processes. At time $t = 1/\omega_p$ the primary adjustments have been substantially completed and a 'secondary' process sets in, giving the final adjustment of screening and producing the observed, more rapid rate of change of current at times in excess of $1/\omega_p$.

The loss peak in the frequency domain is, therefore, seen as a manifestation of the onset of the secondary processes in the time-domain response which are implicit in the non-Debye model. The temperature dependence of ω_p arises from a shift of the demarcation time towards smaller values with increasing temperature, which may be seen as a result of the primary processes occurring more rapidly. The secondary processes also become more rapid, leading to the observed higher values of the exponent, m, in equation $(1)^{1,2}$ as shown in Fig. 2.

I conclude that the loss peak in solid dielectrics arises from an interaction between two separate processes, which may be described as the primary and secondary relaxations in an

interactive assembly. In this interpretation it seems that the determining factor is the duration of the primary process, after which time the secondary process takes over. This time is thermally activated with a well defined energy and so, therefore, is the peak frequency, ω_p^2.

It is not surprising that the loss peak is not caused by a single 'homogeneous' process as in the Debye model. Even in the accepted interpretation through $g(\tau)$ it is the shape of the distribution function and not the frequency dependence of any particular Debye process that determines the loss peak. The physical significance of $g(\tau)$ has never been made very clear but there is no reason to assume that the rising and falling parts of it are determined by a single physical process.

The foregoing discussion is essentially qualitative and its main object is to point towards a new approach to the old standing and unresolved problems of dielectric relaxation. The justification for this qualitative approach is twofold: the very generality of the phenomena that must be interpreted and the lack of rigour in the accepted point of view. There now remain the difficult tasks of developing a more quantitative approach and also of finding critical experimental evidence against which to test the proposed theory.

I thank S. Bozdemir who performed the numerical Fourier transformations of Fig. 1.

Evolution of Proterozoic basement patterns in the Lewisian Complex

Two contrasting structural elements, both of which have affinities with the two Proterozoic mobile belts of Greenland, have contributed to the pattern of structures in the Lewisian complex of the northern British Isles. The evolution of these structural patterns can be interpreted in terms of an integral system of movements which developed under the influence of an evolving linear dislocation that flanked the major Archaean craton of Greenland.

Allowing for continental drift, the Precambrian basement terrains of the North Atlantic Province (Greenland, Labrador and north-western Britain) outline an Archaean craton about 600 km across, which became stabilised about 2,500 Myr ago. Two major Proterozoic mobile belts apparently related to others in the neighbouring Canadian province, border this North Atlantic craton (see ref. 1) to the north, the Nagssugtoqidian, characterised by crustal shortening perpendicular to the belt[2], high pressure regional metamorphism and limited igneous activity, and to the south, the Ketilidian, in which vertical or transcurrent displacements, low pressure metamorphism and widespread magmatic activity occurred The continuations of these belts may intersect in the Lewisian of north-western Britain[2]. The Lewisian comprises a number of small stable blocks of the order of 10 km across composed of Archaean rocks showing relatively slight, late modifications (Scourian complexes) set

in a framework of Proterozoic structures (Laxfordian complexes). North-westerly and north-easterly trending structures within this framework impart the characteristic Proterozoic tectonic 'grain' to the Lewisian, although north-easterly trending Proterozoic structures have only been described in northern Lewis[3].

The occurrence of linear structures along the margins of regions which have been little affected by Proterozoic reworking is a characteristic of north-westerly trending Proterozoic belts in the Lewisian Using Archaean basic igneous complexes as marker horizons, it is possible to identify large-scale isoclinal folds with north-westerly trending axial surfaces, which have existed in the region south of Loch Laxford since at least the end of Archaean granulite facies metamorphism (about 2,800 Myr ago) Other north-westerly trending structures, such as those of the Ness region, Lewis, also seem to have begun to develop in pre-Laxfordian times[3,5]. This suggests that Lewisian structures with north-westerly trends have evolved on, or are related intimately to, a series of lineaments which originated during the late Archaean. Discounting local variations in finite strains, both the Laxford and Ness regions were sites where strain trajectories in the *xy* plane (axial surfaces and schistosity) had gentle to moderate dips and where displacements occurred obliquely to, but effectively perpendicular to, the north-westerly trending lineaments immediately before and after the emplacement of the dolerite Scourie Dykes[7]. At Laxford, movements on shear zones seem to have resulted in local crustal shortening by the overthrusting of Scourian granulites on to remobilised migmatites[8]. Throughout much of the Lewisian of the mainland and the Isle of Lewis, the regions occupied by flat lying, early Laxfordian structures and tectonite fabrics have suffered moderate to high early Laxfordian strains which were apparently caused by large scale, horizontal, ductile shearing

By late Laxfordian times, however, the Ness region was the site of steep *xy*-plane strain trajectories, suggesting displacements around the margins of a more competent block of central Lewis[7]. Similarly, at Laxford, a zone occupied by late Laxfordian granite sheets developed as a steep shear zone[8], parallel to the north-westerly trending lineament.

A north-easterly trending zone of steep dipping foliations lies along western Lewis and intersects the north-westerly trending structures of Ness, in Lewis. This steep zone was probably in existence in pre-Laxfordian times[3] and persisted as a discrete zone of steep foliation compatible with displacements parallel to the margin of the lineament into the late Laxfordian[7]. A similar north-easterly trend has been recognised on geophysical evidence, and is attributed to variations in rock densities, which originated in pre-Laxfordian times[9]; it is also associated with the widespread occurrence of successive groups of late Laxfordian granitic intrusions along the western seaboards of Harris and Lewis.

This arrangement of structures suggests that two systems with contrasting strain trajectories and contrasting major displacements, have acted contemporaneously throughout much of the Proterozoic. Although most influence seems to have been exerted by the zones within which deformation with shallow-dipping *xy*-plane trajectories and displacements mainly perpendicular to the north-westerly trending lineaments occurred during the early Proterozoic, steeply-dipping *xy*-plane trajectories and displacements parallel to the strike were established in the north-easterly trending structure at the same time as displacements on shallow dipping movement planes occurred. Finally, steeply-dipping *xy*-plane trajectories were established parallel to the lineaments in both north-easterly and north-westerly trending structures. Most probably, major discrete dislocations which behaved in a more ductile manner and which separated less ductile 'stabilised' regions, became

more influential during the later stages of Proterozoic evolution in both the Lewisian[3] and in eastern Greenland[15].

Mineral parageneses indicate that a change occurred from the high pressure environment that existed in the Scourian and early Laxfordian[10], to a low pressure environment during the mid to late Laxfordian[11,12]. This off-loading of confining pressure was probably connected with the change from the sub-horizontal crustal shortening (conceivably entailing at least local crustal thickening) that characterised the early Proterozoic to the sub-vertical zones of displacement that dominated the late Proterozoic.

Although it is clear that no single directional element in the tectonic pattern of the Lewisian could be compared directly in scale or behaviour with any individual belt of Greenland, it seems that the Proterozoic patterns in the Lewisian complex are the results of the integration of two nearly contemporaneous but contrasting evolutionary processes somewhat resembling those recorded in separate parts of the adjacent area of Greenland.

In the Lewisian, the north-westerly trending lineaments are distinct sites within which metamorphism and magmatic activity were often directly related to tectonic movements[16], whereas in the north-easterly trending lineaments metamorphism and magmatic activity seem only to be related in a general way to tectonic activity[3,9]. The relatively large, gently dipping zones within which ductile shearing occurred perpendicular to the lineaments under high pressure and temperature conditions during the early stages of development of the Lewisian belts can loosely be compared with the dominant displacements in the Nagssugtoqidian mobile belt[2]. In contrast, the zones of near vertical displacements, relatively low confining pressures and successive granite intrusion, which occurred in both regions during the late Laxfordian could be compared with the dominant regime of the Ketilidian mobile belt.

Since sets of structures compatible with both the major belts of Greenland intersect in the Lewisian, it may be that the two major belts of Greenland simply cross in the Lewisian[2]. But although the Ketilidian seems to be part of a major belt of Proterozoic reworking extending from the south-western United States, around the Canadian province, to the Urals[14], there is little evidence of any continuation of the Nagssugtoqidian Belt (Fig. 1). Alternatively, both the

Fig. 1 The Lewisian in the context of Proterozoic structures from Labrador to Scandinavia. *a*, Archaean craton; *b*, Proterozoic lineament; *c*, tectonic trend lines; *d*, regions of Proterozoic magmatism; *e*, Palaeozoic mobile belts; *f*, Palaeozoic orogenic front.
Greenland belts could have suffered displacements similar to those undergone in the Lewisian and it could be that only the dominant set in each belt has so far been recognised. Evidence which might support this suggestion comes from the intersections between tectonic trends in the mobile belts and major dislocation lineaments which border the cratons of Canada, and indicate a sense of movement on major dislocations similar to those in compatible dislocations in the Lewisian[13]. This interpretation of systems of major dislocations indicates the significance of the directional elements in the Lewisian Complex. The evolutionary aspects become clarified if the system of Lewisian structures comparable with the dislocations of the Nagssugtoqidian regime are regarded as relatively early elements in an integral system related to, if not initiated by, movements along steep dislocations associated with a major continuation of the Ketilidian Belt which eventually dominated the part of the craton which is now the Lewisian.

A psychological analysis of observation in geology

ANALYTICAL methods of experimental psychology applied to observations of geological data reveal that what geologists perceive in, and remember of, rocks is not necessarily the same as what is actually there. For example, when observing folds, professionals give more attention to antiforms than synforms and tend to remember cleavage fans as they ought to be rather than as they are.

Geology is a science which relies very heavily, at the stage of data collection, on the sense of sight. Experimental methods, which allow an assessment of common biases in perceiving and memorising can show where presented evidence could be distorted. Standardised observation tests are also valuable for training because they provide accurate feedback. This is not always obtained easily during actual geological work because 'the solution' is itself what is sought—it is not known beforehand

To avoid continually concentrating on biases in observation the investigation reported here was also directed towards finding evidence of perceptual attributes so that these, if present, can be used more widely.

For standardisation I constructed stimulus items of controlled content and complexity In order, however, for the geologists to construe the items as symbolic of rocks, they were not drawn too schematically.

To examine possible location and shape biases in the visual assessment of folds, 22 geologists and 22 non-geologists were individually shown Fig. 1a They were instructed to look at the picture and, at 10 random moments chosen by the experimenter, to indicate, by pointing, where they were looking. The indicated points were then recorded on an outline copy of the original Figure 1b shows the synopsis of plots from both groups of subjects and Fig. 1c shows the data contoured.

Several points emerge clearly from this simple experiment. First there are far more plots in antiforms than synforms $(0.001 > P > 0.0001)$, more in hinges than limbs and more in the black buckled layers than in the sandwiched, less competent layers (an average of 50 compared with 36). There are also more plots in the upper than in the lower half of the scene (191 plots compared with 133, central layer data neglected). Non-geologists differed markedly from geologists in having more plots in the upper halves of layers than in the lower halves (irrespective of whether antiforms or synforms are considered). Within the upper layer the difference in plots for non-geologists is at the 0.1% level and for the lower layer $P = 0.05$; (for geologists $P > 0.25$ for both). This accords with the introspections of the control group—many saying that they tended preferentially to scan the upper boundaries Non-geologists also gave less attention to the (what is to a geologist) unusual fold at the left in the upper thin layer (see Fig 1b and c).

There was no tendency in either group for there to be more concentration on the outer arcs of folds rather than the inner arcs $(P > 0.25$ for both groups).

Fig. 1 Geologists tend to describe (a) as comparing fairly tight angular upright folds and (d) as comprising well rounded fairly open folds. Yet (d) is merely (a) rotated through 180°. b, Plots of location-of-gaze (i, 22 geologists; ii, 22 non-geologists); c contoured (at 1, 1 5, 2 and >2% intervals) data from (b) (i, 22 geologists; ii, 22 non-geologists).

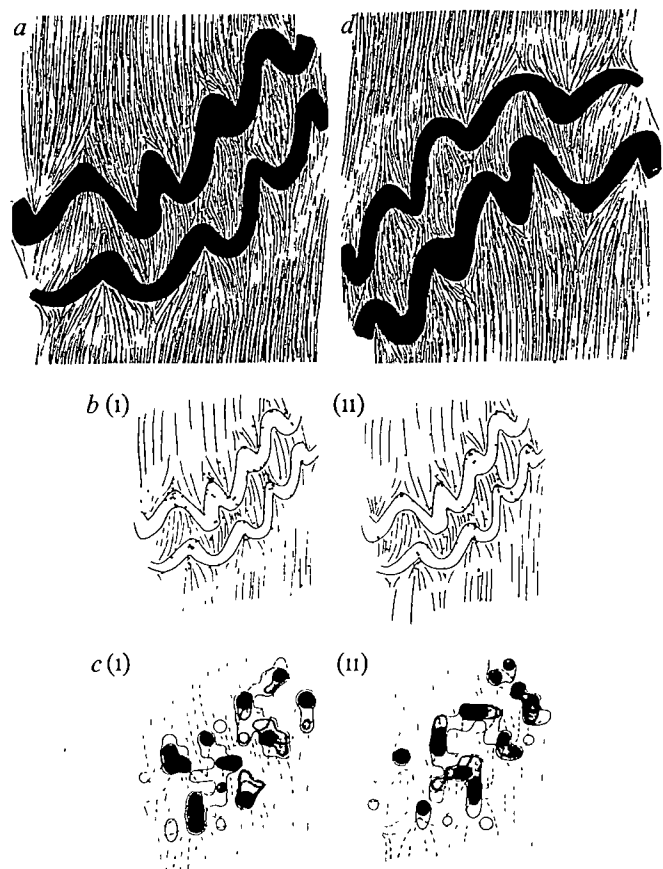
e


Fig. 2 Isogons (lines connecting points at which interface dips are equal) drawn on folds in which the amplitude and arc length of deflection of the inner and outer arcs is unequal. *a–e*, Five randomly selected portions of fold trains of buckled sandy layers in silt (Ordovician, Hommelvik-Hell region, Norway) Black areas, 'zones of no plots' where no isogons are possible.

It seems that irrespective of the speciality of the geologist the buckled thinner layers tend to be perceived as antiform 'chunks' joined at synform hinges, not the converse (compare Fig. 1*a* with Fig 1*d*).

The preference towards selecting antiforms may be reflected neurologically in a biasing at the level of complex cells in the occipital cortex where there is sensitivity to both orientation and spatial location. Alternatively, one could conceive of the preference for antiforms as resulting from a tendency to look at the upper halves of many objects in everyday life in order to extract the maximum amount of most useful information in the shortest time. That strategy may be transferred to scientific work—in this case to the observation of fold pairs—leading to differential visual scrutiny The experiment indicates that when geologists report, say, that "the most common F₂ folds" in an area are of a certain type, they may, to a large extent, be reporting what are really the most common antiformal folds.

That is a serious bias because antiforms and synforms may differ systematically both in geometry and interior

detail when, for instance, a folded layer is graded or current bedded. It is, therefore, important to remember that synforms are just as important as antiforms and should not be neglected in visual work.

The concentration of visual attention on hinge zones of folds at the expense of limbs, may be one of the reasons why one limitation in Ramsay's classification of folds[1] has been neglected. The use of isogons in the analysis of fold

Fig. 3 Geologists were requested to construct axial surfaces through the folded layers in (*a*) (taken from the Dalradian Ballachulish Limestone on Eilean Munde in Loch Leven, Argyllshire); *b*, combined data from all subjects; *c*, my interpretation (most of the construction lines used to locate hinge points have been left on; axial surfaces dashed).

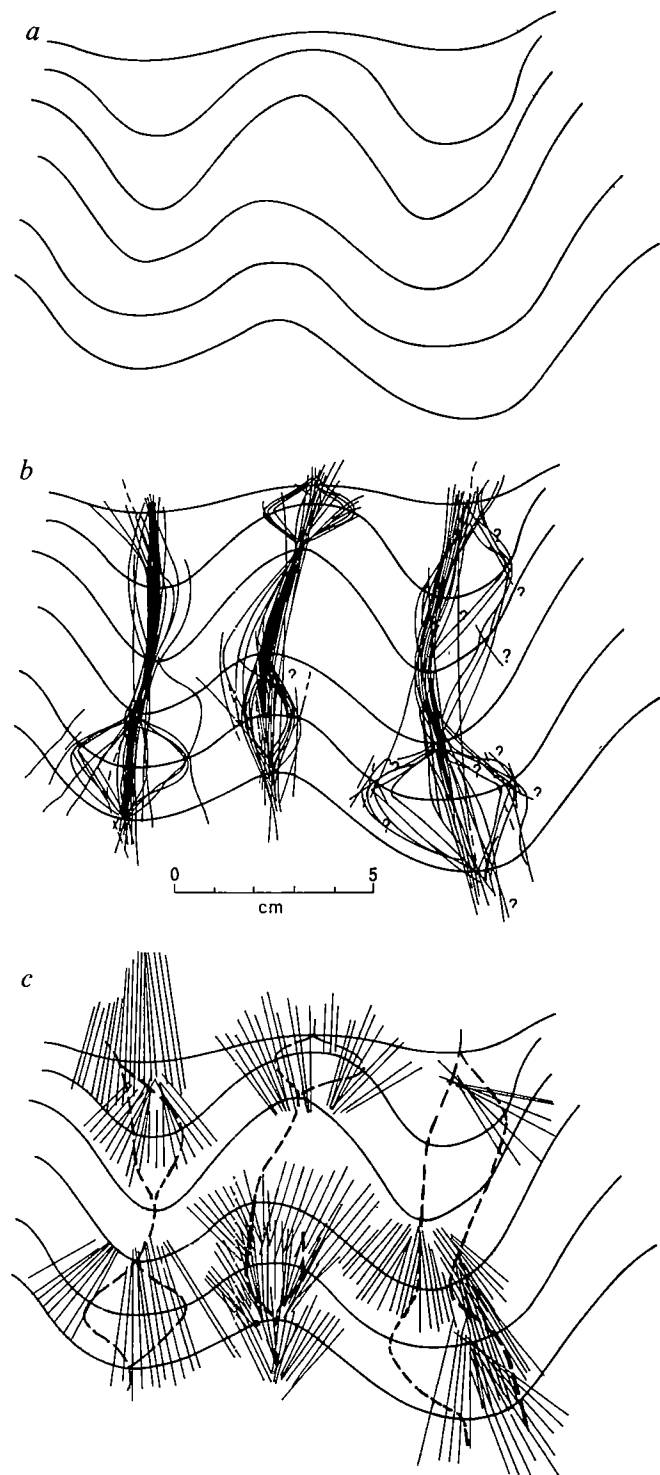
c


Fig. 4 Geologists were requested to locate inflection points on the limbs of the folds shown above Below are microhistograms (ordinate was 10% divisions) of the locations with data combined from 22 structural geologists Arrows, actual inflection points in the original example.

in Fig. 4. In these moderate and high limb dip-folds at least, the inflection points tended to be located too high up on the limb by 17 of the 22 subjects, irrespective of the dip direction of the limb. The overall mean ratio of up-dip to down-dip locations is 3.25: 1 $(0.001 > P > 0.0001)$ Were such folds being so subdivided for Fourier analysis, it would lead to a spurious increase in synform amplitude and wavelength and a complementary decrease. in those parameters in the antiforms. To compensate for the bias the

Fig. 5 A divergent cleavage, when presented in a buckled layer, is reproduced more frequently when presented in the antiform (*A*), than when in the synform, (*B*), irrespective of whether positioned on the left or the right in the visual field. The object was a slide stimulus projected so as to measure about 2 m × 2 m. Subjects were requested to reproduce the item by freehand drawing immediately after stimulus offset, and (*C*) shows the percentage of subjects who remembered the presence of the divergent cleavage in the folded layer (cross-hatching, when the cleavage occurred in the antiforms; criss-crossing, in the synforms). Subjects were tested in groups: *a*, inexperienced and pre-university; *b*, 85 subjects who were beginning geology, were university undergraduates or were 'O' or 'A' level pupils; *c.* 77 subjects with 1–2 years' university experience, *d*, 6 subjects with between 2 and 36 years' experience (Note that in this case experience is correlated with age)

geometry can only be fully applied if the limb dip at the inflection points of the inner and outer arcs is identical To the unaided eye, they seem to be closely the same in strongly flattened folds but at lower shortenings there is usually a portion of the limb which clearly cannot be analysed because of the differential dip of the two layer surfaces In Fig 2 the black areas are those in which isogons cannot be constructed and orthogonal thickness cannot be measured. Differences in amplitude and arc length between inner and outer arc and differences in shape between antiforms and synforms are inevitable in natural folds because the resistance on one side of a layer will never be exactly the same as the resistance to growth in the opposite half space The differences would be even greater if the layer were graded.

Thirty structural geologists were requested to construct axial surfaces through the folded laminations shown in Fig. 3*a*; a synopsis of the constructions from all subjects is shown in Fig 3*b*. with my interpretation constructed on an enlargement (× 3) (Fig. 3*c*) Apart from the expected variability in the constructions, 60% of the subjects tended, in this 'open ended' task, to avoid any construction of bifurcating axial surfaces. Only 12.5% drew all three surfaces as bifurcating in at least some places. This is an omission in analysis which could lead to an inordinately low impression of the prevalence of conjugate and box-fold geometries in naturally deformed rocks. This neglect of multiple-hinged folds is also reflected by the fact that most geologists do not expect conjugate folds to be present on a mappable scale

Twenty-two structural geologists were requested to locate inflection points on the folded layer interfaces shown

Fig. 6 *A*, Percentage of cleavage reproductions that were shown. as symmetrical from synform to antiform by subjects requested to reproduce the asymmetrical cleavage patterns shown in (*B*). *a*, 53 inexperienced subjects; *b*, 31 'O' level pupils; *c*, 54 subjects with 1–2 years' experience; *d*, 41 subjects with more than 2 years' experience. *C*, Common reproduction of (*B*).

inflection points could be located twice with the fold train rotated through 180° for the second analysis. In those cases where the two points are not identically placed a mid-point between them could be used.

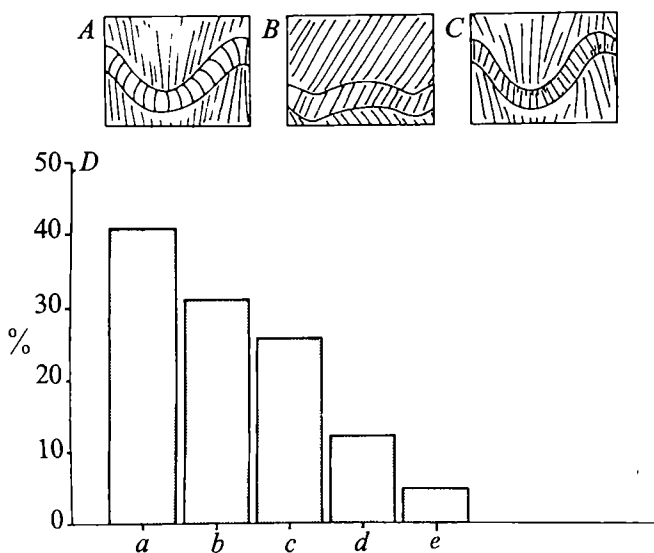
Accuracy of recall from visual short term memory is necessary in observation work; for instance, in making field notebook drawings. To examine such recall, 300 subjects with experience of geology ranging from 2 weeks up to 36 years, in groups ranging from 6 to 50 in number, were shown a randomised sequence of 10 slides which represented varied cleavage fan geometries in folds of single layers. The subjects were required immediately to draw each of the cleavages from memory after viewing the slide stimulus


Fig. 7 Subjects were shown *A*, *B* and *C*, and asked to reproduce them, *D*, percentage of subjects who incorrectly reproduced the layer cleavage in (*C*) as curved: *a*, 44 subjects; *b*, 32 'O' Level pupils, *c*, 40 'A' level and first year university students; *d*, 51 subjects with more than 1–2 years' experience; *e*, 40 subjects with more than 2 years' experience.

for either 7 s or 10 s, depending on the slide. This relatively short viewing time was given because of the limited detail in each slide.

The first conclusion from this experiment is that reproductions of antiformal cleavage fans are much better than those for synformal cleavage fans (Fig. 5). The bias towards better antiform reproduction does not decrease with experience (a divergent cleavage—in the buckled more competent layer—was used here as a stimulus item because it was never, in any of my previous experiments, wrongly reproduced as a guess by any subject when the stimulus item did not contain it). Cleavage fans that were asymmetrical from antiform to synform (Fig. 6), as could occur, for instance, in a folded, graded layer, tended to be reproduced, if at all, as symmetrical from antiform to synform by about 20% of subjects in each experience group.

In some groups the first slide presented had curved cleavage traces and the third was similar to it in many respects, except for the fact that the cleavage traces were straight. The percentage of subjects who misremembered the cleavage in the third slide as curved (that is, the percentage who transposed detail from the first to the third item) did decrease as a function of experience (Fig. 7). On the other hand, cleavage traces which were convergent in the matrix inside the inner arc of the buckled layer were more often misremembered by professional structural geologists as divergent. This is the way matrix cleavage fans are usually represented in text books of structural geology and also, presumably, in the long term memories of the structural geologists.

It was found that the way the object on the screen was construed by subjects could vary as a function of bias introduced by the experimenter and that this could influence the scanning and search strategies used For instance, a palaeontologist who came into a laboratory during the display of one of the sequences (and who had therefore missed the initial instructions) thought that the so-called folds and cleavages were worm-tubes and disrupted laminations. On the basis of introspection he detected no evidence of antiform preference in himself. Rather than looking mainly at th antiforms and. by redundancy, assuming the synform to be symmetrical, he instead scanned along the 'tube' and therefore recognised the differences between the antiforms and the synforms.

Exercise and human sleep

IT has been proposed that slow wave sleep (SWS) in humans is associated with somatic restitution[1], and findings of increased plasma somatotrophin during SWS[2], and of the greater amounts of SWS following exercise[3,4] support this proposal. Others have, however, failed to show any exercise effects of sleep[5,6]. Exercise has been found to increase sleep somatotrophin levels, but not SWS[7]. These contradictory findings may in part be attributed to the large interstudy variations of administered exercise and fitness of subjects (in no study has exercise been standardised against individual work capacity); the time of day of exercise; the need for further qualification of SWS, defined[8] here as sleep stages 3 and 4, respectively containing 20–50% by time of delta activity, and more than 50% delta activity. Up to 20% delta activity is included in the non-SWS stage 2. We have investigated the effects of the time

Table 1 Group means (%) for sleep stages

of day of individually standardised amounts of exercise on subsequent sleep in which stage 2 was subdivided further between 10% and 20% delta activity (2ii).

Eight healthy male subjects (18–22 yr), of average build and fitness, were assessed for individual maximum aerobic power during steady-state exercise on a bicycle ergometer by the Nomogram method[9]. From the maximum work capacity calculated, each subject was prescribed a workload 45% of this capacity. It was further established that this load could be maintained without undue stress for 85 min, with a 15 min break at the half way point. In the main study the exercise was performed by each subject on two separate days, once in the morning, and once in the afternoon. Electroencephalograms were obtained throughout the sleeping period for each exercise night, and for a following 'carryover' night. There were initial adaptation nights and two baseline nights. Subjects were measured in pairs with one performing morning exercise and the other evening exercise on any one day. Diet, naps, extraneous exercise and alcohol intake were controlled. Sleep records were independently scored into the recognised sleep stages[8] and stage 2ii. Group data were compiled for the sleep variables shown in Tables 1 and 2. Related t tests were used to compare the data for each of the experimental nights with the average baseline values.

Tables 1 and 2 show that there are few significant findings. Whole-night percentages of each sleep stage and parameter,

including 2ii, during all experimental nights remained within baseline limits. During the first half of the afternoon exercise night, and particularly before the first rapid eye movement (REM) period, stage 3 showed a significant increase. Although stages 4 and 2ii before the first REM period tended to show increases, they did not individually reach significance. On this night three subjects missed their normally expected first REM period, producing an unusually long delay to a first REM period and enabling more SWS to occur before the first REM period. These three REM period delays seem to be mainly responsible for the longer, but non-significant, REM latency. There are no significant effects for any parameter during the afternoon exercise carryover night. Stage 2ii shows two related significant decreases on the morning exercise night, one before the first REM period and the other for the first half of the night. Any possible loss of delta activity here, however, may have been made up in the slight increase of stage 4, the more substantial delta activity sleep, during the first half of the night. On the morning exercise carryover night, summated delta activity stages 2ii+3+4 showed a significant decrease during the first half of the night, which seems to be reciprocated by a significant increase during the second half. This seems to be a real temporal displacement, rather than an artefact of the division line of sleep into halves. The reason for this is not known.

Our findings seem to show a time of day effect of exercise on

Table 2 Group means for REM parameters

	Baseline	Morning exercise		Afternoon exercise	
Time (min) before first REM period		Recovery night	Carryover night	Recovery night	Carryover night

recovery sleep. The main SWS delta activity increase was for stage 3 during the first half of the night following afternoon exercise, and this seems to be partially counterbalanced by a non-significant decrease during the second half of the night, resulting in no significant overall changes. If SWS reflects enhanced protein synthesis and body restitution[1], then in view of the high workload imposed, more substantial changes in SWS might have been expected. It must be concluded that if a heavy, but tolerable, workload is imposed early in the day then ensuing wakefulness is sufficient for recovery. If this exercise is given later in the day, however, then ensuing wakefulness may not be adequate for recovery, and some of the recovery process may intrude into the earlier part of sleep and be reflected in the sleep EEG.

Dihydroactinidiolide in the supracaudal scent gland secretion of the red fox

IN spite of growing interest in the function of skin glands in mammalian chemical communication[1,2], little is known of either the chemical nature or the behavioural significance of the secretion of the supracaudal (tail) scent gland of the red fox (*Vulpes vulpes*). A recent paper[3] reports observations concerning the histology and histochemistry of this gland, including findings of unusual fluorescent sebum constituents. In this paper, preliminary gas chromatographic–mass spectrometric data are presented indicating the presence of dihydroactinidiolide (I) and related compounds in this secretion and the significance of this finding is discussed.

I   II   III
Particles of waxy yellow-brown stale secretion were separated manually from the hair and skin surface of the supracaudal gland region of eleven male red fox (taken wild, February 14, 1974–April 19, 1974, Wales), bulked (67 mg) and distilled (at 170 °C, air bath temperature, 0.02 mmHg). The distillate was examined by combined gas chromatography–mass spectrometry (AEI MS30 mass spectrometer (24 eV) with a Pye-Unicam 104 gas chromatograph fitted with a 2 m × 2 mm internal diameter glass column of 2% SE-33 on 80–100 mesh Gas Chrom Q; column temperature 116 °C to 280 °C at 5 °C min⁻¹; injector temperature 170 °C; separator temperature 200 °C) following treatment with diazomethane.

A number of volatile components exhibiting mass spectra suggesting monoterpenes or related compounds were observed

in advance of the range of saturated carboxylic acids (starting at C-14, observed as methyl esters) and related compounds expected in a distillate of skin lipids. These more volatile compounds included substances possessing the following observed mass spectra (five most intense ions, plus other significant ions) indicating dihydroactinidiolide (I)[4] *m/e* 180 (M⁺, 22), 165 (7), 152 (11), 137 (30), 111 (100), 109 (30), 43 (25); 6-hydroxy-2,2,6-trimethylcyclohexanone (II)[5] *m/e* 156 (M⁺,6), 128 (31), 110 (35), 95 (39), 71 (100), 58 (34), 43 (36); and *trans*-4-keto-β-ionone (III)[6] *m/e* 206 (M⁺,47), 191 (15), 177 (6), 164 (38), 163 (9†), 121 (53), 43 (100), 41 (38). Other major volatile terpenoid constituents of the secretion distillate are under investigation.

The identity of dihydroactinidiolide was confirmed by gas chromatographic coinjection with authentic material, m.p. 42–43 °C (retention time 4.1 min, 1.5 m × 2 mm internal diameter glass column of 5% Dexsil 300-GC on 80–100 mesh Chromosorb W, AW; column temperature 172 °C, isothermal). A peak of the same retention time was also noted when a thin-layer chromatography fraction (acetone pre-eluted silica gel G (Merck type 60), R_f 0.06 to 0.2 with diethyl ether–petroleum spirit (60–80 °C), 30/70, v/v) of a methanol–chloroform extract of stale secretion was examined by gas chromatography (dihydroactinidiolide, R_f 0.08). The level of dihydroactinidiolide in this sample of stale secretion was < 50 p.p.m.

This is the first report of volatile terpenes in an external mammalian glandular secretion, although it was expected that such compounds might be involved in mammalian communication following the elucidation of the olfactory response of certain Felidae to *cis-trans*-nepetalactone, a major constituent of the essential oil of the catnip plant, *Nepeta cataria*[7]. The early description of the supracaudal gland as the 'violet gland' on account of its odour also suggested such a finding. A number of terpenoid constituents of the plant *Actinidia polygama*, including dihydroactinidiolide, are also reported to have behavioural effects on certain Felidae[8].

The presence of photolabile fluorescent compounds has been reported in the red fox supracaudal gland sebum, and fluorescence and ultraviolet spectra have been described[3]. Field desorption mass spectrometry of the major non-polar fluorescent fraction (Varian CH5D, source temperature 80 °C, emitter current 8 mA) revealed major ions at *m/e* 524, 525, 550 and 552 (no ions in range *m/e* 554–1,200) indicating the presence of compounds in the carotenoid mass range. If carotenoids are present, their occurrence could be related to the presence of volatile terpenes in the secretion[9].

Ethylene in soil

THE origin of ethylene in the soil atmosphere is of interest because the concentrations at which it sometimes occurs can restrict plant growth by inhibiting root extension in cereals[1] and root nodulation in legumes[2]; it has also been suggested that it aids plants by inhibiting pathogenic fungi[3]. Our earlier observations showed that ethylene could be produced by a soil fungus, *Mucor hiemalis*, and two soil yeasts, which have now been identified as *Candida vartiovaarai* and *Trichosporon cutaneum*, when glucose and methionine were available to them[4]. Subsequent investigations in pure culture and in soil have attempted to elucidate mechanisms by which these organisms could synthesise the gas[5-7]. Other investigators[3,8] have proposed that anaerobic spore-forming bacteria rather than fungi are largely responsible for ethylene formation in soil as: (1) heat does not prevent the formation of the gas in soil, (2) anaerobiosis favours its formation and (3) the gas is fungistatic. Further experiments have therefore been undertaken in an attempt to assess if these latter observations cast doubt on our conclusions; the results are reported here.

Using previously described techniques[8] we have confirmed earlier reports that heat[8] and even autoclaving[9] can stimulate the production of ethylene by soils (Table 1). The effect of heat at 100 °C on the release of ethylene from pure cultures of *M. hiemalis* was therefore investigated. No ethylene was produced by heating the culture medium alone but, although the treatment killed the fungus, the evolution of the gas from the treated culture was greatly enhanced compared with that of cultures kept at 25 °C (Fig. 1). Some observations in our earlier work suggest that a possible explanation for this is that *M. hiemalis* forms an intermediate substance in the pathway to ethylene which passes into the extracellular solution and breaks down non-enzymically, a process promoted by heat at 100 °C (ref. 6). Another possible explanation is that heat decreases the growth rate and in the range of growth rates 0.08 h^{-1} to 0.02 h^{-1}, there

Table 1 Effect of heat treatment on ethylene production by two soils

	Ethylene nmol per 100 g soil per 6 d	
	Chalk loam (Gore series)	Basaltic loam (Woodburn series)
Treatment	6.6% organic matter	9.8% organic matter
Boiling (100 °C per 10 min)	8.0	23.4
Autoclaving (121 °C per 60 min)	3.4	7.2
Control (unheated)	0.7	22.9

Soils (5 g) were wetted and incubated in glass vials (14 ml)[8].

is an exponential increase in ethylene production[7]; furthermore the subsequent cell lysis also increases the production of the gas[5].

The production of ethylene after heating soil is therefore consistent with a fungal origin. Moreover we have obtained evidence that although ethylene is normally produced in anaerobic conditions[10], the importance of these conditions seems to lie in the provision of substrates, which we have recently found can be provided by crop residues. When suitable substrates, glucose and methionine, are provided the production of ethylene by *M. hiemalis* and by soil is stimulated by oxygen[5]. Furthermore anaerobiosis can reduce fungal growth rate which increases ethylene production[5,7] and inhibits ethylene breakdown by soil microorganisms[11]. Waterlogging, of which anaerobiosis is a consequence, inhibits gaseous diffusion and retains ethylene in the soil atmosphere.

Fig. 1 Effect of heat (100 °C per 30 min) on ethylene production by pure cultures of *Mucor hiemalis*. The fungus was grown in glucose–methionine medium[5] (100 ml) in flasks (capacity 325 ml) for 48 h to produce 1.5 mg dry weight ml^{-1}. The cultures were then heated and the flasks sealed 30 min after the treatment. The heated medium[5] alone produced no ethylene. ●, Heated; ○, unheated.

Fig. 2 Colonisation of buried straw by a mixed fungal population (identified as *Mucor* sp. and *Fusarium* sp.) in the presence of ethylene; similar fungal development has been observed in the presence of 1,000 p.p.m. ethylene. Saprophytic fungi are the most likely causative agents of ethylene production from organic residues in soil.

If the inhibition of growth by ethylene was a normal characteristic of fungi, they could not be considered as the main producers of the gas in soil. But whereas the pathogenic fungus *Sclerotium rolfsii* is very sensitive to ethylene[3], five other fungal species investigated in this and three other laboratories were found to be relatively unaffected by considerably higher con-

centrations than those found in soil (Table 2). Figure 2 shows the extensive mycelial development which can occur in the presence of high concentrations of the gas and while it might be postulated that ethylene would be fungistatic only in nutrient-limited conditions, we have found little evidence for any soil microbial activity in these conditions.

Table 2 Effect of ethylene on fungal growth			
		Maximum inhibition of growth or germination (%)	
Fungus	Concentration of ethylene (p.p.m.)	In vivo	In vitro
Sclerotium rolfsii[3]	1	100*	—
Fusarium oxysporum[12]	2,000	16†	57
Gloeosporium album[13]	2,000	33†	19
Sclerotinia fructigena[14]	100	22†	12

Aspergillus clavatus	1,000	0‡	—

—, No information.
*Grown in soil.
†On fruit tissue.
‡On decaying barley tissue in soil.
§In 1/100 strength tryptone soya broth.

In our earlier work[4] bacterial isolates from soil produced little or no ethylene whereas fungal isolates produced large amounts. This observation has now been confirmed and in addition studies in pure culture with the ubiquitous soil anaerobe, *Clostridium pasteurianum*, showed negligible production of ethylene. Moreover the only report in the literature on the production of ethylene by bacteria in pure culture relates to *Pseudomonas solanacearum*[15]; in contrast, cultures of over 70 fungi have been shown to produce ethylene[16]. No information now available therefore is inconsistent with saprophytic fungi being responsible for the production of ethylene and in the soils we have studied *M. hiemalis* seems to be a major contributor. This does not prove that anaerobic bacteria do not produce ethylene but indicates that their contribution if any is very minor.

Cytogenetic effects of plutonium-239 in male mice

INCREASING quantities of plutonium-239 are processed in the nuclear power industry. The likely magnitude of the associated genetic risk is still uncertain but thought to be less than the risk of cancer induction[1]. Green *et al.*[2] have recently shown, however, that plutonium reaching the testis after intravenous injection of [239]Pu citrate into CBA mice concentrates in the interstitial tissue, outside the seminiferous tubules. They calculated that the average dose rate to spermatogonial stem cells, in which genetic damage can accumulate, was about 2–2.5 times

that to the whole testis. In these circumstances, the genetically significant dose is higher than the average tissue dose, which is that normally used for protection purposes[1]. To obtain more direct evidence on genetic damage from gonadal plutonium, we are studying the induction of chromosome aberrations in germ cells of male mice after protracted exposure to α particles from [239]Pu. The results of the first experiment, described here, suggest that α radiation has the expected high relative biological effectiveness (RBE)[3] for induction of chromosome damage and that a distribution factor of the magnitude proposed may indeed be operating as well.

Twelve 10-week-old (C3H/HeH♀ × 101/H♂) F₁ male mice were injected intravenously with 10 μCi kg⁻¹ [239]Pu in 1% trisodium citrate solution (about 0.3 μCi per mouse). Three littermate controls were injected with similar quantities of the citrate solution alone. Cages of four treated and one control were kept for 6, 12 and 18 weeks. They were then killed and weighed, as were the testes. Air-dried chromosome preparations[4] were made from cellular suspensions of each right testis, and the left was used for radiochemical assay of plutonium. From each testicular preparation, 100 spermatocytes at diakinesis–metaphase I were scored for chromosome anomalies. Additional procedures on the 18-week batch only were sperm counts from the caput epididymis[5]: examination of 500 spermatozoa from the cauda epididymis for head abnormalities, after staining with eosin Y and making air-dried smears[6]. All slides were coded.

The fraction of injected plutonium retained in the left testis changed very little over the period of the experiment (Table 1); therefore radiation dose was taken to be the product of the assay-derived dose rate (≈ 0.0002 rad min⁻¹) and time. Testis weight declined to 58% of controls after 18 weeks (Table 2). At this time, the mean epididymal sperm count was only 51% of the control value, showing that much of the testis weight loss was the result of germ cell death. The mean frequency of sperm-head abnormalities was 9.0%, compared with 4.6% in controls, but this difference mainly stemmed from one male with 17.2% abnormalities. The causes of these abnormalities are not yet known, but they are thought to indicate genetic damage[6].

In the experimental series, frequencies of autosomal and X–Y chromosome univalents did not differ significantly from control values of $6.0 \pm 1.4\%$ and $12.0 \pm 1.9\%$, respectively. The frequencies of spermatocytes with fragments (Table 2) showed a non-significant increase in the irradiated series; 87% of these fragments were diagnosed as double and thought to be the result of isochromatid breaks. Whereas affected control cells had one fragment each, six cells in the irradiated series had two fragments and three cells had three. Thus the overall fragment frequency after treatment was $3.4 \pm 0.7\%$, compared with the control frequency of $1.3 \pm 0.7\%$ ($P = 0.07$ on one-sided test).

The increase in the frequency of spermatocytes with quadrivalent configurations (Table 2) in the treated series is clearly significant. Most of these were typical rings and chains of four arising from chromosomal reciprocal translocation in spermatogonia, as previously found after X, γ and neutron irradiation of this cell type[7]. A few, however, (especially at the 18-week interval) seemed to resemble more closely the type of quadrivalent previously seen by two of us after X irradiation of

Table 1 Results of radiochemical analysis of left testes of hybrid mice after injection of [239]Pu, with determinations of average radiation dose

Weeks of exposure	No. of mice	[239]Pu in left testis (± s.e)		Dose* (rad)
		% Injected activity	pCi	
0	3	—	—	0
6	4	0.042 ± 0.002	130 ± 9	14
12	4	0.048 ± 0.002	143 ± 13	30
18	4	0.040 ± 0.004	134 ± 28	44

*For calculations of dose, the average of the control and the mean experimental left testis mass for the batch concerned was used, and the mean energy of a single α particle from [239]Pu was taken as 5 15 MeV (ref. 16).

Table 2 Mean testis mass and chromosome aberrations at metaphase I at different times after injection of ^{239}Pu (percentages in brackets)

Weeks of exposure	Testis mass (mg ± s.e.)	Spermatocytes scored	Number with		Reciprocal translocations		
			Fragments	Quadrivalents*	Rings	Chains	Totals

18	73 ± 8	400	12 (3.0)	9 (2.3)	2	3	5 (1.3)

*Resulting from reciprocal translocations arising in spermatogonia (see next columns) or chromatid interchanges in spermatocytes.
†Three cells each had two rings of four.

oocytes in female mice[8], they were therefore thought to be the result of chromatid interchange in spermatocytes during meiotic prophase.

The yield of quadrivalents was reduced at the longest exposure period, the effect being most marked in the translocation group. A similar decline in translocation frequency has been reported after high acute exposures to X rays[9,10] or fission neutrons[11], but not after protracted exposures to the latter. The same phenomenon occurs with specific locus mutation frequencies after acute exposures[12] and is thought to be connected with the preferential killing of the most mutationally sensitive part of the spermatogonial population by high radiation doses. It is possible that a similar explanation could account for the decrease in the present experiment. Consequently, the low 18-week values have been excluded when determining rates of induction.

The data on reciprocal translocation induction can be used to obtain a rough estimate of the relative effectiveness of the α particles. As these translocations would be expected to arise in spermatogonia rather than spermatocytes (where the chromatid interchange type would be found), the time taken for the germ cells to pass through meiosis to metaphase I (13 d)[13] should be subtracted from the actual exposure period, to give the period of spermatogonial exposure. When these amended doses of 10 and 25 rad are used and linearity of response is assumed the rates of induction of reciprocal translocations at the 6-week and 12-week exposure periods are 1.0×10^{-3} and 1.9×10^{-3} rad^{-1}, respectively, with a mean of 1.45×10^{-3} rad^{-1} of the average testis dose. In previous experiments with the same hybrid male mice, a 600 rad spermatogonial dose of γ rays delivered at 0.02 rad min^{-1} (ref. 14) induced translocations at the rate of 2.3×10^{-5} rad^{-1}, whereas a 62-rad dose of fission neutrons, delivered at 0.0005–0.0008 rad min^{-1} (ref.11) induced them at a rate of 0.53×10^{-3} rad^{-1}. These rates are lower than that estimated for ^{239}Pu α particles by factors of 63 and 2.7, respectively. Thus these results are in good agreement with the assumption that α particles have a similar RBE for translocation induction to that of fission neutrons (previously reported as about 23 for chronic exposures)[15] and that the α-particle dose to spermatogonia is about 2.5 times the mean dose to the whole testis[2]. There are, however, wide error limits to some of these values as well as uncertainty on whether more protracted γ irradiation would have the same effect as the 0.02 rad min^{-1} dose quoted above. Therefore further work is in progress, from which we hope to make a direct comparison of translocation induction by ^{239}Pu α particles and by ^{60}Co γ rays, with similar protracted exposures for both types of radiation.

We thank G. Fisher for assistance with dosimetric aspects, D. Papworth for statistical help and Dr J. Vennart for encouragement and advice.

Reversible arrest of mouse 3T6 cells in G_2 phase of growth by manipulation of a membrane-mediated G_2 function

BESIDES replicating their genetic material and subsequently partitioning it between two daughters, cells of higher organisms also generally contain two distinct periods during their growth cycle in which they are engaged in neither activity. The first of these is a gap which occurs between the completion of one division and the onset of the next round of DNA synthesis, and is abbreviated as G_1. The ability to obtain stable populations of cells reversibly arrested in G_1 (refs 1–3) has made possible extensive investigation of this stage of the cell cycle[4]. The second gap (G_2) lies between the completion of DNA synthesis and the onset of mitosis. Chiefly because of the unavailability of techniques for reversibly holding cells at this stage, the possible functions of G_2 have remained largely unprobed[5]. I now report a method by which reversibly-arrested G_2 cells can be obtained and tentatively suggest one function of this phase as being the reorganisation of the cell surface in preparation for the start of mitosis.

It has become increasingly evident over the past few years that cell membranes are fluid regions[6–9] within which movements of constituent macromolecules such as surface antigens[10], membrane-bound enzymes[8], and surface agglutinin receptor sites may occur[11,13]. Such movements have been shown to be temperature dependent[8,11,12], occurring freely above 15 °C, but being greatly restricted when temperatures are lowered below this point[2,11,13,14]. This has also been found to be a critical temperature range for the physical state of the lipid bilayer itself[15], with a phase change occurring from a fluid to a crystal-line gel as the temperature drops to about 15 °C. It is possible to influence the critical temperature at which this phase transition will occur. When this is done the temperature at which mobility of constituent macromolecules becomes restricted is comparably shifted[11]. Such alterations have been accomplished by influencing membrane fatty acid composition[11,19]; a higher degree of unsaturated fatty acids makes the achievement of a crystalline lipid state more difficult, so that membrane fluidity may be retained even at very low temperatures[16–18]. This has been done by growing cells in a serum supplement from which lipid has been removed, thereby shifting the temperature dependence of the mobility of receptor sites for concanavalin A on 3T3 and SV40-transformed 3T3 cells[11]. A similar technique was used in the present study.
Fig. 1 Onset of mitosis after transferring cells from 15 to 37 °C. 3T6 cells were seeded at subconfluent densities (as cell–cell interactions might influence membrane transitions) in the absence of serum and incubated at 37 °C for 3 d. The G_1 arrested cultures thereby obtained were then transferred to rich serum conditions (10% foetal calf serum plus 5% calf serum), but in the presence of 2.88 mM hydroxyurea to hold the cells just at the border of entry into DNA synthesis. After incubation for 15 h in the presence of hydroxyurea, the cultures were washed and changed to fresh, serum-enriched, hydroxyurea-free medium. *a*, Filming was begun immediately after release from hydroxyurea. Incubation was at 37 °C throughout. *b*, Cultures were incubated at 37 °C for a further 9.5 h after hydroxyurea release and then transferred to 15 °C. After 20 h at 15 °C the cultures were shifted back to 37 °C and filming begun immediately *c*, As in *b* except cultures were left at 15 °C for 68 h. In the filming analysis, individual cells were followed and the times at which they rounded up (early metaphase) and divided into two attached daughter cells (late telophase) both recorded. Each horizontal bar starts at the rounded and extends through the double-cell stage for one cell. Each bar, therefore, represents the first mitotic event for one particular cell. The bars are placed on the graph in accordance with the time of occurrence of these events, and if the mitoses of two cells overlap in time, then one is placed above the other.

It has also been suggested that lectin receptors on transformed cells may generally be more amenable to mobilisation than are those of their untransformed counterparts[12,20] (see ref. 6 for review); although untransformed cells presumably take on a similar ease of surface rearrangement at about the time that they enter mitosis[21]. I have reasoned that if membrane reorganisation is a normal part of the progression of cells to mitosis, and if such reorganisation is contingent on an adequately fluid membrane environment, then interference with membrane fluidity should also prevent cells from entering mitosis. Since this sort of reorganisation may be expected to occur sometime between the completion of DNA synthesis and the onset of mitosis, then reversibly 'freezing' the membrane to prevent such movements from occurring, may be equivalent to reversibly arresting cells in the G_2 phase of growth.

I have attempted to 'freeze' movements within cell membranes by lowering the cultivation temperature of the mouse 3T6 cell line to 15 °C. Since a temperature decrease of this sort may be expected to have a variety of effects throughout the cell cycle[16,22–24], cells were first presynchronised to be as near as

possible to the completion of DNA synthesis before the temperature was lowered. Experimental conditions were thus intentionally manipulated with the specific purpose of looking at membrane-related events in G_2, rather than pursuing a general temperature effect on randomly growing cultures. Details of the presynchronisation are given in Fig. 1.

The mitotic responses of cells which had been held at 15 °C for various lengths of time and then shifted back to 37 °C are shown in Fig. 1. Here, mitoses were followed cinemicrographically, with the times of rounding up (early metaphase) and division into two attached cells (late telophase) recorded and plotted for each individual mitotic event. Figure 1*a* shows the profile for onset of mitosis after release of cells from hydroxyurea block and cultivation without interruption at 37 °C. The first mitoses occurred at about 12 h after release, with a broad peak between 14 and 19 h. If, at 9.5 h after release from hydroxyurea, cells were transferred to 15 °C for either 20 h (Fig. 1*b*) or 68 h (Fig. 1*c*) and then returned once again to 37 °C, the ensuing mitotic pattern was altered as shown. In both cases there was a lag of about 2 h before any mitoses were apparent at all. This time lag was not shortened by longer periods at the low temperature, and was followed by a very sharp mitotic burst occurring about 3–4 h after return to 37 °C. This burst was intensified by the longer period at the low temperature (Fig. 1*c*). It would seem from these observations that cells are being arrested, and not just retarded, in their movement through the G_2 phase, and that this arrest is reversible.

I attempted to confirm the conclusion that cells were being held in G_2 by low temperature by measuring the DNA content per cell on a BDH flow microfluorimeter. This is shown in Fig. 2 where the amount of DNA per cell in randomly growing cultures (S) is compared with that of cultures which had been presynchronised and then transferred to 15 °C (F10L63). There is a marked shift of the distribution in the F10L63 cells to the G_2 region. It can be roughly calculated from these distributions that in randomly growing cultures about 17% of the cells are in G_2, whereas in the F10L63 the G_2 population accounts for over 80% of the cells.

If the G_2 arrest is a function of the fluidity of some cellular membrane system, then the maintenance of high fluidity, even at low temperature, should enable the cells to proceed to mitosis even at 15 °C. As has been mentioned above, this can be attained by altering fatty acid compositions by cultivating the cells with a delipidated serum supplement. We treated foetal calf serum as detailed in Fig. 3 and then grew 3T6 cells in this

Fig. 2 DNA contents per cell of randomly-growing and cold-arrested 3T6 cells. Either randomly-growing cells (S) or cells which had been held at 15 °C for 63 h (F10L63) (as described for Fig. 1), were analysed for their DNA contents. Cells were fixed and stained with acriflavine according to the method of Tobet *et al.*[32] and the fluorescence per cell determined on a BDH flow microfluorimeter. The abcissa is in arbitrary fluorescence units, proportional to the amount of DNA, per cell and the ordinate represents the number of cells in that fluorescence channel. Between 1×10^6 and 2×10^6 cells were counted for both S and F10L63 cultivation conditions
delipidated supplement, with an additional supply of biotin, (an essential cofactor for the biosynthesis of fatty acids) through several transfers at 37 °C. The fatty acids of cells which had been grown in normal serum and those which had been cultivated in the delipidated serum ('Delip' cells) were extracted[26] and analysed on a polyethylene glycol–adipate gas–liquid chromatography (GLC) column.

It was found that the proportion of saturated palmitate and stearate fatty acids in the 'delip' cells had decreased about threefold, whereas the unsaturated oleate plus elaidic fatty acids had proportionately increased about 2.5-fold compared with cells which had been grown in whole serum. To test whether this treatment also resulted in the release of cells from the low temperature G_2 block, the 'delip' cells were presynchronised and then shifted to 15 °C (Fig. 1). The DNA content/cell profiles for randomly growing 'delip' cells at 37 °C and cells held at 15 °C are shown in Fig. 3. Cells with the altered fatty acid composition were not held in G_2 at 15 °C. This was in agreement with the finding that the cell number of such cultures gradually increased at 15 °C, although no similar increase in number could be detected for cells which had been grown in whole serum.

I conclude that there is a temperature-dependent transition point in the G_2 phase of normal cell growth which is related to the fatty acid composition of some cell membrane system. I suggest that the G_2 function involved may be an obligatory surface rearrangement before mitosis, and that this rearrangement can be reversibly inhibited by decreasing membrane fluidity. Although fatty acid replacement experiments strongly implicate a fluid membrane function, one cannot identify definitively, from the present experiments, which of the cellular membrane systems may be involved[14,16]. Careful tailoring of membrane fatty acid compositions so as to adjust critical temperature transitions points to more physiological ranges should help both in elucidating this question as well as in providing a possible new method for sharply synchronising cells in the G_2 phase of growth.

I thank Dr Peter Riddle, Mr David Capallero and Miss Jyoti Gohil for assistance and Mr Michael Jones of the Chemistry Department of the ICR Fund for his help with the GLC fatty acid analyses.

Fig. 3 DNA contents per cell of 3T6 cells with altered fatty acid composition. As for Fig. 2 except using cells which had been grown with a delipidated serum supplement. 100 ml of foetal calf serum were stirred with 100 ml acetone at 4 °C for 3 h. After centrifugation at 1,800g for 30 min, the cloudy yellow supernatant was discarded and the pellet resuspended in 150 ml chilled acetone and stirred in the cold overnight. This was then centrifuged, the supernatant discarded, and the sediment collected and dried under vacuum; this yielded 3.52 g of a white powder which could be stored for several months at −20 °C. For use in cell cultivation, 600 mg of the powder were suspended in 10 ml of 0.01 M acetate at pH 4.0 and then dialysed extensively against the acetate buffer in the cold. The suspension was then spun down at 1,800g for 2 h and the supernatant collected. (This was the delipidated serum and it contained ∼ 16.5 mg protein per ml.) The delipidated serum was filter-sterilised before use. S, Randomly growing cultures at 37 °C. F10L63, cells held at 15 °C for 63 hours.

Independent routes for Na transport across dog red cell membranes

PARKER and Snow[1] have shown that extracellular ATP produces an apparently nonspecific and reversible increase in the cation (Na^+ and K^+) permeability of dog red cells, as a result of which the cells swell gradually during suspension in an isosmolar physiological bathing medium containing ATP. This effect contrasts markedly with the usual dependence on cell volume of cation fluxes in this type of red cell[2–6] which, unlike most mammalian erythrocytes, is close to ionic equilibrium with plasma[6–7], and lacks an ouabain-sensitive ion pump[8,9]. Exogenous ATP was found to influence the surface properties of chick embryo fibroblasts[10], and also cause volume changes and cation imbalances in ascites tumour cells[11], and it has been suggested[11] that ATP alters the passive permeability of the membrane to Na^+ and K^+ rather than the cation pumping mechanism *per se*. Effects of ATP on the membrane transport characteristics of various tissue culture cell lines have been studied[12,13], and it has been proposed[12] that the translocation of ATP itself may be linked with ion movement across membranes.

I have now measured $^{24}Na^+$ uptake in dog red cells suspended in various media with and without extracellular ATP, and have found that the steady-state Na^+ influx, referred to cell volume in control isotonic conditions, is not changed significantly by swelling the cells in hypotonic media. In the presence of ATP, however, Na^+ permeability is greatly increased whether the cells are allowed to swell naturally or are shrunken by the osmotic effects of sucrose; in these circumstances it was necessary to estimate unidirectional Na^+ fluxes from the half times for $^{24}Na^+$ equilibration[6]. The sum of the Na^+ fluxes measured separately in cells suspended in isosmolar media

containing ATP, and in cells suspended in hyperosmolar media (+ 100 mM sucrose) in the absence of ATP, is equal to the Na^+ flux in ATP-treated cells after they have been shrunk. Shrinkage of the cells was carried out in the presence of ATP in media containing sucrose (100 mM). This indicates that the 'Na^+ channel' opened in the presence of ATP, when the cells are swollen, is not closed by shrinking the cells, and that the increase in the permeability to Na^+ normally brought about by shrinking the cells occurs by way of a route which is independent of and parallel to the pathway opened in the presence of extracellular ATP.

Quantitative measurements of $^{24}Na^+$ uptake, relative cell volume and intracellular Na^+ and K^+ concentrations were made from a series of single samples of packed cells spun down during the uptake of $^{24}Na^+$. ^{131}I-human serum albumin was used as the extracellular marker. Known volumes of packed cells were sampled with a Hamilton gas-tight syringe fitted with a Chaney adaptor. Details of the method have been described previously[5,6,14].

Figures 1 and 2 illustrate respectively the differences in the haemoglobin concentration (Hb_i) and the rate of uptake of $^{24}Na^+$ by cells in various experimental conditions. Cells suspended in media containing 25 mM and 50 mM less NaCl than the control isosmolar medium swelled by $13.1 \pm 0.7\%$ and $30.9 \pm 0.8\%$, respectively, and were at constant cell volume during the uptake of $^{24}Na^+$. In these conditions Na^+ influx was not altered significantly. By contrast, although the average volume of cells exposed to hyposmolar conditions (-50 mM NaCl) was similar to that of cells exposed to 2 mM ATP in an isosmolar medium (Fig. 1), in the latter group there was a 68-fold increase in Na^+ flux and a net uptake of Na^+ (Table 1).

When cells were suspended in a solution containing 100 mM sucrose, in addition to the usual constituents, they shrank by an average of $24.0 \pm 0.8\%$ and the Na^+ flux increased by a factor of 44 (Table 1). Although treatment with ATP had no significant effect on cell volume in the presence of 100 mM sucrose, the rate of Na^+ exchange was, however, increased even further to 395 ± 46 mEq per l cells (isosmolar cell volume) per h after ATP-treated cells had been shrunken. It is unlikely that the agreement between this value and the sum (437 ± 34 mEq per l cells per h) of the fluxes measured independently was fortuitous, as virtually the same findings were produced by separate experiments with red cells from two other dogs.

A secondary outcome of the present work was the lack of any discrepancy between the equilibrium levels of intracellular and extracellular specific activity of $^{24}Na^+$ in swollen cells treated with ATP. This indicated that the apparent sequestration of intracellular Na^+ in shrunken cells which was found in previous studies[5,6] was in fact the result of partial dehydration of the cells.

The effects of exogenous ATP and cell shrinkage on Na^+
Fig. 1 Haemoglobin content of dog red cells during the uptake of $^{24}Na^+$ illustrated in Fig. 2. These data provide a measure of cell volume in the different media relative to that in control isosmolar conditions: NaCl, 137.2 mM; KOH, 5.0 mM; TES (N-*tris* [hydroxymethyl] methyl-2-aminoethane sulphonic acid), 5.0 mM; Na_2HPO_4, 5.2 mM; NaH_2PO_4, 0.8 mM; glucose, 5.0 mM; and 1% (w/v) bovine serum albumin (Armour, Cohn fraction V). Ca^{2+} and Mg^{2+} were omitted as they greatly inhibited the effect of ATP (ref. 1 and B. C. E., unpublished). pH of solutions containing ATP was adjusted to 7.2–7.4 with KOH (1.2 mM per mM ATP). Washed red cells were preincubated (where appropriate) in an isosmolar medium with 2.0 mM ATP for 2 h at 38 °C, then washed and resuspended in the same solution ($\pm$ sucrose 100 mM) at haematocrit values of about 10%. Control isosmolar, hyperosmolar and hyposmolar groups of cells were treated in a similar fashion with the appropriate bathing medium. Finally, all groups were gently shaken at 38 °C for 75 min in the presence of ^{131}I-albumin before the start of $^{24}Na^+$ uptake. ▲, +2 mM ATP, +100 mM sucrose; ●, +100 mM, sucrose; ○, control; □, −25 mM NaCl; ▽, −50 mM NaCl; △, +2 mM ATP.

fluxes are additive, implying that separate pathways are involved. There is, however, a common factor between the processes controlling the two states of increased permeability to Na^+, as it has been proposed[5] that phosphoglycerate kinase controls the dependence on cell volume of Na permeability in

---

Table 1 Na^+ fluxes in dog red cells as a function of cell volume in the presence and absence of ATP (2 mM)

Experimental conditions	Hb_i (g per l cells*)	Na^+_i (mEq per l cells*)	K^+_i (mEq per l cells*)	Normalised[‡] Na^+ flux (mEq per l cells per h)
Control	325.2 ± 1.4[†]	97.6 ± 0.3[†]	4.3 ± 0.1[†]	3.9 ± 0.1[§]
NaCl, −25 mM	287.6 ± 1.1	86.6 ± 0.4	3.9 ± 0.1	3.7 ± 0.1[§]
NaCl, −50 mM	248.5 ± 1.1	75.0 ± 0.1	3.4 ± 0.1	3.9 ± 0.1[§]

Fig. 2 Uptake of $^{24}Na^+$ by dog red cells in the conditions described in Fig. 1. Symbols as in Fig. 1. Right hand ordinate scale expanded fivefold for influx of $^{24}Na^+$ in control isosmolar conditions (O) and in hyposmolar media (−25 mM NaCl, □ and −50 mM NaCl, V). In groups ●, ▲, △ (all left-hand ordinate) and O, initial values of extracellular specific activity were almost the same (about 3.65×10^6 counts per 100 s per mEq Na^+); in groups □ and V the values were 4.23 and 5.32×10^6, respectively. Half times for the exchange of $^{24}Na^+$ were 7.6 ± 0.8 min (▲), 18.6 ± 3.0 min (●) and 20.4 ± 1.2 min (△), compared with about 780 min for groups V, O and □. Na^+ fluxes estimated from these plots are listed in Table 1.

the dog red cell; and this enzyme catalyses one of the ATP-producing reactions in the glycolytic sequence.

There is evidence[1] that exogenous ATP can alter the metabolic rate of dog red cells; however, it would seem that hydrolysis of the nucleotide is not providing a source of energy for the maintenance of the Na^+ channel, as ouabain (up to 10^{-3} M) has no inhibitory effect on the enhanced Na^+ flux in ATP-treated cells[1]. Note also that the ATP effect is probably not mediated by the removal of membrane-bound divalent cations, as up to 5×10^{-3} M EDTA, which chelates Ca^{2+} and Mg^{2+} more strongly than does $ATP^{15,16}$, has no effect *per se* on cell volume or Na^+ transport in dog red cells; neither does it interfere with the action of ATP in cells suspended in Ca^{2+}- and Mg^{2+}-free media (B. C. E., unpublished). Furthermore, it seems that ADP and other nucleotides are virtually without effect on cation permeability in the dog red cell[1].

The actual mechanisms of the volume-dependent and ATP-induced permeability changes are still unclear[1,4,5,11,12,17,18]; however, because of the large and to some extent cooperative increase in Na^+ flux caused by either ATP[1] or cell shrinkage[6] it is tempting to refer to Na^+ channels being switched on in the two circumstances. It would be extremely interesting if the properties of these channels were to bear any resemblance to the cation channels that have been characterised in nerve preparations[19]. Preliminary experiments, however, have indicated that tetrodotoxin (10^{-6} g ml^{-1}, pH 7.0) has no effect on the Na^+ channel opened in shrunken cells.

Obviously, cells are not going to encounter extracellular ATP concentrations of the order of 1–2 mM *in vivo*. It is clear, however, that ATP provides a specific way of perturbing membranes that gives rise to marked changes in permeability characteristics, not only of dog red cells but of a variety of cell types.

State of molecular motion of cholesterol in lecithin bilayers

CHOLESTEROL is a major constituent of many biological membranes. Although its exact function is not completely understood, a large number of studies have indicated that cholesterol can affect the packing of lipid hydrocarbon chains, both in model and in biological membranes[1]. The interaction is envisaged to be such that above the thermal phase transition temperature (T_C), cholesterol inhibits flexing of the hydrocarbon chains, whereas below T_C it prevents the chains from crystallising into the rigid α gel[2-6].

Rothman and Engelman have argued[7] that the interactions between cholesterol and the phospholipid hydrocarbon chains in a lipid bilayer are primarily steric in nature, and the dramatic effects of cholesterol on the motional state of a phospholipid bilayer resides in the relative cross sectional area of the ring system (the nucleus) compared with that of the aliphatic tail. As the cross-sectional area of the nucleus is approximately twice that of the tail, steric interactions involving these parts of the molecule are thought to be different. If one supposes that in cholesterol-containing bilayer membranes, the upper part of the fatty acid chain is contiguous with the rather bulky cholesterol nucleus and the lower part of the chain with the narrower cholesterol tail, it seems plausible that cholesterol can serve to limit the number of accessible chain conformations along the upper part of the fatty acid chain while simultaneously increasing the number of accessible conformations to the lower part of the chain.

The question of cholesterol mobility is intriguing and important. Although the model of Rothman and Engelman[7], which views the cholesterol nucleus as being rather immobile and the tail as highly mobile, seems reasonable, it is primarily based on model building. Several nuclear magnetic resonance studies[6,8,9] disagree with this notion and claim that the cholesterol molecule as a whole, including the tail, is highly immobile, as a consequence of some specific 1:1 phospholipid–cholesterol complex formation. Unfortunately proton magnetic resonance spectra of cholesterol containing bilayer vesicles are not amenable to unambiguous interpretation. The spectrum is dominated by the broad methylene and methyl resonances of the phospholipid chains (Fig. 1a). Although cholesterol accounts for 25% of the total number of protons in a 2:1 lecithin–cholesterol mixture, none of its resonances could be discerned.

The molecular mobility of cholesterol in lipid bilayers is best ascertained by observing its proton magnetic resonance spectrum in conditions in which it is free of interference from the more intense hydrocarbon chain signals of the phospholipid molecules. The methylene and methyl resonances of the phospholipid chains can be suppressed if the fatty acid chains become totally deuterated. We have accordingly synthesised a series of $\sim 99\%$ deuterated lecithins for this purpose[10]. Figure 1b shows the corresponding spectrum of cholesterol in the deuterated L-α-dipalmitoylphosphatidylcholine (DPL) bilayer vesicles containing one part of cholesterol to two parts of lecithin at 75 °C. A cholesterol spectrum with rather well-defined features is obtained.

The most notable feature of the cholesterol spectrum is the
Fig. 1 Proton magnetic resonance (220 MHz) spectra of hydrocarbon chain protons of DPL vesicles containing cholesterol at 50 °C (a); cholesterol in deuterated DPL vesicles at 75 °C (b), sample b after freeze-drying and redissolved in deuterochloroform containing TMS at 20 °C (c). DPL–cholesterol molar ratio ~2:1 for all samples.

rather sharp, intense doublet which stands out amidst the broad background at −0.9 p.p.m. We assign this resonance by comparison with a spectrum of the same sample dissolved in $CDCl_3$ (Fig. 1c)[11]. There are five methyl groups in cholesterol and each of these shows up clearly in the chloroform spectrum (see spectral assignment indicated in Fig. 1c). Reference to this spectrum suggests that the sharp cholesterol resonance observed in the vesicle spectrum is to be assigned to the terminal C_{26}, C_{27} methyl groups. This assignment is confirmed by the field independent splitting, which is due to spin–spin coupling with the C_{25} methine proton. If this assignment is correct, essentially all the C_{26}, C_{27} methyl groups are contributing to this signal.

The remaining methyl resonances seem to be much broader, which indicates that their segmental motion is much more restricted than that of the isopropyl group of the tail. The degree of segmental mobility of cholesterol can be ascertained from the overall intensity of the cholesterol resonances appearing in the high resolution spectra, including the broader signals. Accurate intensity measurements of broad resonances in a high resolution spectrum are difficult, as the choice of baseline is always open to debate. Nevertheless, on a basis of the comparison of the total integrated intensity of the cholesterol resonances relative to that of the choline proton signal in our deuterated DPL, we conclude that no less than 70% of the cholesterol resonances including those of the C_{26}, C_{27} methyl

groups are observable at 75 °C. As the cholesterol sidechain protons correspond to only 50% of the total number of protons in the molecule, at least some of the cholesterol ring protons must be contributing to the spectrum. Thus cholesterol, when incorporated into a lipid bilayer, does not become totally immobilised. These results provide strong support for the Rothman–Engelman model.

The effect of temperature on the cholesterol spectrum is shown in Fig. 2. As the temperature is lowered the C_{26}, C_{27} methyl resonances show a gradual broadening, the linewidth increasing from ~13 Hz at 83.4 °C to ~23 Hz at 54.5 °C. These observations, we believe, reflect the expected gradual increase in the segmental order and/or a decrease in mobility of the tail as the temperature is decreased. It is significant, however, that even at 26°C a cholesterol spectrum could still be discerned, although the resonances were now very broad. There is thus significant residual segmental motion of the cholesterol molecule even at temperatures 11 °C below the thermal phase transition temperature of DPL[10]. In contrast, small DPL vesicles revealed no high resolution hydrocarbon chain resonances at this temperature in the absence of cholesterol.

Engelman and Rothman[4] have also proposed that a phase boundary occurs in DPL–cholesterol mixtures at 20 °C in the region near 33 mol % cholesterol. To ascertain the existence of this or a similar phase boundary at higher temperatures, we have examined mixed cholesterol–lecithin systems at two

concentrations corresponding to DPL-cholesterol molar ratios of 2:1 and 1:1. Proton magnetic resonance measurements of these two bilayer systems at 83.4 °C (and at other temperatures) revealed no significant difference between the spectra for the two samples, except for an intensity deficiency in the cholesterol C_{26}, C_{27} methyl peaks for the sample more concentrated stoichiometrically in cholesterol. Whereas intensity measurements of the sharp cholesterol methyl signals relative to that of the choline methyl peak of the lecithin indicated that all the cholesterol methyl signal intensity expected is being observed for the 2:1 mixture, 30% of the cholesterol methyl intensity is not accounted for in the 1:1 mixture. This result suggests the existence of a phase boundary in lecithin-cholesterol bilayers at a cholesterol concentration of ~40%.

In summary, we have obtained experimental evidence for a differential mobility of the cholesterol nucleus and its aliphatic tail when cholesterol is incorporated into lecithin bilayer vesicles. The motion of the isopropyl moiety of the tail was shown to be essentially unrestricted, and exhibited a high degree of mobility even at temperatures well below the thermal phase transition of the phospholipids into which it is incorporated. We have also obtained evidence for the existence of a phase boundary in mixed cholesterol-lecithin systems in the region near 40 mol % cholesterol.

Effects of structural defects in sonicated phospholipid vesicles on fusion and ion permeability

ULTRASONICATED lecithin-water dispersions, consisting of single-walled bilayer vesicles, are used as a model for the phospholipid bilayer in biomembranes and have the unique advantage of a well-defined inside and outside[1,2]. The system is well suited, therefore, for studies of transport of solutes across the bilayer membrane[3]. Fusion of these structures may also be used as a model for cell fusion, endocytosis and related phenomena[4,5].

Small sonicated vesicles, because of their large surface curvature, are known to exhibit different physical properties from large bilayer vesicles and multilamellar liposomes[2]. In particular, there is a tendency for the size distribution of a vesicle suspension to change spontaneously by the process of vesicle fusion in certain temperature conditions[6]. As the definition and control of this model membrane system are important, factors influencing the stability of bilayer vesicles are of interest. Here we describe an annealing phenomenon which we have found to be necessary for the stability of vesicle suspensions.

Variations in the vesicle size distribution can be monitored by changes in the proton magnetic resonance spectrum. Previous studies have demonstrated that for large vesicles the proton magnetic resonance spectrum of the hydrocarbon chain protons is broadened compared with that for small sonicated vesicles, together with a concomitant loss of intensity[2]. In addition, small sonicated vesicles exhibit distinct inner and outer choline methyl signals at high magnetic fields because of different surface curvatures between the two halves of the bilayer membrane[7]. This chemical shift non-equivalence enables perturbations on the inner and outer halves of the bilayer to be monitored separately. Large single-walled vesicles which do not possess this structural difference between the two halves of the membrane, however, do not exhibit this chemical shift non-equivalence, but the addition of a paramagnetic shift reagent to the external solution after preparation results in well separated choline signals provided the bilayer membrane is impermeable to the paramagnetic ion[8].

Small sonicated phospholipid bilayer vesicles are usually obtained by prolonged sonication of a phospholipid dispersion at high sound intensity. In view of the high power input to the sample, the local temperature of the solution frequently reaches well above the thermal phase transition (T_C) of the lipids. Recently we have found that vesicles with a controlled range of average sizes can be prepared directly by mild sonication at low temperatures $(< T_C)$, but that subsequent heating of the resultant sonicated lecithin dispersion to a temperature above T_C is an absolute prerequisite for obtaining a bilayer structure which is impermeable to ions. Moreover, there was a pronounced tendency for the sonicated vesicles to fuse, with the rate of fusion depending strongly on whether they have been annealed or not. These observations, we feel, have bearing on a number of reports regarding the rapid fusion of small sonicated bilayer vesicles[6,9].

Figure 1 illustrates both the effects of annealing on the permeability of bilayer vesicles to Eu^{3+} ions and on the rate of vesicle fusion. When $Eu(NO_3)_3$ was added in isotonic conditions
Fig. 1 DSL (2 5 w/v%), purified by a silicic acid column chromatography, was sonicated at high power in a 5 mM solution of $La(NO_3)_3$ in D_2O using a Branson sonicator with Ti microtip. To maintain the solution below T_C during (~56 °C) sonication, it was cooled externally by an ice-water bath, and an alternating sonication sequence of 30-s periods of sonication and 30-s intervals was used After a total of 15 min a practically transparent solution was obtained. This was divided into eight 5-mm nuclear magnetic resonance sample tubes, which were kept at different annealing temperatures (see below) for 30 min The samples were then brought to room temperature (23 °C) and equal volumes of 5 mM $Eu(NO_3)_3$ solutions were added immediately to all the samples, except for the control sample (*a*) to which a 5 mM $La(NO_3)_3$ solution was added. After thorough mixing by shaking, all samples were kept at 69 °C, the nuclear magnetic resonance probe temperature, until the nuclear magnetic resonance spectrum was recorded. The latter step was introduced to fix the state of all the samples before recording spectra. Fourier transform ^1H nuclear magnetic resonance spectra were obtained with a Varian XL-100 spectrometer The temperatures (°C) at which the samples were kept before addition of the La salt solution (the annealing temperature) were: *a*, 23; *b*, 23; *c*, 42; *d*, 49.5; *e*, 52.4, *f*, 55 6 *g*, 59 2; *h*, 63. The spectral assignments indicated correspond to the choline methyl protons ($-N^+(CH_3)_3$) and the methylene and methyl proton of the hydrocarbon chain (CH_2, CH_3). 1 and 2, Choline methyl signals associated with the inside and outside halves of the bilayer respectively. Measurements of the signal intensities of the choline methyl resonances for samples *a*, *b*, and *h* indicate that in excess of 90% of the expected intensities are being observed.

to samples of L-α-distearoylphosphatidylcholine (DSL) or L-α-dipalmitoylphosphatidylcholine (DPL) at room temperature after sonication, the proton magnetic resonance spectrum of these vesicles above T_C exhibited only one methyl signal for both the inner and outer choline groups. The spectral position of this choline signal was shifted to higher fields relative to that in a similar preparation containing only $La(NO_3)_3$ in both the intra and extravesicular solutions, indicating leakage of Eu^{3+} ions into the internal compartment of these vesicles in these conditions. In contrast, when another portion of the same sonicated preparation was heated above T_C before Eu^{3+} ions were added to the solution at room temperature, the proton magnetic resonance spectrum of these vesicles revealed two choline methyl peaks. A more detailed study of this phenomenon involving preheating samples at various temperatures (Fig. 1) after sonication and cooling of the sample back to room temperature before the addition of the shift reagent has led us to conclude that annealing of the vesicles above the thermal phase transition is absolutely essential to obtain bilayers which are impermeable to ions.

Bilayer vesicles which have not previously been annealed above T_C have been found to undergo extensive fusion. The fusion rate increases with increasing temperature and seems to reach a maximum at the thermal phase transition temperature. This vesicle fusion is manifested in the proton magetic resonance spectra in a pronounced way. There is a conspicuous absence of intensity in the high resolution spectra. As the observed spectra do not seem to be significantly broadened from those for small sonicated bilayer vesicles, this intensity anomaly may be caused by polydispersity of the final vesicle suspension as a result of different extents of annealing in the original preparation.

Our experiments also revealed a correlation between the permeability of these bilayers to ions and their tendency towards fusion. As annealing starts around T_C, the bilayer membrane becomes less permeable to Eu^{3+} ions. The fusion rate also goes down abruptly. Because of the relationship between annealing and fusion, kinetic experiments on annealing are somewhat difficult to interpret. Nevertheless it seems that annealing is complete within 2 h if it is carried out at 3 °C above T_C. At higher temperatures the annealing is even faster; for example, annealing is completed within 10 min at 10 °C above T_C After the vesicles are annealed, fusion was extremely slow. For annealed samples of DPL vesicles, proton magnetic resonance and turbidity measurements revealed no evidence for fusion, even when they were kept for 16 h at 42 °C (T_C). Thus the fusion of phospholipid bilayer vesicles depends strongly on the history of the sample with respect to annealing.

The above observations can be accounted for by structural defects within the bilayer structure after sonication below T_C. The high permeability of unannealed structures towards ions may be caused by imperfect boundaries between otherwise homogeneous lipid domains. In fact, we have evidence for structural differences between annealed and unannealed bilayer samples below T_C. Figure 2 shows proton magnetic resonance spectra of a DSL sample before and after annealing (15 min at 67 °C) and recorded at 50 °C (below T_C). Between the unannealed and the annealed sample we observed ~50% increase in the intensities together with a pronounced spectral sharpening of the hydrocarbon chain signal. Identical observations were obtained for DPL. These observations suggest that the unannealed bilayer vesicle below T_C consists of a discontinuous arrangement of highly ordered lipid domains. Unannealed bilayer vesicles could also be permeable to Eu^{3+} because of a highly fluid, but homogeneous bilayer structure. This possibility seems unlikely since such a bilayer membrane would be expected to yield sharper resonances before, rather than after, annealing—just the reverse of what is observed (Fig. 2). Electron microscopic studies also support the idea of cracks in the bilayer structure between well ordered lipid domains. It has not been possible so far to obtain electron micrographs for unannealed phospholipid vesicles by the negative staining
Fig. 2 Fourier transform ^{1}H nuclear magnetic resonance spectra (100 MHz) of the sonicated DSL solutions (2.5 w/v%) in D_2O containing 5 mM $La(NO_3)_3$. Procedure of sonication as described in Fig. 1. Sample b was the same as a except that it has been annealed for 15 min at 67 °C. Nuclear magnetic resonance measurements were made at 50 °C, which is below the phase transition temperature of DSL ($\sim$56 °C), to prevent further annealing during the nuclear magnetic resonance measurement. 1 and 2, Choline methyl and aliphatic methyl and/or methylene signals respectively. *Residual HDO signal, which was partially saturated by the fast pulsing cycle.

method, presumably because the staining solution leaks through these regions in the bilayer structure.

The above observations regarding the relationship between annealing and fusion were observed for DSL, DPL and L-α-dimyristoylphosphatidylcholine (DML). Similar results were obtained irrespective of whether the studies were carried out in pure D_2O or in NaCl solutions, although the vesicle dispersions in these cases were not as clear as in the presence of La^{3+} ions, suggesting that electrostatic surface conditions may influence the formation of vesicles during the sonication procedure. There is a pronounced difference between purified (by silicic acid column chromatography) and unpurified samples in that the fusion rate is much higher for the purified lipids. Rapid fusion of DML and DPL vesicles at the phase transition temperature of these lipids has been reported[6,9]. The problem of annealing, however, especially its effect on fusion, was unknown.

Measurements on mixed lipid systems show analogous results. For a mixture of DPL and DSL (1:1 by weight) the appropriate annealing temperature and the temperature associated with the maximum fusion rate was found to be about 49 °C, midway between T_C for. the respective pure lipids, suggesting ideal mixing within the lipid domains. Other mixed lipid systems, such as DPL with L-α-dipalmitoylphosphatidylethanolamine (DPE), cholesterol or sphingomyelin (bovine brain), show similar behaviour.

In support of our proposal of rapid fusion of unannealed bilayer vesicles, comparative absorbance measurements on mixtures of DSL and DPL vesicles indicated that such mixtures of lipid vesicles exhibit distinct differences in their behaviour on heating, depending on whether the vesicles were annealed or not before mixing of the otherwise homogeneous suspensions. Only when both the DSL and DPL vesicle suspensions were mixed in the unannealed state have we obtained evidence for cross fusion between DSL and DPL vesicles.

Our results, therefore, may have implications for proposed effects of lateral phase separation on the permeability of a bilayer membrane[10-12]. In particular an enhanced Na^+ permeation through membrane vesicles at the lipid phase transition temperature has been reported, and it was proposed that boundary regions between the solid and liquid crystalline phases facilitate this permeability increase[11]. Whether these

boundaries between coexisting solid and liquid crystalline phases at T_C are similar to the metastable structural defects below T_C proposed here is now under investigation.

Neurofilament disguise, destruction and discipline

NEUROFILAMENTS $\sim$100 Å in diameter appear in electron micrographs to be major constituents of most nerve cells, but their function is not clear and their shapes vary[1]. In thin sections of brain they appear relatively thick and knobby[1]; whereas in negative stain, squid neurofilaments appear smooth and cylindrical[2,3]. Only neurofilaments from the squid giant axon[3] and from calf brain[4,5] have been isolated in quantities sufficient for analysis, but these differ in their solubility properties and subunit molecular weights. These inharmonius observations are partially clarified by the transformations reported here of neurofilaments from a new and nearly ideal source, the giant axon of a marine worm, *Myxicola infundibulum*.

Myxicola axoplasm can be extracted from the worm in about 10 s (ref 6) (compare squid, 20 min; calf, 3 h), an important factor in view of the time-dependent changes reported here. *Myxicola* axoplasm is a highly structured gel consisting almost exclusively of neurofilaments[6,7,17]. We have detected no microtubules. Electron microscopy (Fig. 1) indicates that *Myxicola* neurofilaments assume a variety of shapes when processed in different ways. Reasonable care has been taken to identify and control the pitfalls of electron microscope assay, such as sampling errors, and staining, drying and proteolytic artefacts

In thin sections, *Myxicola* neurofilaments resemble most other neurofilaments[1], if fixed in the usual manner; that is, with glutaraldehyde, while inside an intact axon (Fig. 1a; diameters 70–280Å). Finer fibrous arrays (Fig 1b; diameters 15–120 Å), resembling microfilaments[1], appear throughout the axoplasm, if it is fixed after extraction from the axon. Though the fixatives used were identical, the environments of the proteins during fixation and the rates of fixation probably differ in Fig. 1a and b, because the membranes surrounding the axon act as a considerable diffusion barrier in Fig. 1a, but are absent in Fig. 1b. Figure 1, a and b
Fig. 1 Electron micrographs of *Myxicola* neurofilaments. *a*, *b*, Thin sections; *c–h*, negatively stained with 1% uranyl acetate on carbon-formar coated grids. *a*, Whole ventral cord fixed for 90 min (2% glutaraldehyde, 70 mM cacodylate, *p*H 7.2, adjusted to 1.01 osmolal with triple-strength artificial seawater), 23 °C. Postfixed with 1% OsO₄ with similarly adjusted tonicity and *p*H. Dehydrated in ethanol, embedded in Araldite, sectioned, and stained with uranyl acetate and lead citrate. Examined on a Siemens 1A at 80 kV. *b*, Extracted axoplasm, processed as in (*a*). *c*, Extracted axoplasm rinsed in buffer (20 mM cacodylate, *p*H 7.0) fixed 30 min in the above fixative, and homogenised in buffer. *d–f*, Extracted axoplasm homogenised (*d*) in buffer, (*e*) in distilled water, showing frayed filaments (→), and (*f*) in buffer containing 5% sucrose. *g*, Extracted axoplasm homogenised in buffer containing 0.5 M KCl; then rapidly diluted with 5 volumes of water, and applied to the grid. *h*, Reconstituted filaments, from the same fraction described in Fig. 2*f*. Calibration bar 0.5 μm. Abbreviations: F, ∼ 70 Å diameter filament; S, ∼ 280 Å diameter sphere.

indicates that the state of aggregation of the neurofilament proteins can be altered. Negatively-stained preparations (Fig. 1, *c–h*) point to the same conclusion.

Fixation (as for either Fig. 1*a* or *b*), followed by homogenisation and negative staining, yields filaments (F) with irregular, globular projections, as well as roughly spherical particles (S), which often appear attached to the filaments (Fig. 1*c*). If fixation is omitted, or occurs after homogenisation, most filaments have no projections, and detached spheres are numerous (Fig. 1*d*). Filaments are 72 ± 10 Å diameter (mean $\pm$ s.d.), and up to 10 μm long. Spheres are 280 ± 40 Å diameter. Both are proteins, since they are rapidly destroyed by Pronase. Filaments usually taper at their ends, but sometimes appear to untwist and fray into finer fibrous components ($\sim$15–50 Å in diameter, Fig. 1*e*, arrows). Sucrose and glycerol solutions often show projections and spheres attached to the filaments (Fig. 1*f*). High ionic strength solutions (μm$>$0.5) reversibly dissociate both worm (Fig. 1*g, h*) and squid filaments[2,8], but not those from brain[4,5].

Of the several possible interpretations of the above data, we favour this: 70 Å filaments consist of a twisted array of fibrous, largely α-helical[7] subunits, linked primarily by electrostatic bonds, since they are dissociated in solutions of high ionic strength. Non-covalently bonded to the 70 Å filaments are long branches (not easily distinguished from the filaments in Fig. 1*b*), which can coalesce with either the filament, to form the small projections seen in Fig. 1*a, c* and *f*, or with each other, to form the larger projections, and the attached and detached spheres seen in Fig. 1*c–h*.

Sodium dodecyl sulphate (SDS) gel electrophoresis of whole *Myxicola* axoplasm gives a different, and less complex, pattern of polypeptide chains than whole squid (*Loligo*

forbesi) axoplasm (Fig. 2*a, b*). Whole *Myxicola* axoplasm has two dominant bands on SDS gels (Fig. 2*b*) corresponding to chain weights of $152,000 \pm 5,000$ (mean $\pm$ s.d., $n=19$; roughly 40% of total protein), and $160,000 \pm 4,000$ (roughly 10% of total protein). (Standards used for molecular weight determinations were: myosin, c-protein, cross-linked actin, tubulin, bovine serum albumin, lactate dehydrogenase, β-galactosidase and phosphorylase a.) Neither band comigrates with a dominant band from squid axoplasm.

Three observations suggest that *Myxicola* neurofilaments are composed of both the 152,000 and the 160,000 chains, together with lesser amounts of other chains, as shown in Fig. 2*c, d* and *f*. First, and most generally, electron microscopy indicates that neurofilaments account for the great majority of proteins in axoplasm, and these bands account for most of the protein on SDS gels. Second, and more specifically, repeatedly washed *Myxicola* neurofilaments (Fig. 2*d*) show bands similar to those of whole axoplasm, and in approximately their original proportions. Some heterogeneous and largely low molecular weight material is removed by this procedure (Fig. 2*e*). Third, neurofilaments reconstituted after dissociation in high salt concentrations show the same set of bands (Fig. 2*f*). We have not yet eliminated the possibility of contaminants either copurifying, or adsorbed to the neurofilament subunits; nor have we yet identified particular bands with each of the structural components of the neurofilament.

Calcium ions cause major changes in *Myxicola* axoplasm. Incubation with calcium for as little as 15 s causes a shift in the neurofilament gel pattern to lower molecular weight positions (Fig. 2*g–i*). Negatively-stained Ca²⁺-treated filaments fray into fine fibres, then decompose further into ill-defined, flocculent clots. We interpret these events as the action of a Ca²⁺-activated protease, present in whole axoplasm. Washing axoplasm (as for Fig. 2*d*) removes this protease, since washed filaments with added 10 mM Ca²⁺ are stable (as judged by SDS gels and electron microscopy), but alter as described above if the first wash supernatant (Fig. 2*e*) is then added. The protease can be inhibited by PCMB (parachloromercuribenzoate, 1 mM), or TPCK (L-1-tosylamide-2-phenylethylchloromethyl ketone, 1 mM), or TLCK (N-α-*p*-tosyl-L-lysine chloromethyl ketone HCl, 1 mM), but not by PMSF (phenylmethylsulphonylfluoride, 1 mM). No digestion has been detected in the absence of added Ca²⁺, for incubations up to 90 h.

Calcium ions (1–10 mM) also cause a macroscopic, rapid dispersal of whole *Myxicola* and squid[9] axoplasm in water. PCMB (1 mM) inhibits this effect in *Myxicola*, so this seems to be caused by the Ca²⁺-activated protease. Using SDS gels and electron microscopy, we have confirmed the presence of a similar PCMB- and EDTA-inhibited protease in squid

Fig. 2 SDS gel electrophoresis on 5% polyacrylamide of neurofilament preparations, essentially according to Weber and Osborne[17]. *a*, Whole squid axoplasm; *b, c*, whole worm axoplasm; *c*, heavier loading of worm axoplasm, showing minor components. *d*, Washed neurofilaments, prepared by homogenising axoplasm in buffer (20 mM histidine, 0.1 mM PMSF, *p*H 7.0), centrifuging 2 h at 150.000*g*, resuspending the pellet, and repeating this cycle four more times. A low speed spin (20,000*g*; 15 min) was also included to remove particulate matter. The final pellet was used for (*d*), and the first supernatant is shown in (*e*). *f*, Reconstituted neurofilaments, prepared by homogenising axoplasm in buffer containing 0.75 M KCl, removing particulate matter (20,000*g*; 15 min), centrifuging (1.5 h; 250,000*g*), then dialysing the supernatant against buffer containing 0.1 M KCl, and sedimenting the reconstituted neurofilaments (2 h; 150,000*g*). *g, h* and *i*, Whole axoplasm after incubation (40 min, 20 °C) with calcium ions. 20 mg axoplasm ml⁻¹ was homogenised in buffer and incubated with (*g*) 1 mM, (*h*) 5 mM and (*i*) 20 mM CaCl₂, then boiled in 1% SDS, 1% 2-mercaptoethanol, to terminate digestion.

axoplasm[10]. A similar proteolytic activity may be involved in the Ca[2+]-sensitive retrograde degeneration of vertebrate axons, in which a transition from filamentous to flocculent forms also occurs[11,12].

Cytochrome c causes the formation of remarkably ordered aggregates of *Myxicola* neurofilaments (Fig. 3). Fresh, or washed, or reconstituted neurofilaments align side by side to form neurofibril-like structures, which frequently terminate in rings. The rings are similar in size and shape to the neurofibrillar rings found *in vivo*, at synapses, and near cut axons[6,13-15]. Rings lacking stems, figure eights and more complex forms are also synthesised *in vitro*, resembling the range of forms found *in vivo*[13].

In summary, *Myxicola* neurofilaments resemble those of both vertebrates and invertebrates in their appearance in electron microscope sections, and in their neurofibrillar and ring-like assemblies. Different treatments, however, cause marked changes in *Myxicola* neurofilament appearance, which we tentatively identify with different states of aggregation of fibrous subunits. The protein molecule(s) involved have not yet been identified, but their component polypeptide chains give a simple and consistent pattern on SDS gels. The major chains (152,000 and 160,000 molecular weights) are rapidly cleaved by an endogenous, Ca[2+]-activated protease, to give fragments roughly the size of the chains isolated from squid (70,000–90,000 (ref. 3)) and calf (~58,000 (ref. 4)) neurofilaments. But squid axoplasm has no major heavy chains which comigrate with those from *Myxicola*. Therefore present evidence suggests that neurofilaments from different species consist of different polypeptide chains, though possible proteolytic degradation of a common subunit cannot be ruled out.

We thank John Pacy, Brian Kirkham, and John Hopkins for help with the electron microscopy; Peter Knight and Alan Outen for molecular weight standards; Zolly Gabor for preparing the plates, and the director and staff of the Marine Biological Laboratory, Plymouth, for supplying live squid. Persistent innervation of mammalian sympathetic neurones by native and foreign fibres

CONSIDERABLE evidence has been advanced to support the view that the reinnervation of adult mammalian autonomic

neurones is specific[1-4]. Moreover, although foreign nerve fibres by themselves readily form synaptic connections with denervated ganglion cells[5-11], when native fibres are also present their terminals are thought to be preferred to foreign axon terminals, which are eventually rejected[4]. I have re-examined the ability of neurones in the mammalian superior cervical ganglion (SCG) to select between native and foreign nerve fibres during reinnervation using the technique of intracellular recording. An unexpected result was that many neurones were initially reinnervated by both native and foreign nerves, and retained their dual innervation for at least 10 months.
Fig. 1 Diagram of operative procedure (ventral view). NG, nodose ganglion; V, vagus nerve; SUP, superior postganglionic nerve bundle; INF, inferior postganglionic nerve bundle. Drawing not to scale.

The right cervical sympathetic trunk (CST) in 17 adult albino guinea pigs (200–400 g) was aseptically exposed under pentobarbital anaesthesia, and cut 3–5 mm below the lower pole of the SCG. The right vagus nerve was also cut about 2–3 mm caudal to this level, and its proximal end laid side by side with the proximal end of the CST (Fig. 1); the distal end of the vagus nerve was then ligated and the wound closed. After intervals ranging from 23 d to 10 months, the SCG was removed together with suitable lengths of the CST, the vagus nerve, and the superior postganglionic nerve, and placed in a perfusion chamber. In 14 animals, both the CST and the vagus nerve entered the neuroma which had formed at the nerve anastomosis; in three animals the vagus nerve did not enter the neuroma, and these ganglia were not considered further. The CST and the vagus nerve proximal to the anastomosis, and the superior postganglionic branch (Fig. 1), were taken into close fitting suction electrodes for stimulation and recording. Neurones within the ganglion were impaled with glass microelectrodes[12] and their responses to CST and vagal stimulation recorded.

By 23 d after the initial surgery, most impaled neurones
Fig. 2 *a*, Dually innervated neurone impaled 273 d after initial operative procedure. Upper traces show that suprathreshold responses are elicited following stimulation of both the native (CST) and vagus (V) nerves. Lower trace is an extracellular recording from the superior postganglionic nerve bundle. *b*, Upper trace shows that repetitive stimulation (20 s^{-1}) of the vagus nerve causes a depression of transmission in a dually innervated neurone impaled 291 d after initial operative procedure, but does not affect the response to subsequent stimulation of the CST (arrow). This effect can also be seen in the compound action potentials recorded from the superior postganglionic nerve bundle (lower trace). The intracellularly recorded effect was clearer when, as in this cell, the e.p.s.p.s elicited were subthreshold and thus not obscured by action potentials.

were found to be reinnervated. In about half the neurones excitatory postsynaptic potentials (e.p.s.p.s) were elicited after stimulation of only the CST or the vagus nerve; in the remainder, however, e.p.s.p.s were recorded in response to stimulation of both nerves. In a series of 101 neurones impaled in eight ganglia 23 d to 3 months after nerve section, synaptic potentials could be evoked in all but three cells; 60 neurones (59.4%) had e.p.s.p.s after both CST and vagal stimulation and, in many of these cells (28.3%), the response was above threshold for either nerve (Fig. 2*a*). That these neurones were influenced by two separate sets of nerve terminals was shown by summation of the e.p.s.p.s when the two nerves were stimulated at an interval adjusted so that the e.p.s.p.s elicited from both sources occurred simultaneously. Furthermore, depression of transmission caused by repetitive stimulation of one pathway did not depress transmission caused by stimulating the other nerve (Fig. 2*b*). Of the neurones which received innervation from a single source, about half were innervated by the CST, and half by the vagus nerve.

After 6–7 months, 19 out of 41 neurones (46.3%) impaled in two ganglia were found to be dually innervated, whereas after 8–10 months, 42 out of 78 neurones (53.8%) in four ganglia could be shown to receive endings from both sources. Thus little change occurred in the proportion of dually innervated cells over a 10 month period. There was also no obvious tendency for CST synapses to predominate

over vagal terminals: even after 8–10 months the portion of neurones having suprathreshold responses to both vagal and cervical trunk stimulation (Fig. 2*a*) was about one-third. Indeed, a greater number of neurones were innervated by vagal fibres than CST fibres after 8–10 months, although after 23 d to 3 months the number of cells innervated from each source was nearly equal.

These results should not be taken to indicate that connections within the SCG are not normally highly specific[1-5], or that ganglion cells may not have some ability to select correct synaptic connections in other circumstances. It may be, for example, that the large number of vagal fibres which grow into the ganglion overwhelm some more subtle selective mechanism. In the conditions of these experiments, however, mammalian sympathetic neurones show little or no preference for native or foreign fibres during reinnervation, and, over a period of 10 months, have no obvious tendency to reject inappropriate synaptic connections. This latter finding is similar to a recent study of dually innervated muscle fibres in mammals[13] (see also ref. 14). Thus the adult mammalian nervous system seems less capable of selectivity during reinnervation than has previously been thought, and in this regard seems to be quite different from the nervous systems of lower vertebrates in which this ability is clearly present (see, for example, refs 15 and 16).

Sex difference in ontogenesis of circadian adrenocortical rhythm in cortisone-primed rats

The hormonal milieu in the neonatal period has profound influences on the morphological, biochemical and functional development of the brain[1,2]. Krieger reported that the administration of corticosteroid (dexamethasone or hydrocortisone) to 2–4-d-old rats suppressed the circadian rhythm of plasma corticosterone at 30 d of age[3], whereas treatment at 12–14 d of age did not affect the rhythmicity. We have investigated whether the suppression of corticosterone rhythm results in its permanent derangement throughout adult life or merely indicates its delayed appearance. After this paper was submitted, Krieger published the results of a similar study[4].

Litters of Wistar rats were reared in a room with 12-h light and 12-h dark cycle (lights on 0600–1800). Within 72 h after birth, all pups were injected subcutaneously with either 0.5 mg of cortisone acetate (Upjohn Co., Kalamazoo, Michigan) or an equal volume of saline. Rats were weaned at day 27, group-housed by sex and treatment, and handled every day. Food and water were available *ad libitum*. On

Numbers of animals given in parentheses

days 32, 42, 55, 95 and 130, animals were decapitated at either 0800 or 2000 and trunk blood was collected for plasma corticosterone determination[5]. At each sampling time, the experimental groups were arranged so that each group represented a cross section of the litters available. A preliminary study indicated that these two time points gave the trough (0800) and the peak (2000) of plasma corticosterone rhythm in the condition used. On day 55, additional males were tested for plasma corticosterone response to ether stress at 1000. Animals were exposed to ether for 1.5 min and blood was obtained 15 min after the onset of stress[6]. In the other series of experiments, all animals were treated neonatally with cortisone and housed in the same way. On days 55 and 95, the profile of plasma corticosterone over a 24-h period was studied by blood sampling at 6-h intervals starting at 0800.
Fig. 1 Circadian variations of plasma corticosterone in cortisone-treated rats. Each data point represents the mean of six animals. ——, Male rats; •••••, female rats; ●, 55 d of age; ○, 95 d of age. *, $P<0.05$; **, $P<0.01$, compared with 0800 value (Mann–Whitney U test). Dark period is shown as black horizontal bar.

The day–night variation of plasma corticosterone level was apparent from 32 d of age in the control rats of both sexes. Neonatal cortisone administration did not change the 0800 level significantly, but suppressed the rise of the 2000 level completely at 32 d of age in both sexes. At 42 d of age, however, the cortisone-treated female rats showed a small but definite nocturnal rise of plasma corticosterone. At 55 d of age, and thereafter, the adrenocortical rhythm was completely restored. In contrast, the effect of exposure to cortisone was more marked and lasted longer in the male rats. The plasma corticosterone rhythm was absent on day 55, equivocal or diminished on day 95 but ultimately established on day 130 (Table 1). No phase shift in circadian

rhythm was induced by the treatment (Fig. 1). The fact that the response of plasma corticosterone to ether stress was not impaired (Table 2) supports the concept that basal circadian rhythm and stress-induced change in the hypothalamo–pituitary–adrenal axis are regulated by somewhat different mechanisms[7]. Although corticosterone response to ether stress has been reported to have circadian variation[8], we did not test whether neonatal cortisone treatment suppressed such rhythm of stress responsiveness.

Table 2 Response of plasma corticosterone to ether stress in 55-d-old male rats treated neonatally with cortisone

Treatment	Plasma corticosterone (μg dl^{-1}, mean±s.e.)	
	Basal	Stress
Control	7.7±1.0 (6)	50.4±5.0*(6)
Cortisone	11.2±1.5 (6)	47.4±4.5*(6)

*$P<0.01$ against basal by Mann–Whitney U test.
Numbers of rats given in parentheses.

Sex difference in the vulnerability of corticosterone rhythm to neonatal cortisone administration was rather unexpected. In Krieger's study[4], the hydrocortisone-treated rats of both sexes, were reported to have 'normal' corticosterone rhythm at 80 d of age. Since data on earlier days are lacking, the results do not necessarily mean the same recovery course of corticosterone rhythm for both sexes. Furthermore, Krieger's figures show that the mean plasma corticosterone level at 2000 in the hydrocortisone-treated male rats was about half of that in the control male rats. The failure to find a significant difference between the two values might have resulted from the number of animals studied (only three rats at each time point) or a relatively large variation in the corticosterone level at 2000, as shown in our data on 95-d-old male rats treated with cortisone. The results of the two studies are not, therefore, mutually exclusive.

Concerning the sex difference of adrenocortical periodicity, Critchlow et al. have shown that a higher resting level and marked circadian fluctuation of plasma corticosterone are associated with the presence of mature ovary[9]. It has also been shown that a rather marked enhancement in the amplitude of circadian corticosterone rhythm takes place at puberty in the female, and that ovariectomoy attenuates the change[10,11]. Although adrenal–gonadal interactions are multiple and complex[12], a marked sex difference in the circadian rhythm of hypothalamic corticotrophin-releasing factor content and its phase shift by ovariectomy, reported by Hiroshige et al.[13], provide good evidence that gonadal hormones can modulate the pituitary–adrenal periodicity through a central mechanism.

In rats and in many other species, sexual differentiation

of the brain is initiated in neonatal life. The male pattern is programmed by the presence, and female pattern by the absence, of androgen during a relatively short period of infancy known as the critical period[14]. This 'program' is stored for a while and expresses itself at puberty. It is therefore important to study whether the sex difference in the ontogenesis of plasma corticosterone periodicity observed in rats primed with cortisone in infancy is related to event(s) in early sexual differentiation or rather to factor(s) associated with the onset of puberty.

Oestrogen-responsive human breast cancer in long term tissue culture

STUDIES of steroid hormone dependence of human breast cancer have been hampered by a lack of a suitable *in vitro* model system which can reproduce the responses of human breast cancer observed *in vivo*. We now report the characterisation of several human breast cancer cell lines, at least one of which shows marked dependence on oestrogens for growth. This oestrogen dependence seems to be similar in a variety of ways to that observed clinically *in vivo*.

MCF7 cells, a cloned line of human breast cancer, have been partially characterised[1]. This line was found by a specific enzymatic assay in which the synthesis of lactose was confirmed by chromatography of the products (M.E.L. and B. V. Vonderhaar, unpublished), to synthesise α lactalbumin, and formed 7.05 pmol lactose per 30 min per μg protein. Other breast cancer cell lines used—HT39, Kielty and G11—were derived from malignant effusions in patients with metastatic breast cancer. Under the electron microscope, these cell lines appear epithelioid with numerous microvilli, desmosomes, some rough endoplasmic reticulum and Goldi apparatus.

As physiological concentrations of steroid hormones are present in the serum containing media in which the cells are usually grown[6] and as these endogenous hormones may obliterate responses to additional hormones, the serum was stripped of most endogenous steroid by repeated mixing with dextran-coated charcoal at 55 °C for 45 min[7]. Removal of oestradiol was monitored by the addition of a trace amount of tritiated oestradiol at the beginning of the procedure and after the decrease in radioactivity, which was reduced to less than 1% after successive charcoal treatments. Incubations of cells in various hormone combinations were carried out at least in triplicate. After various incubation periods the cells were pulsed for 1 h with labelled amino acids or nucleosides, collected and macromolecular synthesis measured[8].

Table 1 shows the effects of oestradiol on DNA synthesis

in the MCF7 cell line. Oestradiol 10^{-8} M more than doubles nucleoside incorporation in the experiment shown. We noted reproducible increases in macromolecular synthesis with as little as 10^{-11} M oestradiol. If oestradiol (10^{-9}–10^{-7} M) is added to cells in untreated serum no augmentation of macromolecular synthesis is noted. Oestradiol stimulation of these cells shows a clear-cut maximum at concentrations of 10^{-10}–10^{-7} M oestradiol. The concentration of oestradiol which half saturates the oestradiol receptor *in vitro* closely corresponds to that concentration of oestradiol which half-maximally stimulates the cells, as determined by competitive protein-binding assay using dextran-coated charcoal (see below). Higher concentrations of oestradiol are less effective and concentrations of about 2×10^{-6} M clearly inhibit the cells below control levels (Table 1). Diethylstilboestrol, which stimulates these cells as effectively as oestradiol, also inhibits the cells at more than 5×10^{-7} M.

Table 1 Effects of oestradiol, diethylstilboestrol (DES) and Tamoxifen on DNA synthesis

Condition	Thymidine incorporation
Control	18 ± 4.3
Oestradiol 10^{-8} M	41 ± 5.2
Oestradiol 5×10^{-6} M	6 ± 2.6
DES 10^{-8} M	43 ± 3.1
DES 5×10^{-6} M	5 ± 1.7
Tamoxifen 10^{-7} M	4 ± 1.6
Tamoxifen 10^{-7} M + oestradiol 10^{-8} M	26 ± 4.8

Cells growing in log phase were collected and plated in quadruplicate at uniform density in Eagle's MEM supplemented with 10% foetal calf serum, and 2 × glutamine. After 24 h the medium was replaced with MEM containing 2% serum from which endogenous steroids were removed by stirring for 45 min with dextran-coated charcoal at 55 °C twice. The medium was sterilised by filtration. Various hormones were added to the medium as 1,000 × concentrates in ethanol as shown in Fig. 1. After 48 h 0.5 μCi ³H-thymidine (New England Nuclear, 40 Ci mmol⁻¹) was added to each dish. One hour later the dish was washed with phosphate-buffered saline twice and the cells collected after detachment with trypsin–EDTA solution. The cell buttons were suspended in ice water and sonnicated in a Brownson sonnicator for 4 s at the lowest setting. Aliquots were used for determination of protein by the method of Lowry[13] and for TCA precipitation. Acid-insoluble counts were collected on 0.45 μm Millipore filters and counted in a liquid scintillation counter (efficiency 35%). Values (d.p.m. × 10^{-3} per μg protein per h) are averages of quadruplicate determinations ±1 s.d.

This biphasic response to oestrogen suggests that the same population of cells which is stimulated by oestradiol at lower concentrations of oestrogen may be inhibited at higher concentrations. As such concentrations are readily achieved in patients with metastatic breast cancer treated with large doses of oestrogen, our data suggest that this regimen may be effective because the tumour itself is directly inhibited by the oestrogen rather than by an indirect effect of the oestrogen on some other trophic hormone. This is an attractive explanation for the seemingly paradoxical stimulation of some tumours by oestrogen at physiological levels and tumour regression seen at higher doses of administered oestrogens[9]. To demonstrate more clearly the oestrogen dependence of these cells, we used the anti-oestrogen ICI46,474 (Tamoxifen), which is a substituted hexoestrol derivative[10]. Figure 1 shows that 10^{-7} M Tamoxifen depressed DNA synthesis below control levels: this effect could be overcome by simultaneous addition of 10^{-8} M oestradiol. Hundredfold lower concentrations of oestradiol were sufficient to overcome Tamoxifen inhibition of macromolecular synthesis. Similar effects were noted when incorporation of ¹⁴C-leucine into protein was measured.

Figure 1 shows the time course of the response to both oestradiol and Tamoxifen. At varying times after the addition of Tamoxifen to the cells, isotopically labelled pre-
Fig. 1 Kinetics of Tamoxifen inhibition and oestradiol stimulation of human breast cancer *in vitro*. Cell plating and collection, see Table 1. ●, Control cells; ▲, 10^{-7} M Tamoxifen-treated cells. After 24 h, 10^{-8} M oestradiol was added to an additional set of dishes without removing the Tamoxifen (△). s.d. for each point was usually less than 10%.

cursors were added for 1 h for determination of net synthetic rate at that time point. By about 10 h, 10^{-7} M Tamoxifen begins to strongly inhibit macromolecular synthesis which falls to about one-third of control levels by 24 h and remains at this level throughout the duration of the experiment. If at 24 h, 10^{-8} M oestradiol is added to some of the Tamoxifen-containing dishes without removing the Tamoxifen, the inhibition is shown to be completely reversible with recovery beginning about 10 h after addition of the oestradiol. Similar changes are noted when protein synthetic rates are measured. We have observed a rise in thymidine incorporation rates to values which exceed control levels for several hours during the early period of oestrogen stimulation of Tamoxifen-inhibited cells. This suggests that some degree of synchronisation of the cells may have occurred during the incubation in Tamoxifen alone, with a larger cohort of cells entering the DNA synthetic phase of the cell cycle after oestradiol rescue. If a cloned line of the hormone-responsive MCF7 cells are left in Tamoxifen alone, most cells begin to round up, detach from the surface and die after about 4 d although occasional colonies of 'normal' Tamoxifen-resistant and possibly hormone-independent cells are sometimes noted. The phenomenon of Tamoxifen killing is invariably reversible if oestradiol is added to the medium by 48 h even though the anti-oestrogen remains in the medium.

We have duplicated these experiments in serum-free conditions. In spite of the total lack of oestrogen in the medium, Tamoxifen still inhibits the cells below control levels. The possibility that Tamoxifen-oestrogen receptor complexes are binding to chromatin sites leading to decreased transcription of regulatory RNA segments below control levels is under investigation.

That Tamoxifen is inhibiting these cells primarily by interfering with the trophic effects of oestrogen is suggested by three lines of reasoning. First, Tamoxifen inhibition is reversible by the addition of oestradiol. Simultaneous addition of Tamoxifen and oestradiol leads to stimulation if the Tamoxifen is less than 2 logs higher in concentration than oestradiol. Second, in other experiments, Tamoxifen had no effect on cells in culture not responsive to oestradiol, such as hepatoma tissue culture cells, HeLa cells, or the HT39, Kielty and G11 breast lines. Third, Tamoxifen is capable of binding to the same high affinity oestrogen receptor molecules found in the cytoplasm of these cells. Using a dextran-coated charcoal assay[11] one of these cell lines, MCF7, was shown to contain about 70 femtomol oestradiol receptor per mg cytoplasmic protein with an apparent K_d of about 5×10^{-11} M, a value in reasonable agreement with

a previously published value[12]. Tamoxifen binds to this receptor with about a 1,000-fold lower affinity than oestradiol, explaining in part the ability of 10^{-8} M oestradiol to stimulate the cells in the presence of 10^{-7} M Tamoxifen. In fact, the dose–response curve of the inhibition of these cells by Tamoxifen closely approximates the displacement curve of oestradiol from its cytoplasmic receptor by Tamoxifen.

The MCF7 line has been maintained in continuous tissue culture for 2 yr but still demonstrates remarkable oestrogen dependence. The potential value of a hormone-dependent human breast cancer in long term tissue culture for the study of the mechanism(s) by which steroid hormones exert their trophic effects is significant, particularly in view of the likelihood of obtaining regulatory variants or mutants which are hormone independent. In addition these cells may prove useful in the analysis of oestrogen action in non-malignant tissue, as oestrogen-responsive cell systems in continuous tissue culture have not been widely reported.

The Kielty, G11, and HT39 lines are not stimulated by 10^{-8} M oestradiol nor are they inhibited by Tamoxifen. They are, however, killed by 10^{-5} M oestradiol. The specificity of this response is being investigated.

In results to be reported elsewhere, two other human breast cell lines, Evsa T and Evsa E developed in our laboratory, both respond to 10^{-8} M oestradiol with the accumulation of α lactalbumin without a significant increase in general macromolecular synthesis[1].

Non-encephalitogenic antigen-induced suppression and reversal of allergic encephalomyelitis

Experimental allergic encephalomyelitis (EAE) is an autoimmune disease of the central nervous system[1] induced in experimental animals by the myelin basic protein (BP)[2] or specific peptide regions derived from the BP[3] emulsified with Freund's complete adjuvant (FCA).

Previous studies have shown that the encephalitogenic tryptophan region of BP, H–Phe–Ser–Trp–Gly–Ala–Glu–Gly–Gln–Lys–OH (peptide S3) induces delayed type hypersensitivity (DTH) specific for peptide S3 and BP (ref. 4). The DTH determinant was separated from that which produces disease and shown to overlap the C-terminal sequence of peptide S3

Table 1 Suppression and treatment of allergic encephalomyelitis with non-encephalitogenic peptide S42

Group no.	Challenging antigen (µg per FCA)	Treatment FIA	Clinical EAE	Reversal clinical EAE	Histological EAE
1	25 µg S42	None	0/15	None	0/15
2	100 µg S42	None	0/10	None	0/15
3	5,000 µg S42	None	0/10	None	0/10
4	100 µg BP	1 mg S42	2/4	2/4	2/4
5	100 µg BP	FIA	4/4	0/4	4/4
6	150 µg BP	2.5 mg S42	5/5	5/5	2/5
7	150 µg BP	FIA	5/5	0/5	5/5
8	150 µg BP	saline	6/6	0/6	6/6
9	150 µg BP	4.0 mg S42	7/7	6/7	4/7
10	150 µg BP	1 mg BP	4/4	2/4	3/4
11	150 µg BP	FIA	7/7	0/7	7/7

The guinea pigs were challenged with Freund's complete adjuvant (FCA) emulsion of either peptide S42 or bovine basic protein. Groups 1, 2 and 3 received no treatment. For groups 4 and 5, the suppressive treatment in Freund's incomplete adjuvant (FIA) was started on day 8, before the appearance of clinical signs of experimental allergic encephalomyelitis (EAE) and was continued through day 17. For groups 6, 7 and 8, the treatment began the day hind leg paralysis was observed and was continued for 10 consecutive days. For groups 9, 10 and 11, the treatment was started two days after hind leg paralysis was observed and was continued for 10 consecutive days. Surviving animals were killed on day 32 for histological examination of the brain and spinal cord tissue.

(ref. 5). Further, the immunological response of sensitised animals to the EAE or to the DTH determinant could not be distinguished clinically or histologically from similar responses to the intact BP molecule. We have shown[6,7] that the encephalitogenicity of the tryptophan region is destroyed by amino acid substitutions or deletions from the sequence of peptide S3, but this treatment did not abolish the DTH properties of the resulting antigens. Deletion of the Gly–Ala–Glu–Gly sequence gives rise to peptide S17, H–Phe–Ser–Trp–Gln–Lys–OH, previously shown to induce and elicit DTH responses similar to those obtained for peptide S3. Further, animals sensitised to peptide S3, S17 or the BP exhibit DTH responses which were elicited by either of the three antigens[7]. These results indicate that the non-encephalitogenic antigen is recognised by cells sensitised to the EAE-inducing antigen and thus may be useful in the treatment of this cell-mediated disease. Peptide S42 was prepared by the Merrifield solid phase synthesis technique[8] to contain four linearly spaced repeating units of S17. Approximately 700 mg of peptide S42 was prepared at one time. Based on 0.25 mEq glycine per gram resin, a recovery of 40–60% was calculated. The purity of peptide S42 was established by chromatography and high voltage and polyacrylamide disc gel electrophoresis[9]. Amino acid analysis[10] of purified peptide S42, H–(Phe–Ser–Trp–Gln–Lys)$_4$–Gly–OH, gave whole integers of expected residues, including 4 mol tryptophan per mol peptide.

The results of experiments designed to study the efficacy of non-encephalitogenic peptide S42 in inhibiting the development (suppression) and in reversing (treatment) signs of EAE are summarised in Table 1. Daily subcutaneous injections of 1 mg peptide S42 starting on day 8 after challenge, significantly reduced the incidence of disease compared with Freund's incomplete adjuvant (FIA) treated controls (compare groups 4 and 5). Daily treatment of animals in group 6 with 2.5 mg peptide S42 for 10 consecutive days was sufficient to reverse tremor and hind leg paralysis in addition to lethargy and weight loss in the five treated animals. Histological examination of the brain and spinal cord tissues on day 32 after challenge revealed the presence of EAE lesions in 2 out of 5 of the animals in spite of the complete reversal of the clinical signs of EAE. Control guinea pigs similarly treated with FIA or saline (groups 7 and 8) died between days 10 and 14 or were killed because of severe paralysis.

Peptide S42-induced reversal of clinical signs of EAE was further studied in an advanced stage of the disease. The treatment for guinea pigs in group 9 was initiated on the second day after the onset of hind leg paralysis. Within 4–6 treatment days, paralysed animals regained the use of their hind legs and were able to run about the cage; however, one of seven guinea pigs died after the second treatment without evidence of improvement in his disease state. In contrast, treatment of

group 10 with 1 mg bovine BP was partially successful in reversing the disease at this late stage of development. None of the FIA-treated controls, group 11, recovered from EAE.

The mechanism of suppression and reversal of disease cannot be elucidated from this study. The primary event of the immune response requires the combination of antigen with receptors on the surface of reactive cells[11]. Cell surface receptors in BP-sensitised animals are specific and recognise the encephalitogenic protein, the tryptophan region and analogous antigens such as peptide S42. This recognition may be described as antigen-induced paralysis of encephalitogenic cells leading to complete reversal of disease. Compared with the effect of anti-lymphocyte serum and cyclophosphamide[12,13], peptide S42 did not induce transient or prolonged lymphopenia, and the treated animals remained immunoresponsive during and after prolonged treatment with peptide S42. Repeated immunisation with peptide S42 failed to induce the formation of antibodies which reacted with BP or with peptide S42.

Studies have shown that intact BP injected before or shortly after the administration of an encephalitogenic dose of the BP reduces the incidence of EAE[14,17]. The use of the BP for treatment, found to be effective in reversing signs of EAE in monkeys, is predicated on uninterrupted administration of the antigen during the critical period of disease[17]. The possibility of *de novo* induction of EAE with the administration of large doses of the encephalitogen should be recognised, however[18]. A synthetic random amino acid copolymer (cop 1) has been used to suppress disease development in guinea pigs[19]. Unlike peptide S42, cop 1 induces the formation of humoral antibodies. Its amino acid sequence is unknown and lacks phenylalanine, serine, tryptophan and glutamine residues known to be essential in the linear sequence necessary for maximum recognition by the EAE inducing cells.

The use of peptide S42 is advantageous in view of its non-encephalitogenic properties and its ability to interact specifically with disease-inducing cells and thus to inhibit the development of EAE and reverse a full-blown stage of disease.

Isolation of infectious C-type oncornavirus from human leukaemic bone marrow cells

C-TYPE ONCORNAVIRUSES are associated with neoplasms of the haemopoietic organs in several vertebrate species[1]. Molecular hybridisation studies have revealed the presence of an RNA species in human leukaemias that has some homology with animal C-type oncornaviruses[2,3]. In addition, leukaemic cells contain a reverse transcriptase that proves to be serologically closely related to the enzyme from the woolly monkey C-type oncornavirus[4]. Several claims have been made for the presence of C-type particles in malignant cells or plasma of leukaemic
Fig. 1 C-type particles isolated from supernatants of culture fluids. Cleared fluids were spun in cellulose nitrate tubes at 50,000 r.p.m. for 45 min in a Beckman 50 Ti rotor. In the tubes, Millipore membrane filter disks (type 5 VSWP), pore size 25 nm, were positioned on top of supports made of Epon embedding medium. The fluid was mixed with sodium cacodylate-buffered 2% stabilised glutaraldehyde before the run. After the run, the disks were cut into thin oblong strips and immersed in phosphate-buffered 1% osmium tetroxide for 60 min (4 °C). They were then dehydrated in a graded series of isoproponal, treated with toluene, and flat embedded in Epon. Ultrathin sections were made and their contrast enhanced with an aqueous solution of manylacetate and lead citrate. They were examined in a Philips 300 electron microscope. *a*, Particle from phytohaemagglutinin-stimulated bone marrow cells. *b*, Particles from infected human embryonic fibroblasts. *c*, Particle from infected HEK cells. *d*, Budding particles from infected FB289.

patients (for review, see ref. 5). There have also been reports of release of such virus particles in tissue culture lines of leukaemic cells[6,7].

We report here the isolation of a C-type oncornavirus from a 4-yr-old patient with a lymphosarcoma which had progressed to a state of lymphoblastic leukaemia. Bone marrow cells were cultured in liquid suspension in the presence of phytohaemagglutinin (10 μl ml⁻¹, Burroughs, Wellcome, Lot No. 9268). After 3 d culture, the supernatant was examined for the presence of C-type particles using the Millipore filter technique[8] and was found to be positive (Fig. 1).
Fig. 2 XC cells with syncytia formed after cocultivation with human leukaemic bone marrow cells. XC cells were grown in the same medium as the bone marrow cells. Cells were grown in Dulbecco's modified MEM supplemented with 2 mM glutamine, 0.2 mM asparagine, 20% of a mixture of equal volumes of foetal bovine serum, normal horse serum, and tryptose phosphate broth containing 100 IU ml⁻¹ penicillin and 100 μg ml⁻¹ streptomycin. One day after seeding of 2.10⁵ XC cells in 3 ml medium in 50 mm plastic Petri dishes (Greiner, Nurtingen), human bone marrow cells were added in 3 ml medium after removal of the initial medium. Medium was refreshed 3 d later and the dishes were stained with May–Grunwald Giemsa after 1 more d (×105).

Bone marrow cells were seeded on top of a 24-h culture of XC cells. Four days later, conspicuous syncytia were found which were similar to those reported to occur after cocultivation of XC cells and cells infected with a murine leukaemia virus[9] (Fig. 2 and Table 1). In control XC cultures, some small syncytia which contained only a few nuclei were found.

The same cytopathogenic effect was found when fresh leukaemic bone marrow cells were cocultivated directly with XC cells. The production of syncytia persisted on further passage, after trypsinisation of the XC cells which had been in contact with the leukaemic cells.

Cocultivation of XC cells with bone marrow cells from four normal donors, two patients with acute myeloid leukaemia, two with chronic myeloid leukaemia, one with chronic lymphatic leukaemia, one with aplasia and one with secondary polycthaemia vera did not produce syncytia.

The XC cultures which showed a positive cytopathogenic effect released C-type particles, as revealed by electron microscopy (Table 1). Control XC cultures or mixed cultures of XC with normal bone marrow cells were repeatedly negative.

Secondary cultures of human embryonic kidney (HEK) cells were cocultivated with irradiated (9,000 rad X rays) XC cells in their second passage after having been in contact with leukaemic cells. HEK cells proved to replicate the human virus as detected by electron microscopy and the reverse XC cell test[10]. Control experiments with irradiated untreated XC cells did not yield detectable virus. The human embryonic fibroblast line (FB289) exposed to cell-free supernatants of infected HEK cells also replicates the virus.

Table 1 Detection of C-type oncornavirus by mixed cytopathogenicity test with XC cells and electron microscopic examination of culture fluids

Cocultivation of XC cells with:	No. of bone marrow cells plated	No. of syncytia per dish*	Electron microscopy
None	—	17†	—
BALB/c mouse BM infected with RLV	1.0 × 10⁵	1,284	+
Normal human BM	1.0 × 10⁵	10†	
	5.0 × 10⁵	18†	
	1.0 × 10⁶	16†	—
Leukaemic BM, stimulated by phytohaemagglutinin	1.0 × 10⁵	471	+
Leukaemic BM, unstimulated	1.0 × 10⁵	393	+

† Only small syncytia with less than four nuclei.
BM, Bone marrow.

Indirect immunofluorescence tests were carried out on acetone-fixed cultured cells to assess the serological relationship of this putative human virus isolate to other mammalian C-type oncornaviruses, but also to exclude the possibility of laboratory contamination. At the time when the virus was isolated from the child the only C-type viruses used in our laboratories were murine leukaemia viruses (MuLVs). For that reason several antisera to murine C-type viruses were tested on these cultures (Table 2). Polyvalent rat antiserum to Rauscher murine leukaemia virus (RLV) numbers 45 and 76 have been used to study the presence of C-type oncornaviral antigens in human bone tumour cultures[11]. Their specificity has therefore been extensively tested. They show a broad group-specific reactivity with various ecotropic and xenotropic mouse viruses, endpoint ranging from 1:1,280 to 1:10,240. Antiserum No. 45 not only reacts with an antigen in human bone tumour cultures which has been demonstrated to be specfiic for C-type virus[11], but

also weakly with the virus isolated from the leukaemic child and passaged in several kinds of cells. A goat antiserum to an endogenous C-type oncornavirus isolated from the BALB/c mouse mammary tumour cell line EMT6 (ref. 12) gives similar reactions. The strongest antiserum to RLV (76), however, does not react with either the human bone tumour cultures or the new virus isolated from the leukaemic child. This finding strongly indicates that the weak but positive reaction with two antisera is not due to contamination of the cultures with a murine virus but to an interspecies antigenic determinant not detected by antiserum No. 76.

A goat antiserum to the purified p27 antigen of the simian sarcoma virus (SSV)[13] gives a good reaction with cultures harbouring the primate virus, although the acetone-fixed slides have been kept for 18 months at −20 °C. The weak reaction with the new virus isolate is probably not only due to poor replication of the virus and in turn to decreased production of p27 in the cytoplasm, but also to an antigenic dissimilarity between the simian and the human virus.

Another source of contamination may be XC cells. Avian Rous sarcoma virus carried in XC cells does not replicate in human cells and is antigenically completely unrelated to mammalian viruses[14]. Control XC cultures proved to be repeatedly negative with all antisera. The cocultivation procedure may have activated an endogenous rat virus. Rat antiserum No. 76, however, reacts with endogenous viruses activated in XC cells by 5-bromodeoxyuridine (20 μg ml⁻¹) and 2% dimethylsulphoxide[15], but not with XC cells cocultivated with the leukaemic cells. Goat antiserum to E6-MuLV shows quite the opposite pattern, indicating that contamination with endogenous rat virus may be excluded.

A second isolation was made 1 month later from the same patient, while in remission, by cocultivating the buffy coat of the peripheral blood with human embryonic fibroblasts FB289. Within 2 weeks virus was demonstrable by electron microscopy, XC plaque test and immunofluorescence. In the latter, rat serum No. 76 again gave no reaction, whereas goat anti-E6-MuLV was positive (1:40). Our conclusion is that we have twice isolated a C-type oncornavirus from a leukaemic child. The virus can replicate in human embryonic cells and in rat XC cells, in which it has a cytopathogenic effect. Possible laboratory contamination with animal oncornaviruses may be excluded. Biochemical studies of this isolate are required to assess in more detail its relationship to animal viruses and to determine whether it is exogenous or endogenous to human cells.

Table 2 Immunofluorescence endpoint titration of cell cultures with antisera to animal C-type oncornaviruses*

Cell lines	Antisera			
	Rat anti-RLV 45	Rat anti-RLV 76	Goat anti-E6-MuLV	Goat anti-SSV1 p27
BALB/c 3T3 control	—	—	—	—

* Twelve spots on acetone-fixed slides were used for incubation. Nine of the wells were filled with different dilutions of the antiviral serum. Twofold dilutions were made in PBS, beginning at 1:10. One well was used for normal serum, one for only the fluorescein isothiocyanate (FITC)-conjugated anti-IgG serum and one for only PBS.
ND, Not determined. As two different FITC-conjugated antisera to goat IgG reacted with HEK cells the tests with goat antiviral sera were not carried out on HEK cells.

Department, Antoni van Leeuwenhoek Hospital, Amsterdam, and p27 antigen by Dr S. T. August, Department of Molecular Biology, Albert Einstein College of Medicine, Bronx, New York.

Fig. 1 Profile of Sepharose 4B agarose filtration of the 38–52% ammonium sulphate fraction of platelet actomyosin before (*A*) and after (*B*) phosphorylation. For both samples, a 1.65 ml aliquot containing 7.5 mg protein was applied to a 1.5 × 88 cm column equilibrated and eluted at 21 ml h^{-1} with 0.5 M KCl 15 mM Tris-HCl (pH 7.5), and 1 mM EDTA and 2.5 mM dithiothreitol. Samples (3.5 ml) were collected of which 0.05 ml was used for ATPase assay (shown above). Ordinate indicates A_{720} of the ATPase assay (control sample was incubated for a longer period of time than the phosphorylated sample). Void volume and salt boundary are indicated (V_0 and $V_0 + V_i$). Fractions were pooled as indicated for SDS–polyacrylamide gel electrophoresis (Fig. 2) and ATPase assays (Table 1). Protein concentration of pooled fractions was 0.2–0.3 mg ml^{-1}.

Phosphorylation of platelet myosin increases actin-activated myosin ATPase activity

HUMAN platelet myosin, which is similar to other myosins isolated from non-muscle cells, has a molecular weight of 460,000 and is composed of two heavy chains (200,000) and two different light chains (20,000 and 15,000)[1-3]. The 20,000 light chain can be phosphorylated by a kinase endogenous to human platelets[3]. This enzyme, which has been isolated and partially purified[4], transfers ^{32}P from γ-^{32}P-ATP to the 20,000 light chain of platelet myosin in the presence of Mg^{2+}. So far, the biological significance of this phosphorylation has been unknown, but we report here that phosphorylation of platelet myosin results in an increase in the actin-activated myosin ATPase activity measured at low ionic strength. Dephosphorylation of phosphorylated myosin results in a decrease in the actin-activated ATPase activity.

A 38–52% ammonium sulphate fraction of platelet actomyosin, containing the platelet myosin light chain kinase, incorporates 0.8–1.0 mol P$_i$ per mol 20,000 light chain[3]. To study the effect of phosphorylation, the unphosphorylated ammonium sulphate fraction was divided in half. One half was phosphorylated with 3 mM MgCl$_2$ and 0.2 mM ATP and incubation at room temperature, pH 7.5 for 30 min. The control half of the sample was treated in the same manner but without ATP or MgCl$_2$. Both the control and the phosphorylated myosin were then chromatographed on columns of Sepharose 4B (Fig. 1). In the case of the phosphorylated sample, agarose filtration terminated phosphorylation.

Two peaks of K$^+$-EDTA-activated ATPase activity were eluted for each sample. As shown in Fig. 2, the first peak of ATPase activity is caused by platelet actomyosin and the second peak by platelet myosin alone. Representative fractions from each peak were analysed for actin-activated myosin ATPase activity measured in the presence of Mg^{2+} at low ionic strength and K$^+$-EDTA- and Ca^{2+}-activated myosin ATPase activity assayed at high ionic strength.

Table 1 shows the effect of phosphorylation on myosin ATPase activity. The low ionic strength Mg^{2+} ATPase activity

of phosphorylated myosin is 0.17 μmol P$_i$ per mg protein per min after addition of rabbit skeletal muscle actin. Control (non-phosphorylated) myosin has a significantly lower specific activity (0.029) after the addition of the same amount of rabbit skeletal muscle actin. K$^+$-EDTA- and Ca^{2+}-activated ATPase activities, measured at high ionic strength, are essentially the same for phosphorylated and control myosin.

The enzymatic activities for the initial peaks (actomyosin) from Sepharose chromatography are also shown in Table 1. Again, the actin-activated ATPase activity for phosphorylated myosin was more than four times greater (0.126 compared with 0.028) than for non-phosphorylated myosin. The ATPase activity for phosphorylated myosin without added actin (0.052) is increased, reflecting the presence of platelet actin (Fig. 2).

Having found an increase in the actin-activated myosin ATPase activity after phosphorylation, it was interesting to see if dephosphorylation would decrease the enzymatic activity. Myosin was first phosphorylated with γ-^{32}P-ATP to contain 0.8–1.0 mol phosphate per mol 20,000 light chain[3]. Labelled myosin was incubated with *Escherichia coli* alkaline phosphatase which released 70–80% of the covalently bound ^{32}P in 10 h, whereas a control sample incubated in the absence of alkaline phosphatase retained all incorporated ^{32}P.

Both dephosphorylated myosin and the control sample were chromatographed on a column of Sepharose 4B (for the
Fig. 2 1% SDS–7.5% polyacrylamide gels of non-phosphorylated (*a, b*) and phosphorylated (*c, d*) platelet actomyosin (*a, c*) and myosin (*b, d*) eluted from Sepharose 4B (Fig. 1). Letter above each gel refers to the pooled fraction indicated on the Sepharose 4B elution profile in Fig. 1. H, myosin heavy chain; A, actin; T, tropomyosin; LC₁, 20,000 myosin light chain; LC₂, 15,000 myosin light chain. Dye marker can be seen below LC₂. Migration was from top to bottom. Gel electrophoresis was carried out as described previously[10].

Table 2 Effect of dephosphorylation on ATPase activity

| | ATPase (μmol P_i per mg protein per min) | | | |
| | Actin-activated | | K^+-EDTA | Ca^{2+} |
	$-$Actin	$+$Actin		
Phosphorylated myosin	0.037	0.14	0.53	0.55
Dephosphorylated myosin	0.013	0.04	0.40	0.40

Labelling of platelet myosin: conditions for phosphorylation were as in Table 1 except that γ-^{32}P-ATP was premixed with ATP to give a final concentration of 20 μCi ml⁻¹. Labelled samples were dialysed against 0.5 M KCl, 15 mM Tris-HCl (pH 7.5) and 2.5 mM dithiothreitol before dephosphorylation.

Conditions for dephosphorylation: 2.8 ml labelled myosin (35–55% ammonium sulphate fraction, 9 mg ml⁻¹, 600,000 c.p.m. mg⁻¹) was adjusted to pH 8.0 with Tris base and divided into two equal aliquots. To one, alkaline phosphatase (*E. coli*; BAPF, Worthington) was added in a ratio 1:7 (mg/mg, enzyme/substrate). To the other, an equivalent volume of 65% ammonium sulphate was added. Both samples were incubated at 23 °C for 10–22 h. Incubation was terminated by Sepharose 4B chromatography of the entire sample (1.5 ml) using the same size column and elution buffer detailed in Fig. 1. Concentration of the pooled fraction eluted from the column was 0.3–0.4 mg ml⁻¹. ^{32}P release was measured by precipitating aliquots (50–100 μg) in cold 10% Cl₃CCOOH, 2% sodium pyrophosphate, heating at 96 °C for 20 min, chilling on ice and filtering the precipitate through Millipore HA filters in a Millipore sampling manifold. Filters were washed repeatedly with cold 5% Cl₃CCOOH, 1% sodium pyrophosphate and counted in Aquasol (New England Nuclear) in a Packard Tri-Carb liquid scintillation counter. Identification of 20,000 myosin light chain as the only phosphorylated protein has been described previously[3]. Conditions for ATPase assay are given in Table 1. Data are from duplicate determinations on three different preparations.

sample treated with alkaline phosphatase, this was necessary to separate the enzyme from myosin). Tubes containing myosin ATPase activity were pooled and assayed for actin activation. Table 2 shows the effect of dephosphorylation on actin activation: a decrease in actin-activated ATPase activity from 0.14 to 0.04 μmol P_i per mg protein per min. The K⁺-EDTA- and Ca²⁺-activated myosin ATPase activities measured at high ionic strength were not significantly altered. Furthermore, when the two samples were electrophoresed in 1% SDS-7.5%

Table 1 Effect of phosphorylation on ATPase activity

| | | ATPase (μmol P_i per mg protein per min) | | | |
| | | Actin-activated* | | K^+-EDTA | Ca^{2+}† |
		$-$Actin	$+$Actin		
Myosin	Phosphorylated	0.006	0.170	1.00	0.41
	Control	0.002	0.029	0.90	0.38
Actomyosin	Phosphorylated	0.052	0.126	0.54	0.37
	Control	0.007	0.028	0.38	0.38

Conditions for phosphorylation: 1.5 ml 38–52% ammonium sulphate fraction of platelet actomyosin[1] (3.5–6 mg ml⁻¹) was incubated in 0.1 M KCl, 5 mM Tris-HCl (pH 7.5), 1 mM EDTA, 4 mM MgCl₂, 0.2 mM ATP and 2.5 mM dithiothreitol at 23 °C for 30 min (ref. 3) (total volume 1.65 ml). Phosphorylation was terminated by chromatography of the entire sample on Sepharose 4B. Control samples were treated in a like manner with the omission of MgCl₂ and ATP.

* Assay conditions: 10 mM Tris-HCl (pH 7.2), 1 mM ATP, 1.4 mM MgCl₂ and 30 mM KCl. Platelet myosin or actomyosin 0.06–0.10 mg ml⁻¹, rabbit skeletal muscle actin, 0.6–1.0 mg ml⁻¹, 37 °C.

Rabbit skeletal muscle actin was prepared by the method of Spudich and Watt[7] and migrated as a single band in 1% SDS-7.5% polyacrylamide gel electrophoresis and 8 M urea-polyacrylamide gel electrophoresis, pH 8.6. Specific activity excludes added rabbit skeletal actin.

† Assay conditions: 20 mM Tris-HCl (pH 7.2), 2 mM ATP, 2 mM EDTA or 10 mM CaCl₂ and 0.5 M KCl. Platelet myosin or actomyosin, 0.02–0.04 mg ml⁻¹, 37 °C.

Data are from duplicate determination on three different preparations. P_i production was measured by a modification of the method of Martin and Doty[8]. Phosphate production was linear with time during the period used for assay (0–60 min). Protein concentration was determined by the method of Lowry *et al.*[9] after Cl₃CCOOH precipitation, bovine serum albumin was used as standard.

polyacrylamide gels, the patterns were identical. Gel electrophoresis revealed the presence of platelet actin in these preparations, similar to Fig. 2*a* and *c*, and this is reflected in the ATPase activities (Table 2).

Phosphorylation of a light chain from skeletal and cardiac muscle myosin by a kinase isolated from rabbit sarcoplasm has been reported[5]. This kinase differs from that purified from platelets by us in requiring Ca²⁺ for activity[4]. In addition, the platelet myosin light chain kinase does not phosphorylate skeletal or cardiac muscle myosin but does phosphorylate mouse fibroblast[6] and chicken gizzard myosin[4].

The identification of actin and myosin in a large number of vertebrate as well as invertebrate non-muscle cells[2] raises questions as to how the interaction of these proteins is controlled. We have described the effect of phosphorylating the 20,000 light chain of a non-muscle myosin: an increase in the actin-activated myosin ATPase activity. The finding that platelet myosin light chain kinase phosphorylates the 20,000 light chain of fibroblast and smooth muscle myosin suggests that phosphorylation may have a role in controlling actin–myosin interaction in other cells.

Oxygen reduction and optimum production of ATP in photosynthesis

THE accepted pathway of CO_2 fixation in plant photosynthesis requires that the photosynthetic light reactions produce ATP and reduced pyridine nucleotide (NADPH) in the molar ratio 3:2 (ref. 1). Early studies of photosynthetic phosphorylation suggested that non-cyclic electron transport could produce only equimolar amounts of ATP and NADPH, and the source of the extra ATP was presumed to be cyclic electron flow[2]. The view that the non-cyclic system is by itself able to produce twice as much ATP as NADPH has been expressed[3,4], and removes the need for the *in vivo* operation of a cyclic electron flow which can be demonstrated *in vitro* only in artificial conditions[5]. An inflexible ATP-NADPH ratio of 2:1 for the products of the light reactions would, however, result in a feedback inhibition of electron transport, with ADP concentration as the limiting factor. One way of achieving flexibility in the relative production of ATP and NADPH would be for a low
Fig. 1 The combined reduction of oxygen and of NADP by non-cyclic electron transport. The reaction of ferredoxin with oxygen makes possible the synthesis of ATP without the production of NADPH. Stoichiometries are discussed in the text and are not implied in the diagram.

absolute stoichiometry of non-cyclic photophosphorylation (corresponding perhaps to a 1 : 1 ratio) to be accompanied by an ancillary reaction producing ATP but not NADPH. Such an ancillary reaction would be especially important in situations where ATP might be required for phosphorylations additional to those of the reductive pentose phosphate pathway.

Figure 1 outlines a mechanism by which an optimum balance
of ATP and NADPH could be maintained by non-cyclic electron transport in photosynthesis. Here the ancillary reaction is assumed to be oxygen-reducing electron transport, and the mechanism, therefore, relies on a "pseudocyclic" contribution to overall ATP synthesis, as suggested previously by Heber[6]. The novel feature of this scheme is a competition for reduced ferredoxin by NADP and oxygen. Production of too little ATP would inhibit the dark regeneration of NADP, and ferredoxin would then be oxidised only by oxygen. With oxygen as the effective electron acceptor, ATP but not NADPH would be produced, and a higher concentration of ATP would be restored. Excess ATP would lead to pyridine nucleotide being present predominantly in the oxidised form, and thus to electrons being diverted from oxygen to NADP. In this way the active non-cyclic electron transport chain would continually meet the requirements of CO_2 fixation, and would be able to respond to any changes in the metabolic demands made on it by synthesis of carbohydrate, protein or lipid.

Ferredoxin is an effective mediator of photosynthetic oxygen uptake by isolated chloroplasts[7], a reaction which accompanies non-cyclic (in this case also termed "pseudocyclic") photophosphorylation[8]. It is also the penultimate component of the photosynthetic electron transport chain, and as such is essential for the reduction of pyridine nucleotide in photosynthesis[9]. The hypothesis represented in Fig. 1 requires ferredoxin to perform both of these functions simultaneously, a situation which is demonstrated experimentally in Fig. 2. In the absence of both NADP and catalase, the rate of photosynthetic oxygen uptake by isolated chloroplasts is a function of ferredoxin concentration (curve *a*), and this oxygen uptake is abolished by addition of catalase (curve *b*). The photosynthetic oxygen-consuming reaction can, therefore, be written as the reversed dismutation of hydrogen peroxide:

$$H_2O + \tfrac{1}{2}O_2 \rightarrow H_2O_2$$

This describes non-cyclic transfer of one electron pair from water to oxygen. In the presence of NADP a catalase-insensitive evolution of oxygen should occur as transfer of one electron pair from water to NADP results in the reaction:

$$H_2O + NADP^+ \rightarrow NADPH + H^+ + \tfrac{1}{2}O_2$$

In this situation, however, catalase stimulates observed oxygen evolution (curves *c* and *d*), and the degree of this stimulation increases with increasing ferredoxin concentration. This stimulatory effect of catalase on net oxygen evolution can be considered to be no more than an inhibitory effect of catalase on a "background" oxygen uptake. If, of each pair of electrons from water, an average of *n* electrons are transferred to oxygen and $2 - n$ to NADP, then the overall reaction occurring in the

Fig. 2 The effects of catalase on ferredoxin-mediated uptake and overall evolution of oxygen by illuminated spinach chloroplasts. For curves *c* and *d* oxygen evolution was supported by the presence of NADP (2 mM). Curves *b* and *d* represent rates obtained in the presence of 8×10^3 U catalase (Boehringer). For curves *a* and *c* sodium azide (2 mM) was present as an inhibitor of any endogenous catalase.

Oxygen exchange was measured in a Rank oxygen electrode, with illumination by two 300-W slide projectors. Broken, washed chloroplasts had been isolated from spinach by a method described previously[14], and the reaction vessel contained sorbitol (0.1 M), $MgCl_2$ (5 mM), NaCl (20 mM), EDTA (2 mM), HEPES (pH 7.5, 50 mM), NH_4Cl (5 mM) and chloroplasts (100 μg of chlorophyll) in a final volume of 2 ml. Ferredoxin, isolated from *Spirulina maxima* by the method of Hall *et al.*[15], was added as a 1.4-mM solution. Substantially similar results have been obtained with a number of plant-type ferredoxins (unpublished work). The extent of stimulation of net oxygen evolution by catalase is apparently unaffected both by omission of NH_4Cl and by addition (in the absence of NH_4Cl) of ATP or ADP with phosphate (these results also unpublished).

absence of catalase activity (curve *c*) becomes

$$H_2O + \frac{n}{4}O_2 + [(2-n)/2]NADP^+ \rightarrow \frac{n}{2}H_2O_2 +$$

$$+ [(2-n)/2](NADPH + H^+) + [(2-n)/4]O_2$$
and the ratio of oxygen molecules evolved to electron pairs transferred is given by

$$(O_2/2e^-)_{-cat} = [(2-n)/4] - (n/4) = [(1-n)/2]$$

In the presence of catalase, however, the compensatory reaction

$$\frac{n}{2}H_2O_2 \rightarrow \frac{n}{4}H_2O + \frac{n}{4}O_2$$
also occurs (curve *d*), and so the corresponding ratio is merely

$$(O_2/2e^-)_{+cat} = [(2-n)/4]$$

For any absolute rate of electron transport which is unaffected by catalase, the ratio *r* of the observed rates of net oxygen evolution in the presence (v_{+cat}) and absence (v_{-cat}) of catalase will be given by

$$r = v_{+cat}/v_{-cat} = (O_2/2e^-)_{+cat}/(O_2/2e^-)_{-cat}$$
$$= (2-n)/[2(1-n)]$$

and thus *n* ($0 \leqslant n \leqslant 2$) can be calculated from the relationship

$$n = [1/(1-2r)] + 1$$

In Fig. 3*a* this measure of the contribution of the oxygen-reducing reaction to total electron flux has been calculated
Fig. 3 *a*, *n* is the average number of electrons which go to oxygen, per pair transferred through the photosynthetic chain. *b*, v_e- is the rate of electron transport in μEq ×2 per mg chlorophyll per h, units comparable with similar units involving μatoms oxygen exchanged or μmol NADP reduced. Values for each variable (*n* and v_e-) were calculated as described in the text from the data in Fig. 2, with individual values corresponding to observed rates of oxygen evolution at each ferredoxin concentration.

from the data in Fig. 2, and is plotted against the same scale of ferredoxin concentration. As v_{-cat} is related to the absolute rate of electron transport (v_{e-}) as follows

$$v_{-cat}/v_{e-} = (1-n)/2$$

the absolute rate of electron flux can also be calculated. The dependence of electron transport *per se* on ferredoxin concentration is shown in Fig. 3*b*. As in the case of net oxygen evolution (Fig. 2), a saturated rate of electron transport is achieved at a ferredoxin concentration of 15–20 μM. Unlike net oxygen

evolution, however, the rate of electron transport does not significantly decrease with higher ferredoxin concentrations. The decline in the observed rate of oxygen evolution with high ferredoxin concentrations (Fig. 2) presumably reflects an increasing displacement of NADP by oxygen as the terminal electron acceptor (Fig. 3*a*). At these saturating ferredoxin concentrations of >15 μM n ⩾0.3, and so not less than 15% of total electron transport is supported by reduction of oxygen.

These results question Arnon's statement[8] that in photosynthesis reduction of oxygen cannot occur simultaneously with reduction of NADP. Using mass spectrometry Egneus *et al.*[10] have identified an uptake of $^{18}O_2$ by CO_2-fixing chloroplasts in a reaction apparently unrelated to glycolate synthesis. This provides independent support for a competition of oxygen with NADP for electrons from the photosynthetic chain. Whitehouse *et al.*[11] have suggested that a significant rate of reduction of oxygen occurs in the presence of added FMN even where the artificial electron acceptor ferricyanide is used instead of NADP and ferredoxin.

The importance to photosynthesis of electron flow to oxygen has also been suggested by Heber, whose detailed measurements of the quantum requirements of various photoreductions support a contribution of oxygen-reducing electron transport to overall ATP synthesis[6], and point to a flexibility in the stoichiometry of photosynthetic phosphorylation and NADP reduction[12]. The work of Patterson and Myers[13] with *Anacystis nidulans* indicates that an *in vivo* photosynthetic production of hydrogen peroxide may indeed occur.

I thank the SRC for a research studentship. The ferredoxin was a gift from Dr K. K. Rao.

Agonism and antagonism of γ-aminobutyric acid

EVIDENCE that (+)bicuculline (BIC) is a competitive antagonist of the central inhibitory transmitter γ-aminobutyric acid (GABA) is based[1] mainly on apparent similarities between the molecular structures of BIC, GABA and agonists of GABA. Until recently, there has not been any explanation of the differing potencies of the agonists, or why BIC is an antagonist instead.

In 1970 it was noted[1] that the N and lactone C–C=O in BIC could be isosteric with the N and carboxylate COO of an extended (that is fully *trans*) GABA molecule (zwitterion at physiological *p*H) and its equivalent (O–C=N) in the agonist muscimol. Alternatively[2], a partially folded GABA molecule could have its N and COO congruent with the N and lactone

O–C=O of BIC. The discovery of conformationally restricted GABA agonists[3,4], notably 4-aminotetrolic acid[3], however, gave some support to the extended charge separation—measurements[3] on Drieding models gave 5.2–5.8 Å. General agreement was also obtained from EHT MO predictions of minimum-energy conformations for isolated molecules of GABA[5], muscimol[5] and other agonists[6,7], and for protonated BIC (HBIC—as administered)[6]: a value of 5.8 ± 0.2 Å was obtained[7] if intercharge distances were related to the onium → one carboxylate O in the GABA zwitterion and the onium →

suggests that there is more to its "recognition" of a drug molecule than a single charge separation.

The feature of structure not included in any of the discussions, but now available from CNDO/2 calculations (refs. 9, 22 and unpublished work), is the distribution of charge within the molecules. (Such details were used in the conformation against potency correlation[12] above.) Comparisons of the three-dimensional patterns of charge show features that may distinguish between agonists and antagonists. The charge distribution in the lactone ring in HBIC is of particular interest (Fig. 1a),
Fig. 1 Skeletal outlines and associated charges (a.u.) for: *a*, HBIC in approximate solution-conformation $(T \sim -90°)$; *b*, GABA zwitterion (charges not significantly altered when molecule is partially folded as described in text). Torsion angle T(N2.C1–C9.O10), positive when N2.C1 is rotated clockwise to eclipse C9.O10, as viewed along C1→C9. (H atoms not shown have a charge of 0.0(5) or less.)

carbonyl O in BIC. Although the EHT method is inadequate with strongly polar molecules[8], and the more folded conformations that would be expected in flexible molecules are predicted by CNDO/2 (ref. 9) and PCILO[10,11] MO calculations, general agreement with EHT results is fortuitously re-established when allowance is made in the CNDO/2 calculations for an aqueous medium[9].

A preliminary analysis of the role of agonist flexibility has now revealed[12] a correlation between relative potency and interaction probability calculated from (potential energy) conformation population distributions corrected for the charge-separation tolerance of the receptor.

Concerning BIC as a competitive antagonist, the crystal structure determination[13,14] of (+)BIC showed[15,16] that the model originally portrayed[1] was the wrong diastereomer—adlumidine (1S,9S)[17] instead of 1S,9R (ref. 17) (Fig. 1a). Also the methyl substituent at the N is pseudoaxial to the pyridine ring, not pseudoequatorial. Theoretical calculations show, however, that in HBIC[6,13,18], and in the potent N-MeBIC[13,18], there is appreciable torsional freedom about C1–C9 from about $-60°$ to $-120°$, and within this angular range it is again possible to obtain the isosteric match with GABA which was originally reported[1] for the wrong BIC configuration. Congruence with a partially folded GABA[2] is not easily attainable but it could be achieved accurately by δ-aminovaleric acid, a GABA agonist[19]. The BIC torsion-angle range also makes available a flexibility of charge separation comparable with that of some GABA agonists. BIC should therefore be "recognised" by the GABA receptor as an agonist[20], and its action as a competitive antagonist, by which it blocks the permeability change in the postsynaptic membrane, may therefore be due to some further feature of its structure. The report[21] that (–)BIC is inactive is relevant. Although such selectivity is common, this evidence that the GABA receptor is chirally specific

showing an appreciable difference between the alternatives described earlier, C2′.C11.O12 and O10.C11.O12; the second bears a closer resemblance to the COO of an amino acid zwitterion. More significant, however, is the smaller charge on the above negatively charged atoms in the lactone ring compared with those in the GABA COO group (Fig. 1b). This, and the differences in the spread of positive charge, are the first intimations of a possible mechanism of competitive antagonism: a charge pattern sufficiently similar to that of an agonist to be "recognised" and attracted to a receptor, but with charges too weak and/or diffuse, or too shielded by the remainder of the molecule, to enable the receptor to bind the drug and then undergo the conformational change believed to be associated with the final stages in the action of a transmitter. The charges on the remainder of the BIC molecule may have a role, perhaps contributing to binding around the receptor site, preventing fast removal of the antagonist molecule and thus blocking the receptor.

Further analysis of the causes of the chiral selectivity of BIC and the mechanism of its antagonism will be aided by results of physiological tests on the other related phthalideisoquinoline alkaloids.

Differences in natural carbon isotope ratios of milk and hair from cattle grazing tropical and temperate pastures

ABOUT 99% of all carbon is the ^{12}C isotope while 1% is ^{13}C. The precise ratio of the isotopes will vary depending on the material analysed. In plants, fractionation of carbon is brought

reported for temperate and tropical pastures (ref. 3 and M.M.L., J.H.T., and R.J.J., unpublished). There were also large differences between the ratios for milk and hair produced from C_3 and C_4 pastures, although the mean difference was reduced from -14.0% with pasture to -9.8% for the tissues. This narrowing of the ratio may be due to differences in discrimination against ^{13}C during transformations by the rumen microorganisms or within the tissues of the animal. Alternatively, the animals grazing C_4 pastures may have selectively grazed a small amount of C_3 weeds which would increase the carbon ratio relative to that of the feed sample. Similarly, selection of C_4 weeds in C_3 pastures would reduce the ratio below that expected. Values for milk and hair were identical at three of the four locations, indicating that differences in the carbon ratios of the feeds are reflected in both long term and short term animal products. The cause of the difference in ratios for milk and hair at Swan's Lagoon is unknown. Since the carbon ratio of milk and hair are similar, it is likely that the ratios for other animal tissues, including muscle and fat, will show similar differences between feeds.

These results show that the carbon ratios of animals reflect the carbon ratio of the feed being eaten, and that these ratios can be used as a naturally occurring marker of carbon. This finding could have important implication for animal physiology, forensic science and studies of animal evolution. It should be possible to calculate the proportion of carbon in milk coming from feed and body reserves or to determine the

Table 1 $^{13}C/^{12}C$ ratios of pasture and of milk and hair of grazing cattle

*Also *Trifolium repens* and other temperate species.

about primarily by carbon dioxide assimilation in photosynthesis and is due to preferential utilisation of ^{12}C and exclusion of ^{13}C. Curiously enough, it has been found recently[1,2] that higher plants which fix carbon dioxide by way of the Calvin C_3 cycle pathway differ in $^{13}C/^{12}C$ ratios from plants which fix carbon dioxide through the C_4-dicarboxylic acid pathway. Temperate pasture species fix carbon by way of the Calvin pathway and have $^{13}C/^{12}C$ ratios of approximately -28% (ref. 3 and M.M.L., J.H.T., and R. J. Jones, unpublished), whereas tropical pasture grasses fix carbon through the C_4-dicarboxylic acid pathway[4] and have $^{13}C/^{12}C$ ratios of approximately -12% (ref. 2 and M.M.L., J.H.T., and R.J.J., unpublished). $^{13}C/^{12}C$ ratios are expressed relative to a carbonate standard[5].

Smith and Epstein[5] suggested that isotope ratios of marine animal tissues reflect the ratio in their presumed diet, but there seem to have been no direct comparisons of the isotope ratios of higher animal tissue with those of the food eaten. Our aim, therefore, was to compare the carbon ratios of tissues from animals grazing pasture with contrasting $^{13}C/^{12}C$ ratios. The tissues sampled were hair and milk, representing the products of long and short term absorption of nutrients respectively, whereas the pastures grazed were composed of either temperate C_3 species or tropical C_4 grasses, each grazed at two locations (Table 1). Pasture was the only source of carbon except at Wollongbar where 2–3% of the predominantly C_4 diet consisted of bran/oaten chaff (C_3). The isotope measurements of pasture, hair and milk samples were made with a ratio mass spectrometer[6]. Differences between single replicates are usually less than 1‰.

The carbon ratios of the pasture samples (Table 1) reflected their botanical composition with values close to those previously

rate of exchange of body protein and fat. This would be achieved by feeding a completely C_4 diet to animals that had previously been given only C_3 feeds so that all their tissues had carbon ratios characteristic of C_3 species. In temperate zones C_4 diet could be based upon either the forage or grain of *Zea mays* or *Sorghum bicolor*. Alternatively, animals on a C_4 diet could be changed to one comprised of C_3 feeds. In forensic science this observation could prove valuable in determining the diet and hence the origin of animals or animal products. It should also be possible to determine the diets of ancient animals by measuring the carbon isotope ratios of their remains.

We thank Ms J. Clark, Dr J. C. Radcliffe and Messrs R. G. Holroyd and A. J. E. Royal for providing the samples of pasture, milk and hair.

reviews

Makings of a great physiologist

THIS book* is largely directed to a critical account of the development of the ideas and of the experimental research of the great French physiologist, Claude Bernard, during the period 1842–48. From 1841–44 Bernard was *preparateur* to Magendie at the Collège de France but he was already slowly evolving into the great creative investigator that he later became, with ideas and discoveries that ultimately overshadowed those of his teacher. In his discussion of the research Bernard carried out between 1842 and 1848 Professor Holmes has focused on studies of digestion, nutrition and related problems. Although the subject of the study is Claude Bernard much of the book is necessarily concerned with the activities of others, particularly with the adventures in animal chemistry of the two great organic chemists Liebig and Dumas, with their respective supporters.

In his thesis for the Doctorate of Medicine published in 1843 under the title *Du suc gastrique et de son rôle dans la nutrition*, Bernard described the results of investigations which revealed that when sucrose is injected into the veins of a dog it is excreted in the urine largely or completely unchanged; but sucrose given preliminary treatment with digestive juices before its intravenous injection is not so excreted. This was a very important discovery for a young man but afterwards, until 1848, Bernard published few scientific articles.

For a study of Bernard's early scientific development Professor Holmes has been able to consult much manuscript material from the Collège de France, including Bernard's early laboratory notebooks, classified and catalogued between 1962 and 1965 by Professor M. D. Grmek. As Professor Holmes writes in the introduction to his book, "Bernard's notebooks show that the papers he published in this period [1843–48] were only superficial markers of the trail that he was following. . . . His reasoning was often incisive, but occasionally vague, just as his experimental procedures were in some respects unusually rigorous but in

"For more than two years, at the beginning of my career, I wasted my time pursuing theories and chimeras. It was not until after a long period of deception that I ended by reflecting and thinking that . . . my will could not change the laws of nature".

CLAUDE BERNARD

Ronan Picture Library

other respects below the best standards of his time". Professor Holmes's book throws important light on the years of preparation which until now have been very little documented. We can now see for ourselves the evidence for what I suppose most of us guessed at all along, that Bernard must have gone through periods of doubt and made false starts, had prejudices and frustrations, and that in fact he did not spring fully armed into the scientific arena but went through the painful processes of initiation and struggle to which the experimental scientist is naturally subject.

Although Bernard was skilled in experimental surgery his knowledge of chemical methods was much less developed, and his dependence upon the chemical expertise of his colleague C.-L. Barreswil was here of great importance. Barreswil had developed a method for the detection and estimation of glucose by a reduction of an alkaline solution of copper salts which, in many modified forms, had a long life.

In the first chapter of the book, entitled "Chemists, Physiologists, and the Problems of Nutrition", Professor Holmes summarises the conflicting views which prevailed about nutrition in the early years of last century, and some of the controversies in which

Dumas and Liebig figured prominently. In 1841 Magendie presented, on behalf of a commission which had been appointed to adjudicate claims about the alleged special nutritive value of gelatin, a report on 10 years of study. The French Academy were anxious to have an authoritative statement on a topic which was extremely controversial. During the previous century, and subsequently, gelatin had been regarded by some as the basic nutrient substance from which the tissues of the body are formed. The conclusion of the commission, that gelatin in itself is not adequate nourishment, evoked a storm of controversy. But the activities of the commission had an important effect on Claude Bernard since, by carrying out a number of extended feeding experiments for Magendie at the Collège de France, Bernard was initiated into the experimental investigation of animal nutrition. In that way the lectures and writings of Dumas, Liebig and others came to bear on the developing mind of the young Bernard. And the controversies that ensued induced Bernard to ally himself with those who were critical of the uninspired application of chemical methods to the solution of biological problems, although he himself made much use of chemistry in the service of physiology.

In 1848 Bernard began the series of investigations on the nature of the processes to which substances absorbed from the gastro-intestinal tract of animals were subjected during their passage through the body. The results of these investigations were summarised in Bernard's thesis for the Doctorate of Science, which was published in 1853 under the title *Nouvelle fonction du foie*. It described his perhaps most famous discovery: the glycogenic function of the liver. From 1853 onwards many publications by Bernard document his scientific development.

Bernard's *Introduction à l'étude de la médecine expérimentale*, published in 1867 as the result of a period of illness which kept him from his lecture room and research bench, gives what can be perhaps an idealised treatment of his subject and of the views that he had assumed by the time he had become an internationally distinguished investigator. Professor Holmes quotes from Bernard's writings later in life the statement that "For more than two years, at the beginning of my career, I wasted my time pursuing theories and chimeras. It is a remark-

able fact, that one imagines that the truth is in himself, and I insisted on repeating experiments which insisted on responding to me always in the same way, contrary to my views. It was not until after a long deception that I ended by reflecting and thinking that . . . my will could not change the laws of nature".

As Professor Holmes states, Bernard's strength was tied to some serious limitations, and his avenue towards greatness was at first a narrow one. There was no guarantee that his will, his insights and his technical skill would lead him to the heights. During the 1840s he was not somebody consciously advancing towards his position of the 1850s and 1860s, but one whose fate was uncertain. "The prospect of returning to Villefranche as a village doctor was as real for Claude Bernard as the prospect of ascent to the Académie des Sciences, the Académie Française and the adulation of his peers".

All who are interested in the way scientists develop will find fascinating material in this study of Claude Bernard during his early years.

F. G. Young

Scientific knowledge and sociological theory

Scientific Knowledge and Sociological Theory. By Barry Barnes. Pp.x+192. (Routledge and Kegan Paul: London, December 1974.) £3.95 cloth: £1.95 paper.

IN spite of its Germanic title and subject matter, *Scientific Knowledge and Sociological Theory* is a brief, elegantly written, and even occasionally witty discussion of the social and cultural factors affecting the development of scientific knowledge. It represents an ambitious attempt to apply the perspectives of Mannheim's sociology of knowledge to science.

Barnes rejects conventional distinctions between false beliefs, which require causal explanation, and "naturally reasonable inductions", which do not. He also rejects the definition of science as rational, rather than true, knowledge, on the grounds that there are no adequate criteria for comparing the rationality of different statements: simplicity is ambiguous, and conventional; falsifiability is impossible to establish, and rarely used in practice; and *ad hocery* is merely a derogatory term for secondary elaboration or rational modification. For Barnes, all knowledge is necessarily theoretical, for there is no direct language of observation, and theoretical acceptability is culturally conditioned. Therefore, all knowledge is equally susceptible to sociological explanation.

Normality, defined by the actors themselves, is substituted for truth or ration-

ality as the yardstick for comparing different beliefs; abnormality, rather than falsehood or irrationality, requires causal explanation. "Where actors or groups hold idiosyncratic beliefs as judged against some background of normality, some special cause or condition must be identified which distinguishes that actor or group from that background" (p. 42). Barnes, therefore, focuses upon the maintenance of normality and the development of innovation within scientific sub-disciplines. Normal beliefs are learned through socialisation into the distinctive metaphors and procedures of scientific subcultures, by following exemplary procedures, and by acquiring practical experience. Innovation occurs through differentiation, transfer from one sub-discipline to another, or simply from creativity based upon "a universal human propensity to create and extend metaphors" (p. 87). Such innovations occur partly through the intellectual evolution of conventional paradigms within science itself, and partly through the need to develop new beliefs to fulfil purposes external to science. Thus, the Scientific Revolution resulted partly from the re-emergence of Platonism, and partly from the disintegration of feudalism as a political and social system: "in the general context of post-feudal Europe, teleology had to decline" (p. 117).

The substitution of normality for truth or rationality represents only a formal, if fashionably relativist, advance upon

previous usage. What are the criteria for 'normal'? Is normality to be interpreted in a statistical or cultural sense? Are actors always conscious of the normality or otherwise of their actions? Moreover, rationality can, for 'practical purposes', provide a basis for comparing beliefs in terms of given means–ends relationships. Problems arise with the concept of rationality only when it is impossible to specify ends, that is, at the most general level. But, as Barnes points out, science consists of a number of differentiated sub-cultures, each with distinctive procedures and ends. The problems of rationality are, therefore, less than Barnes initially suggests.

In general, the sociology of knowledge provides an unsatisfactory basis for explaining scientific knowledge, for the connections between specific beliefs and the social structure remain tantalisingly vague. Barnes argues sensibly that "the sociologist should consider beliefs in terms of their functions in practical activity" (p. 39) and brings out clearly the general factors that might connect science with that activity. But the illustrations of those connections are disappointingly brief and often unconvincing: uniformitarianism as the credo of an emerging industrial order in early nineteenth century Britain and eugenics in Britain before 1914 as a response of the declining ruling class are presented as self evidently plausible examples. At the very least, some attempt at a comparative analysis of alternative reactions is required. Moreover, Barnes shows considerable sympathy for materialist explanations of scientific development (for example, pp. 149–50), but does not discuss the connection between the material bases for the production of science and the content of scientific beliefs in any detail.

The approach to sociology adopted by Barnes is explicitly 'phenomenological', although his use of the approach is valuably flexible. This involves "an appreciation of actors' normal practice as it is, and of its inadequacies as they themselves define them" (p. 43). In practice, however, the author disregards the self imposed limitations this perspective volves, and his analysis of innovation acknowledges the problematic validity of actors' own explanations. This tension, if not inconsistency, stems from the author's recognition that actors' accounts cannot in themselves provide a basis for sociological generalisation and explanation.

In spite of these unresolved problems *Scientific Knowledge and Sociological Theory* represents a valuable and interesting contribution to sociology. At the very least it provides sociologists with an unusual gritty insight into the reality of science. But I doubt whether the book will persuade scientists that sociology has much to offer them in their own 'practical concerns'. **Roderick Martin**

Finite Groups and Quantum Theory.
By D. B. Chesnut. Pp. xiii+254.
(Wiley Interscience: New York and
London, December 1974.) £7.25.

THIS book satisfies nobody. It is nicely
written and clear, but as a physicist I
could not possibly recommend it to my
students as there are no physical
applications. It is indeed remarkable
that a book on finite group theory
advertised as being suitable for
physicists contains no mention of
crystal structure This is presumably
because the author is a chemist. But
when I asked my colleagues in chemistry
for their opinion I was told that the
single chapter on the application of
group theory to chemical bonding was
far too slim and that it could not
compete with several other books in the
field.   **Norman Dombey**

Pest Control and its Ecology. (The
Institute of Biology's Studies in Biology,
No. 50.) By Helmut F. van Emden. Pp.
59. (Edward Arnold: London, January
1975.) £1.90 boards; £0.95 paper.

THIS 59-page book with its list of 17
references is intended to help "teachers
and students at school, college or
university . . . to keep abreast of recent
trends and know where the most sig-
nificant developments are taking place".
It aims to cover primarily the control
of insect pests on growing crops and,
except for occasional excursions into
other hemispheres, it devotes most
attention to British insects.

The author deals realistically with the
modern vogue for the uncritical con-
demnation of pesticides, in particular
providing yet another disparaging per-
spective of Rachel Carson's *Silent
Spring* which started so many hares
running and seemingly also set in-
numerable hounds into perpetual mo-
tion in hot pursuit.

In this book, unfortunately, the possi-
bilities for classical biological control,
in the sense of introducing natural
enemies of pests of exotic origin, are
blurred and diluted by being confused
with the mass production of agents for
use in flooding techniques. Doubtless,
this is because the author lives in a
country where there is generally con-
sidered to be relatively little potential for
the introduction of exotic agents. It is a
pity that the more generally applied
type of biological control is sold short
by mention of such remote or largely
misleading concerns as "imported para-
sitic insects may occasionally carry a
crop pathogen externally and thus bring
a new problem into the crops" and that
its use means that "control is slow, it is
not exterminant, unless 'misused', it is
often unpredictable, it is difficult and

expensive to develop and apply, and it
requires expert supervision" (pp. 19–20).

Those comments do a serious dis-
service to a flourishing branch of
entomology which is pollution-free,
involves finite energy input and may
produce valuable results lasting long
into the future.

In general, however, this book is up
to date, eminently readable and conveys
much useful information.
                              D. F. Waterhouse

Books brief

Protein–Calorie Malnutrition. (The
Nutrition Foundation: A Monograph
Series.) Edited by Robert E. Olson
Pp. xxiv+467. (Academic: New York
and London, February 1975.) $29.50;
£14.15.

ALTHOUGH this book contains many
papers of a high scientific standard it
is difficult to be totally sympathetic to
its aims or its achievements. The
majority of nutritionists now agree that
protein–calorie malnutrition (PCM)
can be prevented by eating more food
That being so, symposia on the bio-
chemical and physiological aspects of
the disease—which is essentially what
this book is—are open to a charge of
irrelevance.

Those who accept that metabolic
research is still required will find, no
doubt, that this book is a useful guide
to such projects They may be irritated
by the inclusion of a few papers with
virtually no bearing on PCM, and by the
fact that a publishing delay of two
years has made the contributions some-
what out of date. They will, however,
find it a useful text to consult, if it is at
times somewhat tedious to read.

It is a pity, though, that the editor
did not substitute some practically
useful papers for the interminable
discussion sections. Then it might have
been the important landmark that the
Nutrition Foundation claim it to be.
                              John Rivers

*Topics in Carbon-13 NMR Spectro-
scopy,* vol. 1. Edited by George C. Levy.
Pp. x+292 (Wiley-Interscience: New
York and London, December 1974.)
£9.45.

THE remarkable technical advances
made over the past five years have
allowed access to NMR spectra of
dilute spin systems to the extent that
^{13}C spectra are now commonly observed
on a routine basis. The considerable
advantages of the ^{13}C NMR technique

have engendered much interdisciplinary
interest. *Topics in Carbon 13 NMR
Spectroscopy* is a useful supplement to
existing monographs on the subject. It
contains a number of articles by well
known authors, which review aspects of
the ^{13}C NMR technique. The articles
vary from a detailed description of
theoretical work, by Professor Ditch-
field, which presents some astonishingly
accurate calculations of ^{13}C chemical
shifts (and which I found most interest-
ing), through articles on relaxation
studies (Lyerla and Levy), substituent
effects (Maciel), polymer studies
(Schaefer), ^{13}C at high-fields (Anet), to
dynamic studies (Stothers). The re-
viewers present well balanced appraisals
of their subjects up to late 1973, and
generally elucidate the shortcomings of
the methods as well as their advantages.
Regrettably, that is not the case in the
chapter on dynamic studies. In such
systems, which are non-linear, the
Fourier transform of a free induction
decay is not necessarily identical to the
continuous wave spectrum for 90° pulse
angles, although their identities become
closer as the pulse angle decreases; this
caveat should have been covered more
explicitly than by the inclusion of one
reference.

Overall, the volume has much of
interest to offer to spectroscopists and
to chemists and biochemists generally. I
look forward to the continuation of
what promises to be a stimulating and
informative series.   **J. M. Briggs**

*Flow· Its Measurement and Control in
Science and Industry.* Vol. 1, part 3:
Flow Measurement and Control. Edited
by W. E. Vannah and H. Wayland.
Pp. xliii+1049–1493. (Instrument
Society of America: Pittsburgh; Wiley:
Chichester, November 1974.) £19.60.

IN order to bring together experts in
many branches of fluid flow and to
review the most recent advances in the
subject, an international symposium
was convened in Pittsburgh in the
Spring of 1971. Some three years later
the Proceedings of that symposium have
been issued. All possible facets of
flow measurement and control have
been considered and the editors have
managed to classify the papers into
four rather vague themes entitled
"Flow characteristics", "Flow measur-
ing devices", "Flow measurement" and
"Biological fluid flows". This excellent
and ambitious book, comprising as it
does a comprehensive range of almost
200 theoretical and experimental con-
tributions, is very well produced and in
spite of the high total cost will prove to
be the ideal reference source for workers
in the entire field of fluid flow.
                              P. A. Davies

obituary

Ernst David Bergmann, professor of organic chemistry at the Hebrew University and one of Israel's leading scientists, died on April 6 at the age of 71.

Born the son of a Rabbi in Germany, he obtained his PhD at Berlin in 1933, and arrived in London during that year. There he met Chaim Weizmann, with whom he was to form a close working relationship, lasting 18 years. He left for Palestine in 1934 to head the Daniel Sieff Institute (later the Weizmann Institute), which he had helped to plan. Before accepting the professorship of organic chemistry in Jerusalem (where he resigned from the post of vice-president only last March) in 1953, he had been Scientific Director of the Sieff (Weizmann) from 1934–51. From 1953–66 he was chairman of the Atomic Energy Commission and director of defence research in the Ministry of Defence, and currently had been director of the Harry S. Truman Research Institute at the Hebrew University and Honorary President of the Ben-Gurion University of the Negev. His early studies on the stereochemistry of the Walden inversion and on polycyclic hydrocarbons, and his later work on the toxicity of organic fluorine compounds and on the role of steroids in insect growth, had gained him international fame. His research had been mainly in the fields of petroleum and photochemistry; on receiving the Solomon Bublick Prize in 1973, he had predicted the oil crisis that would beset the world, and proposed the establishment of an international agency for oil—along the lines of the International Atomic Energy Agency, in which the Arab states were participants. In recent years he had also been involved in developing contacts between the scientific and technological communities of Israel and West Germany. Among many prizes recognising his lifelong contributions to science, Professor Bergmann had received the Israel Prize for Natural Science and the Rothschild Prize.

announcements

Appointments

The Trustees of the Nuffield Foundation have appointed **John Maddox** as Director of the Foundation. **Robin Matthews** has been appointed a Trustee.

J. R. Parratt, reader in physiology and pharmacology, has been appointed to a personal professorship at the University of Strathclyde.

Birkbeck College, London has appointed **Judith Greene** as professor of psychology.

International meetings

October 2, **Current nutritional developments,** Manchester, UK (Mr J. Crowther, The Metal Box Co. Ltd, Monmouth House, Monmouth Road, Cheadle Hulme, Cheadle, Cheshire SK8 7BJ, UK).

October 6–10, **Nuclear techniques in animal production and health,** Vienna (International Atomic Energy Agency, Kartner Ring 11, PO Box 590, A-1011, Vienna, Austria).

October 6–10, **Remote sensing of environment,** Ann Arbor (The University of Michigan, Extension Service, Conference Department, Ann Arbor, Michigan, 48104).

Person to Person

London accommodation. American pharmacologist and wife, without children or pets, seek small furnished flat (1 or 2 bedrooms) in central London for October and November, 1975, while working on sabbatical leave at University College (Dr J. P. Green, 33 Avenue de Breteuil, Paris 75007, France; tel. no. 734-37-36).

Nuts. Scientist requires small samples of edible nuts without fleshy layer for photographing. Botanical description or description by use. Entry permits will be forwarded (Dr Arnold Krochmal, 13 Veterans Drive, Asheville, North Carolina 28805).

There will be no charge for this service. Send items (not more than 60 words) to Holly Connell at the London office. The section will include exchanges of accommodation, personal announcements and scientific queries. We reserve the right to decline material submitted. No commercial transactions.

October 13–15, **Electronic and aerospace systems,** Washington DC (The Institute of Electrical and Electronics Engineers Technical Activities Board, 345 East 47th Street, New York, New York 10017).

October 13–17, **Gas cooled reactors,** Jalich, German Federal Republic (IAEA/NEA International Symposium on Gas Cooled Reactors with Emphasis on Advanced Systems, c/o International Atomic Energy Agency, PO Box 590, Kartner Ring 11, A-1011, Vienna, Austria).

October 14–16, **CAMAC in computer applications,** Brussels (Dr H. Meyer, Commission of the European Communities, CRC-CBNM, Steenwegg naar Retie, B-2440 GEEL, Belgium).

October 16–18, **Platinum,** Denver (G. A. Desborough, Convenor US Geological Survey, Building 25, Denver Federal Centre, Denver, Colorado 80225).

October 20–24, **Safeguarding of nuclear materials,** Vienna, Austria (International Atomic Energy Agency, PO Box 590, Kartner Ring 11, A-1011, Vienna).

October 20–24, **Clean air and pollution control,** Brighton (National Society for Clean Air, 136 North Street, Brighton BN1 1RG, UK)

October 22, **Molecular beam–surface interactions,** London (The Meetings Officer, The Institute of Physics, 47 Belgrave Square, London SW1X 80X, UK).

nature

What can scientists contribute to arms control?

ARMS control and disarmament have had an unexpectedly active summer. Not that anybody has actually done anything about controlling arms or putting them out of harm's way, but there has been more public talk than for a long time. *Daedalus* has followed up, fifteen years on, its immensely valuable Fall 1960 issue on arms control with a Summer 1975 issue devoted to "Arms, Defense Policy, and Arms Control." The World Federation of Scientific Workers (WFSW) has recently held a major symposium ("The role of scientists and of their organisations in the struggle for disarmament") in Moscow. And the thirtieth anniversary of Hiroshima has occasioned some thought-provoking events, particularly (on BBC Television) a remarkable interview with Professor Philip Morrison who gave a lucid description of the way things were and the way people thought in those days.

There has been a nice contrast about it all; the harsh realities of Morrison, the populist aspirations in Moscow, the purring sophistications of Cambridge, Massachusetts. But have science and the scientist any future in the field of arms control? The WFSW has no doubt; "scientific workers can provide the ammunition to make the force of public opinion [for ending the arms race] overwhelming". *Daedalus* is less sure: ". . . arms control and disarmament now appear to be politically more complex than they did in 1960, while the technical aspects (of verification and the like) appear somewhat less complicated and perhaps therefore less consequential", writes Franklin Long.

The similarities between atomic weapons and arms control are striking. There was a time when certain key scientists could make direct approaches to politicians and be given a fair hearing for their views on whether and how a bomb should be built. But once government had been told how to do it, a large machine took over and nuclear weapons became no longer a crusade but an industry. So it was with arms control. There was a time when scientists had governments' ears for their views on verification; a black box here, Mr President, a satellite there, two dozen seismometers here. There were heady times, as many will testify, when it really looked as if significant nuclear limitations might have been negotiated on the basis of straightforward technical advice. No longer; the scientists gave what they knew, the machine of state absorbed it and moved on. Even arms control became less of a crusade and more of an industry.

It also became infinitely more complex, of course.

Whereas it used to be possible to talk of banning this or that, it is now necessary to deal in packages; restricting (not banning) this or that, swapping information on space medicine and wheat yields, exchanging works of art, making visas easier to get and so on. The scientist's role as an input of scientific information is a pretty minor one and at least in the nuclear field is likely to remain so.

It has also to be remembered that for every one scientist who sincerely deems it his or her responsibility to speak out in the few forums available (in the UK practically none at all, since the community of intellectuals is otherwise preoccupied) there is at least one other scientist who deems it his or her responsibility to work diligently to keep the nation's defences intact. Thus talk of Hippocratic oaths for scientists to eschew work on projects which might injure or kill humans or calls for scientists to measure up to their social responsibilities might, if taken seriously, lead to holier-than-thou witch-hunts in the scientific community.

If one cannot be optimistic that scientists *per se* have a major role to play in arms control discussions in general, there are perhaps two areas in which they can be particularly effective. The first includes weapons of the twenty-first century (perhaps, in particular, environmental weapons). Since none of these are at the research and development stage yet, there is likely to be a much greater agreement that they should be eschewed. Scientists are notoriously conservative in predicting the future of their subject, but surely if a major international effort were to be devoted to identifying danger areas, it is not inconceivable that an international consensus could be reached on control measures before rather than after the threat was in existence. Second, scientists could make a ruthless examination of the research and development aspects of every proposed arms control measure and ensure the appropriate publicity.

● Research and development is the mainspring of military improvement; beware of any agreement that leaves the laboratories intact.

● The Partial Test Ban Treaty was even used as a justification for the United States to increase its nuclear research and development activities.

● SALT has been a positive encouragement to qualitative improvement of missiles.

Nobody knows this as well as the informed scientist, and it may on occasions even be necessary for apparently benign measures to be opposed.

The East is read

To explore one important facet of the visible tip of the iceberg of Chinese science, S. Dedijer and B. Billgren ask: what was the effect of the Cultural Revolution on Scientia Sinica, *the principal journal of the Chinese Academy of Sciences? How and to what extent has politics caused it to depart from the international scientific tradition?*

AS the chief Academy journal, *Scientia Sinica* occupies a unique position both inside and outside China. Although, as a result of the Cultural Revolution, the journal ceased publication for seven years in 1966, it is in China the standard bearer of science and the most prestigious channel for scientific communication. Abroad it is the official broker of knowledge on the state of China's science and stakes out China's claims amongst world scientific competition. Thus, focusing on this very visible yet little studied face of Chinese science, one learns not only about changes from 1965 to 1974, but gains an insight on the present state of the scientific community in China.

Our basic materials are the four v o l u m e s ((XIV–XVII: 1965–1974) with 28 issues and 405 articles) of the foreign language edition of *Scient. sin ,* identical to the Chinese edition (we compared two 1973 issues of each). To this material we applied a number of simple qualitative and quantitative indicators for the international scientific tradition and its change by politics.

Tradition: (1) the journal as communication channel; (2) absence of politics in articles; (3) structure of the journal; (4) structure of articles; (5) science norms; (6) style; (7) priority protection.

Changes by politics in: (1) editorial policy—including "mass science" and "serve the people"; (2) political content of articles; (3) authorship of articles; (4) research programme in journal; (5) language of articles; (6) institutional changes; (7) origin of references; (8) rapidity of publication.

An analysis of the 405 articles shows that all overt political statements in them can be classified under one of the following categories—

● Mao citation: "Chinese medicine is a great treasure which should be investigated and further developed for the welfare of mankind (quoted twice during 1973).

● Political statements: "Since the founding of New China and under the correct leadership of the Chinese Communist Party" in "Cure of Choriocarcinoma and Chorioadenoma Destruens Chemotherapy" (No. 2, 297; 1973).

● Sentences with overt marxist-maoist orientation: "The correct road of dialectical materialism can be only assured by going deeply into the essence of this problem" in "Crustal Structure and Crustal Movement" (No. 4, 520; 1973).

● Policy Statements: "We are still a developing country. Steps have just been taken to study the aforementioned significant theoretical problems of science" (such as pulsars, quasars and background cosmic radiation), in "Heliocentric Theory in China" (No. 3, 376; 1973).

The political content of articles is measured on a 0, 1, 2 scale: 0 for articles without a single overt political sentence, 1 for one or two such sentences, 2 for more than two.

At the beginning of the Cultural Revolution in 1965–66 there were strong hints in the literature that the publication of scientific journals was anti-revolutionary. The most revolutionary impact of the Revolution on *Scient sci.* was that it ceased publication for almost seven years together with all the other journals, except *Chinese Medicine,* which continued until 1968 in a highly political form. With the renewed publication of the foreign and Chinese editions of *Scient. sin.* (and 19 other journals) in 1973, China returns not only to the 300-year-old international tradition but also to its pre-1949 tradition. For *Scient. sin* is the new name given in 1955 to the Chinese Academy journal *Acta Scientia Sinica* begun in 1952, which in its turn succeeded *Science Record,* the main Academy journal in 1942–45 under Ch'ang Kai Shek's government The editor of that, as well as of *Acta scient. sin.* from 1952 was the Chicago

trained physicist Y. H. Woo, vice-president of the Academy from 1949 until after the Cultural Revolution.

Exactly resembling the corresponding Western academy journals and its Chinese predecessors, *Scient. sci.* throughout its history up to issue No. 2 of 1974 consisted exclusively of articles communicating to the Chinese and the world scientific community the latest research results in "pure science, technology, agriculture and medicine wtih emphasis on basic theoretical research". Several scannings of the 405 articles show that all those in 1965–66 and 74% of those in 1973–74 follow the Chinese and Western tradition: they contain not a single overt political sentence.

All the 405 scientific articles from 1965 to 1974, even those with political content 2, have like their Chinese predecessors the traditional article structure. The title is followed by the name of the author(s), the institution(s), "date received", "abstract", "introduction", followed by the traditional sections "method", "experimental results", depending on the subject. All the articles in *Scient. sin.* close as elsewhere with sections "conclusion" or "discussion", "acknowledgements" and "references".

The fact that following the international tradition all the 1973–74 articles record the date the article arrived on the editor's desk is related —as are all other components of the standard article structure—to specific socia-cognitive components of the research process. This "date received" usage has at least two functions: it stakes a scientist's claim to priority in his field, and it measures the speed of publication. Encouragement of international competition in science and technology has been a constant policy of the Chinese leadership. Mao, Lin Piao, Liu Shao Chi, and Chou En Lai have continuously stressed that "the country will certainly catch up with and surpass advanced world science levels in the not distant future" (*Scient. sin.,* No. 2, 279; 1973). Of the 235 articles in 1965 only one was published within a month of receipt. This was the most significant Chinese contribution to world science since 1949; synthesis of the insulin molecule by a group of 21 authors (*Scient. sin.,* No. 11, 1965). The three articles on the subject in 1973 and the two in 1974 were also published more rapidly than the average waiting time of six months. The only two articles in 1973–74 published within two months of receipt had definite political overtones, both were results of collaboration between an American (of Chinese descent) and a Chinese scientist.

A detailed study of the style and content of articles in 1973–74, even the

most political, shows a consistent effort to be impersonal and objective in style. The authors express themselves with the usual professional researcher's methodological reservations and scepticism. They relate their ideas and results to those of others and to knowledge already confirmed. There is a continuous professional striving toward a scientific approach, results and conclusions. Hence all the articles—even the most political—follow at least three of Merton's "institutional imperatives" of professional ethics of science. The 300 of 405 1973–74 scientific articles with no political statements can be said to follow the fourth, the "disinterestedness" imperative, they contain no explicit statements on the social significance of the reported research either in "serve the people" language or any other.

Only two out of 93 articles in 1973–74 are directly related to the important goal of the Cultural Revolution—"science by the masses". One in 1973 is by a peasant on "Using Chairman Mao's Philosophical Thinking to Guide Scientific Experiment in Peanut Cultivation". The second in 1974 is by a "worker-instructor" on "A Mathematical Analysis of Involute Gear Periodic Errors". Both articles—one with a political content of 2, and the second with 0, follow closely the traditional article structure.

The political content of articles and of the journal are shown in Fig. 1. As seen, there was no politics in 1965–66 articles. During 1973, 56% (24 out of 43) had no political content compared with 86% (43 out of 50) in 1974. From 1973, issue No. 1, the political content of articles decreased continuously and in 1974 it amounted to one or two points per issue. These "political bits" are to be found with few exceptions in the introduction or conclusion sections, and many are repeated in several articles giving the impression of being insertions by the editors.

With No. 2, 1974, two sorts of purely political articles began to appear. The first, at the beginning of each issue are poltical editorials criticising Lin Piao, Confucious and "the theory of innate genius". The second, placed at the end of the issue are philosophical "Studies on History of Natural Sciences". Such articles (Fig. 1) take about 10% of the pages of the journal. Thus it seems that the political bias of purely scientific articles is being replaced by a more pronounced political editorial policy with the double goal of guaranteeing the political correctness of the journal and the ideological education of the readers.

Figure 2 shows some significant changes, probably politically induced, in the articles in 1973–74 as against

Fig 1
X No of articles in given issue cf Sc S with pol points ●

Fig 2   Changes in Sc S

1965–66   :   1973–74
1965–66. From *a* we note a significant decrease of articles by 1, 2 or 3 authors and an increase in collective authorship giving only the name of the institution(s). This may turn to be temporary for it makes difficult the communication a m o n g researchers working on the same subject. Figure 2*b* shows a shift between 1965 and 1973 from the theoretical work in fundamental to non-fundamental sciences. It seems that *c* shows no significant shift in the pattern of institutions performing the work except for the decrease of that in universities. As regards the national origin of references (a total of 3,533 in 1965–66 against 1,242 in 1973–74) we note in a 6.9% decrease of Russian and 5.9% of Western, the latter amounting to 60% of all 1973–74 references. In 1965–66 there were 22 articles in Russian and 9 in French compared with 1 and 2 in 1973–74.

Although our method is relatively simple, it seems to us that a more refined one would not lead to radically different results. We conclude, first, that our results from *Scientia Sinica* do not support such widespread general conclusions by visitors, as for example by A. Peyrefitte, namely, that in the Cultural Revolution "Scientists have been dealt a body blow. The functioning of research has been revolutionised to a degree which is hard to imagine, except, however, for national defence projects".

We find quite the contrary situation. Except for a very significant quantitative decline (312 articles and notes in 18 issues in 18 months of 1965–66 against 93 articles in 8 issues of 24 months of 1973–74) our results indicate that the goals of the Cultural Revolution are not reflected to any significant degree in the 1973–74 *Scientia Sinica*. All our evidence shows that the science China is most proud to show the world is still done entirely by professional scientists, who for their ideas and research problems still turn, as in the rest of the world to national and international science itself and not to the masses. This points to the existence of a scientific community in China which functions by the same traditions, norms and usages as in USSR, USA and Europe. We also note that in the period studied, the Chinese have not made any new innovations in this tradition which are visible in *Scientia Sinica* except for the radical increase of "collective authorship" of dubious value. Consequently we conclude that—with the exceptions noted —the *Scientia Sinica*, has followed in 1973–1974, as throughout its history, the international tradition of science, according to chairman Mao's directive "Make the past serve the present and foreign things serve China".

Barefoot in the field

Though a thorough study of the barefoot doctor system has yet to be carried out, there is no doubt that it represents the first successful, large-scale attempt at the delivery of total health care in a developing country cut off from Western civilisation. Alexander Dorozynski discusses the system by which, in the space of a few years, China has managed single-handedly both to overcome chronic malnutrition and to bring under control most of the epidemic diseases which have plagued it in the past.

THE really significant developments in health care delivery in China have taken place during the past 10 years, since 1965, when Chairman Mao issued the "great call": "in medical and health work, put the stress on the rural areas." The results, although now taken for granted, have been amazing and unequaled anywhere else.

Child mortality has been reduced in a spectacular fashion, and something that seems to be a nationwide family planning programme has been set up. In a truly revolutionary process, the Western 'medical monopoly' has been overturned, yet its achievements have been incorporated into a truly national medical system that has drawn both from the experience of countless generations of traditional practitioners, and from modern science.

The term "barefoot doctor" is now known the world over. It seems that it was first used in the Chiangchen People's Commune on the outskirts of Shanghai in 1965, where a medical team started teaching young farmers to perform some medical tasks. These farmers continued to work in the fields, but also cared for their fellow farmers, who affectionately called them "barefoot doctors". A Chinese delegate at the 27th World Health Assembly has said that since then, about 1 million barefoot doctors, of different levels adapted

to the needs of their community, have been trained in China.

In developing countries, medical doctors tend to congregate in the cities, largely leaving rural areas unattended, with the exception of occasional visits or vaccination campaigns. In China, many mobile medical teams tour the countryside, transporting with them especially designed equipment that allows even major surgery to be performed 'in the field'. They attend to the most serious cases, teach, and give refresher courses to barefoot doctors.

An important aspect of this programme was pointed out at the World Health Assembly by Dr Wang Kuei-chen, a 37-year-old barefoot doctor— "There is no barrier between the doctor and the patient"—white coats, impersonal offices, gleaming instruments and the medical language, all of which often contribute to isolate the patient in the West, play no part in this patient–doctor relationship. Barefoot doctors, she pointed out, are called 'doctors', not paramedicals or auxiliaries; but the relationship is close enough, she said, for her usually to be called "little sister" or "little daughter".

The major concern is with preventive medicine, and this may well be the principal reason of the system's success. Basic preventive medicine, immunisation, health education, well-baby clinics, and surveillance of communicable diseases are enough to cut down radically the incidence of the most common illnesses in rural areas. Labour-intensive techniques have been used effectively against epidemics. For example, millions of schistosomiasis-bearing snails have been picked by hand and destroyed, and there have been similar campaigns against bedbugs, mosquitoes, rats, and flies. As one medical professor has put it: "Each of us, regardless of whether he was a janitor or university president, had to carry around a big fly swatter and a vengeful lust for dead flies. Everyone had his or her quota to fulfil by the end of the week."

This did not exclude curative medicine. The recognition and treatment of diseases such as respiratory infections and diarrhoea, which are among the most widespread causes of infant mortality, is in most cases a simple task, which requires neither a medical degree nor eight years of medical training. In such instances barefoot doctors practise what is referred to as "the New Chinese medicine", an integration of western and traditional procedures including acupuncture, herbal treatment, modern drugs and sometimes relatively complicated surgical procedures such as appendectomies. According to most reports, female barefoot doctors also routinely perform abortions, using the aspiration method. □

international news

THE Atomic Energy Commission (CEA) in France has reached the most important turning point in its history since its creation in 1945. On August 6, in a decision running counter to demands expressed by industrial syndicates that the total nuclear sector be placed under public responsibility, M Valery Giscard d'Estaing approved the separation of the production side of the atomic energy industry in order to form a limited private company, a wholly owned subsidiary of the CEA.

In practice, the Directorate of Production constitutes a homogeneous entity with a wide range of activities, providing the military sector with strategic nuclear equipment and the public sector with all the services required for the fuel cycle—ores, enrichment, fabrication of fuel, treatment of irradiated fuel, storage of waste and so on. With the acceleration of the French nuclear programme, the resources of this department of the CEA have grown rapidly during the past few years, and in 1974 it even managed to defray 59.2% of its own costs. Because of budgetary and human imbalance in this sector as compared with the whole of the CEA, it follows quite naturally that it should become an industrial company.

At the same meeting, President Giscard d'Estaing agreed that the CEA, through the new company, should buy a stake in Framatome, now the sole construction company for nuclear reactor steam generators in France. Since 1973, two companies making nuclear generators have been competing for the French market, Framatome (a multinational corporation, 51% of which is owned by Creusot-Loire, 45% by the American Westinghouse group, and 4% by the Empain-Schneider group) and

Restructuring the French nuclear industry

from the staff of La Recherche

the General Electricity Company (CGE). The former is licensed by Westinghouse to use the pressurised water method. The government, going back on its two-year-old decision to go nuclear, decided at the beginning of the year to slow down the projected generation of nuclear energy. Since then, profiting partly from its former position in the French market and partly from a larger slice of the French industrial cake, Framatome has come through as the sole constructor of nuclear reactors. The government now has to negotiate the purchase of some of the interests of the American company. Although nothing is known about the talks in progress with Westinghouse, it seems that it might be persuaded to keep only an 11–12% stake in Framatome, which would give the CEA a minority block (with veto power) within the company.

Another industrial rearrangement adopted at the August 6 meeting is the setting up of a common structure between Framatome and the two companies making turbo-alternators in France, CGE and CEM (the latter a subsidiary of the German-Swiss group Brown-Boveri). As a result they can offer the world entire nuclear reactors, complete and ready to go.

The official arguments behind the new decisions are clear. The arrangements provide independence from the American license, gallicise the electro-

nuclear industry, create a powerful, competitive company to compete in the world construction market, and provide control over exports.

Industrialy, the arguments are also very clear, but present distinctly divergent points of view, reflecting three main lines of thought. First, in gallicising American technology, and thereby raising France to the rank of a partner, the result will be to make available the multinational Empair-Schneider-Westinghouse group the scientific, technical and financial potential of a public body.

Second, the creation of a production subsidiary actually prolongs the gradual breaking up of the CEA, already initiated several years ago in the field of computing. The government has formed a limited company with state capital from a body which, having obtained resources for 20 years from the public sector, had arrived at a peak as regards work done on the fuel cycle Though the principal client in France will still be the EDF, the French electricity authority, there is no benefit, either technical, industrial or even commercial, in forming this subsidiary company, unless it is derived from a progressive entry into the multinational market and from the involvement of other private groups, in particular of the Pechiney–Ugine Kuhlmann group, which is already a rival in the fuel cycle area.

Finally, the industrial groups view this gradual movement towards the formation of private companies with concern, lest the laws governing profit should impinge on production matters. In a phase of fast industrial development, where considerations of profitability and production predominate, the position of workers will remain at risk.

A DISCOVERY which, if confirmed, would rank as a major milestone in physics and which would upset some of the most sacrosanct physical equations, was reported in the United States last week. Physicists at the University of California at Berkeley and at Houston University believe they have detected a magnetic monopole in the upper atmosphere.

The evidence comes from a track made in a package of plastic sheets and a photographic plate flown from a balloon at 130,000 feet in 1973. The belief is the track was made by a magnetic monopole with a magnetic

charge of 137 and a mass of more than 200 times that of a proton, which was travelling toward the Earth at

Monopole evidence

about half the speed of light.

One of the team, P. Buford Price said last week that "from any piece of our evidence you might conclude a different particle passed through our detector. But all the findings put together force the conclusion that it was

a monopole. There is no other known explanation".

First predicted by Dirac in 1931, magnetic monopoles have been hunted intensively and their possible existence has been hotly debated ever since. Physicists have anticipated confirmation of their existence with mixed feelings, since although they would add symmetry to the world of particle physics—they would be the magnetic equivalent of electrons and protons—their existence is incompatible with the Maxwell's equations, which have stood since 1865 as the basic equations of electromagnetism.

THE success of the Ariel-5 satellite has produced an unfortunate outburst of parochialism in some sections of the British press, with comments such as "Britain leads the world in X-ray astronomy" and "most discoveries are British" recurring among reports of the latest discovery. This may be true at the present moment, since the US Uhuru satellite is no longer effective, plans for a European X-ray astronomy satellite have yet to be finalised and clearly the UK national press finds the Netherlands too small to notice. But the reaction is a particularly unfortunate one in view of the great importance of international cooperation in X-ray astronomy, and the great success of that cooperation so far.

Data from the pioneering Uhuru satellite, for example, were made widely available outside the circle of US experimenters directly concerned with its design and operation; the widely publicised Copernicus satellite combines both US ultraviolet telescopes and UK X-ray detectors: and indeed Ariel-5 itself carries a US experiment, and was, come to that, launched by a US rocket. The series of letters beginning on page 628 of this issue gives some idea of the extent of international cooperation in this sophisticated area of research; an even better indication is provided by the four letters on pages 107–112 of this volume, in which groups from three countries using observations from four satellites and from the ground combine to describe a change in the X-ray and radio emission from the source Cygnus X-1.

Of course there is an air of friendly rivalry between the different groups, especially in the urge to publish observations of an exciting new discovery first; but everyone involved in X-ray

Astronomy in Britain

astronomy is well aware of the need to make the best use of the limited funds available. This will not be achieved if we move towards a situation where the rivalry becomes real and deep, with data being hugged close to the chests of the discoverers while they indulge in mutual claims that "my satellite is better than yours". It is to be hoped that the discoverers of exciting new phenomena in space will in future, when they announce how remarkably clever they have been to find anything at all, encourage the listening reporters to present a balanced view of the remarkably succesful international collaboration behind the whole story. To many people, it is more significant to learn that scientists from different parochial groups can work together in effective harmony than to learn that something has been discovered and that no one quite knows what it is, but at

least it was a British discovery.

● Minor Planet Circular 3827 of the International Astronomical Union announces the names accorded to a number of Minor Planets discovered by Dr L. Kohoutek with the 80-cm Schmidt Camera of the Hamburg Observatory, Bergedorf. A singularly appropriate one is MP 1896, named Beer, in honour of Dr Arthur Beer, formerly of the Cambridge Observatories, who recently celebrated his 75th birthday. The citation refers particularly to his 20 year editorship of the series *Vistas in Astronomy,* first produced in 1955 in honour of Professor F. J. M. Stratton, but continued as a serial publication that is highly regarded by astronomers for the wide ranging nature of its articles, essays and reviews. Dr Beer joins the small number of astronomers in England with a planet named after them in their lifetime—others were Stratton, and Dr G. Merton of Oxford.

The same Circular names planets 1897–1899 after J. R. Hind, the English astronomer who discovered 10 minor planets in the middle of last century, and after P. H. Cowell and A C Crommelin, distinguished in this century for their contributions to computational methods in minor planet and comet theory. Together they investigated the orbit of Halley's comet and identified its apparitions back to 239 BC.

UNDER a new agreement between the United States and Israel a water desalination project likely to cost $55 million has just been started. A test module is to be built at the Mediterranean port of Ashdod, about 40 km south of Tel-Aviv, to be followed by a prototype plant with a desalting capacity of 10 million gallons a day, linked with the local Eshkol power plant. America's contribution will amount to $20 million.

American interest in Israeli desalination has a long history. Section 219 of the Foreign Aid Bill approved by Congress in 1969 provided for the joint participation of the U.S. government and the State of Israel in the development of a large desalination plant, including the construction of a prototype for such a plant and its test operation. For this the sum of $20 million dollars was allotted by Congress.

In February 1971 the Israeli National Council for Research and Development (NCRD) presented to the US, on behalf of the Israeli government a detailed draft of a proposed Multi-Effect Distillation process (MED), developed by Israel Desalination Engineering Ltd (IDE), and backed by NCRD since 1970 as

Israel and US in water deal

from Kapai Pines, Jerusalem

probably the best desalination system in the world.

In November 1972 a memorandum of understanding was signed between both governments to construct an MED prototype plant at Ashdod, and on May 13 this year the US Secretary of the Treasury and the Israeli Minister of Finance signed a joint statement in Washington while meeting at a US–Israel Joint Committee for Investment and Trade. They said that the proposed joint water desalination project had undergone a lengthy period of evaluation, and they agreed that it was now feasible to proceed with the arrangements for the design, construction and initial operation of a large-scale prototype plant and to negotiate a technical agreement subject to the necessary consultations with Congress. Subsequently, a US technical mission came to Israel, and on May 21 a joint agreement was negotiated between the two countries to carry out the project.

A small MED pilot-plant inaug-

urated near Eilat in June last year, produces about 1 million gallons of potable water per day. This water is integrated into the regular water supply system of Eilat, and the technology of this plant forms the basis for the proposed large-scale plant in which the Americans are interested. The new distillation process is said to cut the cost of desalted water from 60 American cents per 1,000 gallons in other distilling processes to less than 24 cents. One of the distinguishing advantages of the IDE process is that it can efficiently employ low-pressure, low-temperature steam, while other distillation processes require higher temperatures for efficient operation Furthermore, the overall process is characterised by maximum energy recovery and minimal waste.

Another distinguishing feature resulting in economic advantage involves the use of aluminium tubing rather than copper in the fabrication of heat exchangers. The use of the aluminium is made possible by the relatively low temperature of the process, and also results in a substantial savings, since heat exchangers comprise a major cost-element in plant construction.   □

Tumour virus proteins at the cell surface

from Reinhard Kurth

THE enveloped RNA-containing viruses are oncogenic for a wide variety of species, of which the avian, murine and feline systems have received considerable attention. Following the discovery that these viruses replicate by reverse transcription by way of a DNA provirus (Baltimore, *Nature*, **226**, 1209, 1970; Temin and Mizutani, *Nature*, **226**, 1211; 1970), it was shown by nucleic acid hybridisation that all cells of the species tested contained chromosomally integrated provirus information. Depending on the genetic background of the host, the interaction between endogenous virus and host cell can lead to different states of virus expression, ranging from complete repression, partial expression of some virus polypeptides (VPP) to complete particle production. Silent endogenous viruses can often be activated by (mis-) treating cells with chemical or physical agents (Lowry *et al.,* *Science,* **174**, 155; 1971; Aaronson *et al.,* *Science,* **174**, 157; 1971). The question why these and possibly all animals (and humans?) harbour endogenous virus genomes is a mystery, which may now be gradually resolved.

If endogenous virus genomes were consistently silent with no potentially harmful effects, it would be understandable that no selective evolutionary pressure has operated against them. As mentioned above, this does not seem to be the case: provirus information can be translated into VPP. Gross obtained evidence a long time ago that a vertically transmitted and *in vivo* activated murine leukaemia virus was indeed oncogenic (*Proc. Soc. exp. Biol. Med.,* **76**, 27; 1951). Recent work by Aaronson's group seems to indicate also that *in vitro* activated endogenous viruses can be oncogenic (Stephenson *et al*, *J. Virol.,* **13**, 237; 1974; Greenberger *et al., Cancer Res.,* **35**, 245; 1975). Why then has natural selection failed to eliminate this information from the cell?

The answer could lie in some new data which indicate that endogenous viral information may also become activated *in vivo* under specific and so far little characterised circumstances to play a part in differentiation and/or in the prevention of oncogenesis by exogenous oncorna viruses. In such

specific instances, the expression of endogenous viral information may confer a selective advantage for the host.

Progress in the understanding of virus–host cell interactions has advanced with the isolation of the major structural VPP (see table). The individual VPP are biochemically and immunologically distinct, the only cross-antigenicity existing between the glycosylated envelope proteins of a given virus strain. On the other hand (glyco-) proteins of the same size are biochemically very similar and cross-antigenic for virus strains of the same or related species. They exhibit both group-specific and interspecies-specific antigenic determinants in addition to their distinct virus type-specific antigens (reviewed recently by Bauer, *Adv. Cancer Res.,* **20**, 275; 1974).

Plasma membrane of tumour cells

For the sake of this discussion, it is necessary to distinguish between VPP inserted into the surface membranes of uninfected and of oncorna virus-infected cells. For more than a decade it has been known that virus envelope glycoproteins (gp85 or gp69/71) are often inserted into the membranes of oncornavirus-infected cells, which is not too surprising as these viruses bud from the host cell membrane. What is unexpected, however, is the more recent finding that p30, the major structural internal protein of oncornavirus particles, can also become inserted into the plasma membranes of exogenously infected cells (Ferrer, *Int. J. Cancer,* **12**, 378; 1973; Yoshiki *et al., Proc. natn. Acad. Sci. U.S.A.,* **70**, 1878; 1973; and *J. exp. Med.,* **139**, 925; 1974). These first observations have now been confirmed and extended by several other laboratories to show that in addition to the large envelope glycoproteins, p30, as well as the small VPP p15, p12

and p10 can be expressed either alone or in different combinations on the surfaces of a wide variety of tumour cells (Friedman *et al., J. Virol.,* **14**, 1126; 1974; Ikeda *et al., J. Virol.,* **14**, 1274; 1974; Billelo *et al., Proc. natn. Acad. Sci. U.S.A.,* **71**, 3234; 1974; Moroni *et al., Intervirology,* **3**, 292; 1974; Knight *et al., Int. J. Cancer,* **15**, 417; 1975; Del Villano *et al., J. exp. Med.,* **141**, 188; 1975; Hunsmann *et al., Virology,* in the press; Schwarz *et al., Virology,* in the press).

Furthermore, some chemically induced mouse tumours can express gp69/71 and low levels of p30, p15, p12, and p10 at their surface (Grant *et al., Proc. natn. Acad. Sci. U.S.A.,* **71**, 5037; 1974; Ikeda *et al., J Virol.* **14**, 1274; 1974; Yoshiki *et al., J. exp. Med.* **139**, 925; 1974). In these instances the VPP must be coded by activated provirus. These observations extend earlier data on endogenous virus activation by physical and chemical agents (reviewed by Todaro, *Persp. Virol.* **8**, 81; 1972).

On the other hand, transformation events do not always lead to the insertion of viral products into the plasma membrane (Rapp *et al., Virology,* **65**, 392; 1975) and we know little about what (genetic) factors determine the transformed phenotype. Qualitatively similar results have also been obtained in the feline (Yoshiki *et al., J. exp. Med.* **139**, 925; 1974; Ikeda *et al., J. Virol .,* **14**, 1274; 1974; Essex, personal communication) and the avian (Kurth and Bolognesi, unpublished) oncornavirus models.

Plasma membrane of normal cells

The detection of non-glycosylated VPP on the transformed cell surface cannot easily be explained. Why are they there? What is their function, if any?

Major structural polypeptides of oncornaviruses							
Species		Virus polypeptides (VPP)					
Avian*	gp85‡	gp37	p27§	p19	p15	p12	p10
Murine*	gp69/71	gp45	p30	p19	p15	p12	p10
Feline†	gp100　gp70		p30	p21	p15	p11	p10

*,† Data from: *August, Bolognesi, Fleissner, Gilden, and Nowinski, *Virology,* **60**, 595; 1974. †Essex, *Adv. Cancer Res.,* **21**, in the press.
‡gp85 = glycoprotein of molecular weight 85,000.
§p27 = non-glycosylated protein of molecular weight 27,000.

The attempt to find a general explanation is further complicated by the recent discovery that certain normal, uninfected cells also synthesise VPP which are expressed in their plasma membrane.

Experiments with tumour cells and monospecific sera directed against individual VPP have often given background reactions with normal mouse, rat, cat or chicken fibroblasts (Grant, Ikeda, Yoshiki, cited above; Hunsmann *et al., Virology,* in the press; Schwarz *et al., Virology,* in the press; Kurth and Bolognesi, unpublished; Hogg, personal communication). Some groups decided to neglect the normally weak antiserum reactivities by preabsorbing their sera on normal fibroblasts. This approach may be justified, as the purified VPP used for immunisation may have been slightly contaminated with normal cellular material. It is, however, just as conceivable that normal fibroblasts express some VPP, perhaps in a form structurally modified by the host cell. Data obtained in the avian oncornavirus system seem to support the latter interpretation; gp85 and p27 seem to be present in comparatively high quantities in the membranes of most if not all uninfected chicken fibroblasts derived from embryos of various flocks (Smart, Bosch, Kurth and Bolognesi, unpublished).

A role in differentiation?

It is not surprising that normal lymphoid tissue from high leukaemia mouse strains express gp69/71 and p30 in their membranes (Yoshiki *et al, Proc. natn. Acad. Sci. U S.A.* **70,** 1878; 1973; Kennel *et al., Virology,* **55,** 464; 1975; Del Villano *et al., J. exp. Med.* **141,** 172; 1975), as these cells might be considered premalignant. Less expected, however, are the recent results obtained by the virologists of the Scripps Clinic: they now find gp69/71 not only on mouse lymphoid cells, but also on certain foetal and adult tissues, notably epithelial cells (Lerner, Wilson, Del Villano, McConahey and Dixon, unpublished). The data indicate that the membrane expression of endogenous VPP might follow a precise pattern with respect to tissue distribution and kinetics of appearance/disappearance. It has been suggested repeatedly for various animal model systems that morphogenesis and subsequently the maintenance of a differentiated state could be mediated (among other factors) by cell surface receptors (for reviews see *Humoral Control of Growth and Differentiation,* Academic Press, New York, 1973). If endogenous VPP are indeed among those receptors possessing a transmitter function in the exchange of information between cell and environment,

they would have a role in the induction and maintenance of established morphogenetic patterns. Such a role could explain the positive selective advantage in having potentially oncogenic endogenous virus genomes integrated into the cellular genome.

At this point, one is left with a complex situation. On one hand, VPP coded by endogenous or exogenous oncornaviruses can become expressed on the transformed cell surface and could therefore be considered as tumour-specific antigens. On the other hand, certain normal tissues also seem to express endogenous membrane VPP. The picture is further complicated by the concomitant presence of natural antibodies directed against endogenous VPP (Hanna *et al., Cancer Res.* **32,** 2226; 1972; Ihle *et al , J. exp. Med.* **138,** 194; 1973 and *J. exp. Med.* **139,** 1568; 1974; Lee *et al., J Virol* **14,** 773; 1974; Aaronson and Stephenson. *Proc. natn. Acad. Sci. U.S.A.* **71,** 1957; 1974). This situation is reminiscent of tumour-bearing animals in which tumours and their specific antigens coexist with anti-tumour antibodies and lymphocytes.

Anti-tumour response

Could VPP on tumour cells be used as tools in vaccination or immunotherapy? This seems unlikely as immunisation with isolated VPP could greatly enhance the risk of autoimmune diseases or glomerulonephritis. In fact, Hanna and coworkers (*Cancer Res.* **32,** 2226; 1972; *J. natn. Cancer Inst.* **52,** 117; 1974) have described a correlation between the development of glomerulonephritis and the persistence of high titres of natural antibodies.

In contrast, there are experimental situations in which the anti-tumour response is clearly mediated by VPP located in the transformed cell surface (Knight, Mitchison and Shellam, *Int. J. Cancer,* **15,** 417; 1975; Gorczynski and Knight, *Br. J Cancer,* **31,** 387; 1975) or in which immunisation with exogenous gp69/71 leads to significant anti-tumour protection (Hunsmann, Moenning, and Schäfer, *Virology,* in the press). A comparison of the antigenic determinants accessible to antibodies on the cell surface (not necessarily of the VPP molecules in the cell membrane) with antigenic sites in the viral particle may resolve these discrepancies. There is preliminary evidence that endogenous VPP in the cell membrane may have undergone somatic cell modification (Del Villano *et al., J. exp. Med.* **141,** 172; 1975; Tung *et al., J. exp. Med.* **141,** 198; 1975). Thus it may turn out that the anti-tumour response is (predominantly) directed against antigenic sites restricted to exogenous VPP of the

transforming virus which are not concomitantly expressed by endogenous membrane VPP in normal cells For both theoretical and practical reasons, this problem deserves further clarification.

Control of VPP expression

A final question concerns the control of endogenous virus expression, especially in differentiating tissue. There are at least two model systems where this question can be studied further. First, recent work from Boyse's laboratory at the Memorial Sloan–Kettering Cancer Center proved convincingly that the G_{IX} antigen on normal thymocytes of certain mouse strains (Stockert, Old and Boyse, *J. exp. Med.* **133,** 1334; 1971) is biochemically and immunologically related and possibly even identical to Gross leukaemia virus gp69/71 (Obata *et al., J. exp. Med.* **141,** 188, 1975; Tung *et al., J exp. Med.* **141,** 198, 1975). The second model exists in the avian system, where the helper activity of normal chicken fibroblasts to complement the defective Bryan high titre strain appears to be correlated with the synthesis of a chicken helper factor thought to be gp85 (Payne and Chubb, *J. gen. Virol* **3,** 379; 1968; Weiss and Payne, *Virology,* **45,** 508; 1971).

In general, the membrane insertion of individual VPP seems to be a non-coordinate event; different combinations of VPP have been detected on normal and transformed cells. Their expression appears to be governed by autosomal dominant genes (Strand, Lily and August, *Proc natn Acad. Sci. U.S.A.* **71,** 3682; 1974), just as in the G_{IX} and chicken helper factor models. (For recent reviews see Lilly and Pincus, *Adv. Cancer Res.* **17,** 231; 1973; Weiss, *Persp. Virology,* **9,** 165; 1975.)

It has been a drawback for progress in cell surface immunology, including tumour immunology, that many of the groups involved were predominantly occupied with the mere description of the distribution of cell surface moieties. Very few attempts have been made to investigate their function, for example with respect to enzymatic activities or transport processes. Since it is now possible to purify endogenous or exogenous VPP in milligram quantities, one may soon be able to test them for possible functions which may explain their cell surface location Additional data on the distribution of endogenous VPP in different organs and the kinetics of their appearance and disappearance in differentiating tissues may establish further associations between the expression of a virus-related phenotype and the process of cellular differentiation. □

More RNAs for oocytes

from Pamela Hamlyn

ALTHOUGH *Xenopus laevis* oocytes are interesting in themselves as a means of studying gene action, their more familiar role is that of an assay system for the translation of injected messenger RNAs. They have many advantages for this purpose, not least their ready availability—several thousand mature oocytes from one adult female. (Compare this with scanning the shelves of health food shops for just the right wheat germ.) Injected messenger RNA is translated with a high efficiency, globin mRNA being translated at nearly the same rate as in intact reticulocytes. Because of this very high efficiency only minute amounts of mRNA are required to produce detectable amounts of protein product and consequently mRNA activity can be detected even when crude RNA fractions containing very little mRNA are injected into oocytes.

van der Donk made use of this property in some experiments that are reported in this issue of *Nature*, **256**, 674; 1975). He is interested in the mechanism by which the style of *Petunia hybrida* is able to recognise and to differentiate between its own pollen and that of another plant. (Pollen tubes only grow after cross-pollination.) Total RNA extracted from self-pollinated styles stimulated

A hundred years ago

AMONGST the objects which have been recently added to the galleries of the Paris Industrial Exhibition of Geography, and are attracting public notice, we may mention a collection of French birds exhibited by M. Bouvier, the collection of apes from the Gaboon, by the Marquis de Compiègne, and a number of antediluvian fossils from the Mentone Caves. The skeletons of two children which had been buried together are in a splendid state of preservation, exhibiting admirably the characteristics of prehistoric cave-life. These two young people were buried in the home of their parents, very probably because it was the only means of defending their bones against the teeth of ferocious hyænas and other large carnivorous animals which were disputing with man the empire of the future Gaul.

from *Nature*, **12**, 358; August 26, 1875.

protein synthesis (by about three times) when injected into *X. laevis* oocytes. A fractionation of the RNA according to molecular weight showed that it was the RNA between 5S and 18S that gave the biggest stimulation. But stimulation of protein synthesis is completely inadequate as proof that the injected RNA is being translated. Stimulation of endogenous protein synthesis cannot be ruled out as an explanation unless the protein for which the injected messenger codes is shown to be synthesised in the oocytes. The endogenous protein synthesis in the oocyte is higher than in some cell-free systems. In spite of this disadvantage van der Donk was able to demonstrate the appearance of several new protein bands on gel electrophoresis of proteins synthesised in oocytes injected with plant RNA. Nonetheless it could be argued that these bands were oocyte protein whose *de novo* synthesis was stimulated by the plant RNA. To identify them as plant proteins van der Donk has attempted to demonstrate their function in the inhibition of pollen tube growth. Protein can be isolated from styles after self-pollination which, when transferred to a style that has been cross-pollinated, will inhibit the growth of pollen tubes in that style. Therefore a solution of proteins synthesised in oocytes in the presence and absence of RNA isolated from self-pollinated styles was applied to styles that had been cross-pollinated. Only the proteins synthesised in the presence of the plant RNA were able to inhibit the growth of the pollen tube. Van der Donk takes this as a clear demonstration that at least part of the proteins translated from plant RNA are those involved in the incompatibility reaction (the inhibition of pollen tube growth), and that by partially isolating the RNA coding for these proteins a further step has been made in the elucidation of the intriguing mechanism by which a plant distinguishes between self and non-self.

Gurdon and his colleagues have demonstrated the very long life—up to 10 days—of globin mRNA after injection into oocytes (Gurdon, Lingrel and Marbaix, *J. molec. Biol.*, **80**, 539; 1973). Allende and coworkers reasoned that this must be because oocytes contained a very low level of ribonuclease activity or else the RNA was protected in some way from degradation (Allende, Allende and Firtel, *Cell*, **2**, 189; 1974). To distinguish between these two possibilities they injected a variety of radioactive natural and synthetic RNAs into oocytes and followed their degradation with time. They were able to show that some RNAs were degraded and others were not, and concluded that the oocytes contained enough ribonuclease activity to degrade

injected RNAs so that those remaining must be protected in some way. They next focused their attention on yeast tRNA—one of the species that survived undegraded in oocytes even after 20 h. In this issue of *Nature* they report their demonstration that oocytes are capable of aminoacylating yeast tRNAs injected into cells even at final concentrations which were much greater than that of their endogenous tRNA content (page 675). They showed that oocytes can be injected with tRNA for phenylalanine to a final concentration in the cell 500 times the normal concentration—acylation taking place so that there is 150 times as much Phe-tRNA as normal. The authors plan to study the effects of this imbalance on the mechanism of protein synthesis.

Nuclear spectroscopy

from P. E. Hodgson

IN a nuclear transfer reaction angular momentum is conserved vectorially, so that the spin of the final state of the residual nucleus $J_R = J_T + j$, where J_T is the spin of the ground state of the initial (or target) nucleus and j the angular momentum of the transferred nucleon. This j is itself composed of its orbital and spin angular momenta, $j = l + \frac{1}{2}$. The angular distribution of the outgoing particle, for example that of a proton in a (d,p) reaction, is usually characteristic of the orbital angular momentum transfer l, and thus l can be determined. Since J_T is known, this suffices to set limits on J_R and to determine it in some special cases.

For example, if $J_T = 0$, $J_R = j = l + \frac{1}{2}$, so that $J_R = l \pm \frac{1}{2}$. So if $l = 2$, the final state is $d_{3/2}$ or $d_{5/2}$. This ambiguity may be resolved either by rather difficult measurements of the polarisation of the outgoing particle, or by careful examination of some special features of the differential cross sections (*Nature*, **250**, 464; 1974; **253**, 501; 1975).

The situation is more complicated if J_T is greater than zero, for then several values of j may be possible in reactions to states of the same J_R. Thus if $J_T = \frac{1}{2}$, $J_R = 1$, and $l = 1$, then j can be $\frac{1}{2}$ or 3/2. It is an interesting problem to determine j, for if this can be done we can learn more about the reaction and also use such reactions to determine J_R in cases where it is not known. Furthermore, j has to be known in order to apply the j-dependent sum rules to determine nuclear spectroscopic factors (*Nature*, **249**, 695; 1974).

Some years ago Kocher and Haeberli (*Phys. Rev. Lett.*, **23**, 315; 1969) showed that the vector analysing power in one-nucleon transfer reactions is

sensitive to the value of j and thus provides a good way of determining it. They obtained the vector analysing power from the left-right asymmetry of the protons emitted from a reaction initiated by a polarised beam of particles. The $j=\frac{1}{2}^-$ reactions ^{52}Cr(d,p)^{53}Cr ($Q=5.17$ MeV) and ^{54}Fe(d,p)^{55}Fe ($Q=6.60$ MeV) at 10 MeV had vector analysing powers quite different from the $j=3/2^-$ reactions ^{52}Cr(d,p)^{53}Cr ($Q=5.73$ MeV) and ^{54}Fe(d,p)^{55}Fe ($Q=7.01$ MeV) at 10 MeV. In the mixed-j reaction ^{53}Cr(d,p)^{54}Cr ($Q=6.71$ MeV) at 10 MeV, both these values of j were possible, and the vector analysing power closely followed a curve obtained by adding together in definite proportions the vector analysing powers found in the other two reactions. This proportion gave the relative contributions of the $j=\frac{1}{2}$ and $j=3/2$ components to the reaction. The technique of finding the mixing parameter in mixed-j transitions has the special advantage of being independent of detailed theoretical calculations, but is somewhat laborious to apply in practice.

A new method of finding the j value has recently been proposed by Dohan and Summers-Gill (*Nuclear Phys.*, **A241**, 61; 1975), and applied to the ^{69}Gd(d,p)^{70}Gd and ^{71}Gd(d,t)^{70}Gd reactions to the same state of ^{70}Gd. It depends on the fact that, on the simple shell model, the $2p_{1/2}$ neutron state is empty in ^{69}Gd, half-full (containing one neutron) in ^{70}Gd and full in ^{71}Gd. Thus the (d,p) and (d,t) reactions on ^{69}Gd and ^{71}Gd respectively go equally well, and thus have very similar spectroscopic factors. The $2p_{3/2}$ state, on the other hand, is full for all these nuclei, so the (d,p) reaction on ^{69}Gd is forbidden, as there is no room for another neutron, while the (d,t) reaction on ^{71}Gd takes place easily as there are plenty of $2p_{3/2}$ neutrons to be removed. This picture is expected to be somewhat blurred as the simple shell model is not followed exactly, but nevertheless we expect to find very similar amplitudes for $2p_{1/2}$ transfer and very different amplitudes for $2p_{3/2}$ transfer in the two reactions.

In practice these expectations are remarkably well fulfilled. The transitions to the lower states up to about 1 MeV have almost the same amplitudes for the two types of reaction while those above 1 MeV have very small amplitudes for the (d,p) reaction and large amplitudes for the (d,t) reaction. Thus we can with some confidence assign the first group to $2p_{1/2}$ transfer and the second group to $2p_{3/2}$ transfer. This is a very simple and direct way of determining the j value of the transferred particle, and is applicable to reactions where the sub-shell corresponding to one j value is filling more rapidly than the other. It

will be interesting to see how far it can be extended.

In heavy ion reactions the situation is more complicated since the transferred particle can have an angular momentum greater than zero in the projectile. Thus the neutron in the deuteron has $l=0$, whereas the proton in ^{7}Li that is transferred by the (^{7}Li,^{6}He) reaction has $l=1$, $j=3/2$ as it comes from an $p_{3/2}$ orbit in ^{7}Li (*Nature*, **253**, 501; 1975).

Sticky actin

from Dennis Bray

MUSCLE biochemistry is not usually the place to look for the bizarre; but what else could one call an association between muscle actin and an enzyme that digests DNA? The story is a curious one. As long ago as 1943, it was found that pigeon thymus contains a protein that inhibits deoxyribonuclease I—the abundant endonuclease of pancreas. This activity was found in other tissues but little else was learnt about its biochemistry until the late 60s when Lindberg—at the Karolinska Institute, Stockholm—began a careful study. He found that the inhibitor had a molecular weight close to 42,000; that it could be purified and even crystallised by conventional procedures; and that it formed a tight 1 : 1 complex with the nuclease. Among its notable characteristics, at least in retrospect, was its abundance in tissue (5–10% of the protein in a soluble extract), and its tendency to form aggregates of high molecular weight.

Then last year, at Cold Spring Harbor, New York, Lazarides and others interested in cell motility heard at first-hand of the DNase inhibitor. They also had a protein with molecular weight close to 42,000 which was strangely abundant in cells: only they called it actin. The amino acid compositions of the two proteins were encouragingly similar and the unlikely possibility was put to the test. Sure enough, the fingerprints of the two are the same, they cross react immunologically, and analytical-grade muscle actin sticks so tightly to DNase I that denaturing agents are needed to part them (Lazarides and Lindberg, *Proc. natn. Acad. Sci. U.S.A.*, **71**, 4742; 1974).

The interaction is unquestionably real but why does it occur? It is unlikely to be accidental because the binding is so tight. It may have some purpose, but it links two cellular processes that are normally considered to be independent. The puzzle is compounded by indications that actin forms other unexpected associations. Before the work mentioned above, Laki and Muszbek (*Biochim. biophys. Acta.*,

371, 519, 1974), had shown that actin in its filamentous form binds strongly to fibrin—the major structural protein of blood clots. And a recent paper examines the long known association between glycolytic enzymes, such as aldolase and triose phosphate dehydrogenase, and filamentous actin (Clark and Masters, *Biochim. biophys. Acta.*, **381**, 37; 1975). Still only in abstract form are claims that an interaction exists between actin and spectrin, the major protein of red blood cell ghosts (Tilney, *J. Cell Biol.*, **63**, 349a; 1974); and another report that actin might be identical to the γ-subunit of dogfish muscle phosphorylase (Fischer *et al*, *Hoppe-Seylers Z. Sür Physiol. Chem.*, **356**, 381; 1975)

If we consider the proteins that associate with thin filaments in muscle —troponin, tropomyosin, myosin and actinin—then we have ten or so that all bind to actin. The list might well be longer, for any club that includes both deoxyribonuclease and myosin must surely have a wide membership. It begins to look as though we are in the presence of a Phenomenon; but what it might mean is hard to say. Either actin is generally sticky and able to adhere to proteins it does not normally encounter, or many proteins have evolved binding sites that hitch them to this abundant and phylogenetically stable component of the cell

Evolution of *E. coli* chromosome

from Millicent Masters

IT has been possible to observe the intact chromosome of about half-a-dozen species of bacteria. In each species the DNA was found to be a closed circle. The circular chromosome of the best studied species of bacterium, *Escherichia coli*, contains enough DNA to code for about 3,000 average-sized polypeptide chains. Specific functions have been assigned to about 500 of these genes and the well developed genetics of *E. coli* has permitted their positions on the chromosome to be determined. Genes specifying proteins with related functions such as isoenzymes catalysing the same reaction or groups of enzymes involved in sequential metabolic conversions may be either close together or distant on the circular chromosome. Some related genes are close together because they are transcribed together (that is, they form an operon). Other related genes however are close together without sharing such a common control mechanism. Still other related genes, such as the five genes concerned with pyrimidine synthesis or seven of the 11 genes responsible for arginine biosyn-

thesis, occupy widely disparate locations on the chromosome.

David Zipkas and Monica Riley in a recently published article (*Proc. natn. Acad. Sci. U.S.A.*, **72**, 1354; 1975) have examined the locations of 125 genes, each of which was judged to be biochemically related to at least one other gene among the 125. With the help of a computer they analysed the distances between all pairs of genes and between all those pairs judged to specify biochemically related functions. They found that pairs of related genes were not placed randomly relative to one another but, rather, that they were almost twice as likely to be located 90° or 180° apart than might be expected by chance. To explain this remarkable observation the authors propose that the chromosome of *E. coli* is the product of two successive duplications of a primitive genome which was one quarter the size of the present-day chromosome. This event, postulated of course to have occurred a very long time ago, would have resulted in a tetrameric structure with each gene present four times at 0°, 90°, 180° and 270° positions.

In support of this idea they cite Wallace and Morowitz (*Chromosoma*, **40**, 121; 1973). These authors tabulated the genome sizes of about 70 species of bacterium and found that the sizes, which vary from about 0.5 to 3.0×10^9 daltons, do not vary continuously. *Mycoplasma* species have chromosome sizes of either 0.5×10^9 or 1.0×10^9 daltons. The other species recorded have genome sizes clustered around peaks at 1.4×10^9 and 2.8×10^9 daltons. These provocative data are consistent with the idea that smaller genomes have given rise to larger ones by a process of genome duplication.

Zipkas and Riley further propose that the dimeric or tetrameric products of genome duplication evolved to their present forms by mutation of, and divergence in function among, the duplicate gene copies. For example, duplicate copies of an ancestral gene, concerned with tryptophan metabolism could have evolved differently to yield in one case the gene for the tryptophan synthetase B protein and, 180° distant from it, the gene for tryptophanase. Both of these proteins can catalyse the conversion of indole and serine into tryptophan. Other cases however are more difficult to explain. The genes *arg* F and *arg* I which are neither 90° nor 180° apart both specify an ornithine transcarbamylase. Zipkas and Riley suggest that, although they specify proteins that carry out the same reaction, these two genes may have had independent origins (and as a consequence might be expected to have different sequences). Recent work, however, by Kikuchi and Gorini (reported at the

Fifth International Conference on the Biology of Temperate Bacteriophage, 1975) showing that the *arg* I and *arg* F genes have similar base sequences is inconsistent with this idea, and suggests that one of the genes arose by duplication of the other. Thus Zipkas's and Riley's suggestion that functionally related genes not 90° or 180° apart evolved independently is proved invalid in the one case where information on sequence homology is available.

It will obviously be difficult to either prove or invalidate the theory of Zipkas and Riley concerning the origin of the *E. coli* chromosome. Further information regarding sequence homology to support the necessarily somewhat arbitrary assignment of functional relationships will certainly be necessary. None the less, whatever the outcome of such studies, their provocative observation will remain to be explained.

Mitochondria and chloroplasts

from John Ellis

A pre-FEBS symposium on "The Structure, Synthesis and Functions of Nucleic Acids in Organelles" was held in Paris on July 19.

WITHIN the next year the complete genetic map of yeast mitochondrial DNA should be known. This bold prediction was made by P. Borst (Amsterdam University) whose optimism was generated by two recent technical advances. The first is the availability of restriction endonucleases, bacterial enzymes which cleave double-stranded DNA at specific base sequences into defined fragments which can be separated by gel electrophoresis. Hybridisation of the fragments with mitochondrial ribosomal RNA has revealed that the two ribosomal cistrons in yeast are not linked as they are in bacteria, but are located on opposite sides of the circular mitochondrial genome. This is not a constant feature of the mitochondrial genome however, since I. B. Dawid (Carnegie Institution, Baltimore) showed that the two cistrons are separated by a spacer region of only 120 base pairs in the mitochondrial genome of *Xenopus*, HeLa, and *Drosophila*.

The second advance is the production of a new class of mutations in the mitochondrial genome. P. Slonimiski (Gif-sur-Yvette) pointed out that, with the exception of mutations that confer resistance to antibiotics, most mutations in the yeast mitochondrial genome were of the so-called *rho* minus type where

large deletions of the mitochondrial DNA have occurred. In such mutants the protein-synthetic system of the mitochondria is not functional, and so no genetic mapping is possible. What is needed is a class of point mutations where proteins continue to be made but which lack specific enzymic activities. Recombination between such structural gene mutations should restore wild-type mitochondria and hence permit genetic mapping. Slonimiski reported the isolation of 120 such *mit* minus mutants; some confer normal cytochrome spectra but have no cytochrome activity, whereas others give abnormal spectra. Mapping to a resolution of 30–50 base pairs is in progress. It would be a mistake to think that there is a universal mitochondrial map however; Dawid pointed out that the mitochondrial DNA of sheep and goats differs by 80% in base sequence, thus lending substance to an old parable.

Restriction enzymes have also been used to study the DNA of the kinetoplast, an organelle related to the mitochondrion, and characteristic of trypanosomes and related protozoans. Each kinetoplast contains many thousand DNA minicircles of contour length 0 45 µm, as well as longer linear molecules. G. Riou (Gustave-Roussy Institute, Villejuif) reported kinetic complexity measurements on restriction fragments of this DNA; the minicircles show about 2% heterogeneity in base sequence, while the linear molecules contain a sequence of kinetic complexity similar to that found in mitochondrial DNA. No genes have yet been located in the kinetoplast genome, nor is the significance of multiple minicircles understood.

Higher plant and yeast mitochondrial DNA has a contour length and a kinetic complexity of 25–30 µm, while animal mitochondrial DNA is only 5 µm in length. Why should more genes be needed in plant mitochondria than in animal mitochondria? Borst suggested that 5 µm is sufficient for the structural genes required for all mitochondria, and that any extra length contained regulatory sequences. Slonimiski amplified this notion by pointing out that lengths longer than 5 µm were found either in facultative aerobes such as yeast, which might need more control sequences than obligate aerobes such as animals, or in green plant cells where the mitochondrion interacts metabolically with the chloroplast.

Chloroplasts from several higher plants and algae contain DNA circles of contour length about 45 µm: this has been regarded as a universal size for the chloroplast genome but R. Herrmann (University of Dusseldorf) reported that in the liverwort *Sphaerocarpus* the size was nearer 37 µm. Much less information is available about the function

of chloroplast DNA than about that of mitochondrial DNA. This is surprising in view of the primary role of chloroplasts in maintaining all living organisms. The view was expressed that this situation stems from the failure of too many departments of botany and biochemistry to promote interest in the biochemistry of plants; consequently far fewer biochemists study chloroplast development than study mitochondrial development. Several groups are currently preparing restriction fragments of chloroplast DNA, so some progress in mapping the chloroplast genome can be expected. One structural gene firmly established as located in this genome is that for the large subunit of Fraction I protein (ribulose–*bis* phosphate carboxylase). R. J. Ellis (University of Warwick) reported that this subunit was made *in vitro* by the free ribosomes of the chloroplast but not by the membrane-bound ribosomes. Isolated spinach chloroplasts will use light energy to incorporate ^{3}H-uridine into a discrete RNA species of molecular weight 2.7×10^6; M. R. Hartley (University of Warwick) and H. J. Bonert (University of Dusseldorf) reported hybridisation data which showed that this RNA species contains cistrons for both 16S and 23S chloroplast ribosomal RNA.

It is clear that most of the proteins of both mitochondria and chloroplasts are made on cytoplasmic ribosomes, and are then imported across the bounding membranes into the developing organelle. G. Schatz (University of Basle) suggested that the mechanism of specific protein uptake into these organelles is a major problem in cell biology, but no new data were presented at the meeting that shed any light on the process.

More and more promising

from David J. Miller

The International Particle Physics Conference was held in Palermo on July 23–28, 1975.

AT last year's International Particle Physics conference in London, some theorists placed bets that "charm" would be discovered before this year's conference in Palermo. Charm is a suggested new quantum number, like the well-established "strangeness" number carried by hyperons and K-mesons. It had been incorporated into a very plausible scheme to explain the weak interactions, including the recently established neutral current effects, but no one had seen a "charmed" particle.

Now the Palermo conference has passed, but it is still not clear who has won the bets.

Remarkable things have been discovered during the year, the psi (or J) and psi' particles in particular. In the last few weeks a collaboration working at the DORIS electron–positron colliding-beam machine near Hamburg has reported a new intermediate state between the psi and the psi'. They claim that when their e^+e^- collision energy was 3.7 GeV (that is, when they were making psi') they saw a number of events whose final state particles consisted of two fixed energy gamma rays and a psi. The psi was recognised when it delayed to a muon- or electron-pair with a mass of 3.1 GeV. The production of the two gamma rays is interpreted as a two-stage de-excitation cascade (psi'→new particle + gamma ray, followed by new particle→psi + gamma ray). Such cascades are encountered frequently in atomic or nuclear spectroscopy. Rumours from the SPEAR storage rings at Stanford, California suggest that similar intermediate levels have been observed there.

Charm lovers know exactly what they want these new objects to be. They say that the intermediate particle(s) are the p-wave states of "charmonium", that is, states with one unit of angular excitation. The psi is supposed to be an s-wave ground state, and the psi' is the first radial excitation. The states have been called charmonium by analogy with "positronium", a short lived atom-like structure formed from an electron and a positron. Charmonium should be made in a similar way from a charmed quark and a charmed antiquark. The only doubts one can have about this argument are that no one has yet proved that charm exists, and we haven't seen any quarks.

But progress has been made on both of these problems. The Stanford–Berkeley collaboration at SPEAR has now had time to collect e^+e^- annihilation data up to about twice the energy at which the psi' is produced. They have seen one other bump, wider than the psi and psi', centred at about 4.15 GeV, but they have also made a high-statistics run at a fixed rate collision energy of 4.8 GeV. This energy was chosen just because there seemed to be no specially interesting energy-dependent behaviour there. In the final states of this sample they have found evidence for another new phenomenon, the correlated production of muons and electrons. Combinations of a positive muon with a negative electron or of a negative muon with a positive electron have both been recognised, but there are no signs of combinations with the same charge for both the muon and the electron. The measured momenta

of the electrons and muons show that they do not carry 4.8 GeV of energy between them, so neutral particles must have escaped undetected.

Charm lovers are, once more, ready with an explanation. A pair of charmed mesons (real charmed particles, not charmonium) has been produced, they say. They must carry opposite charges, and they decay just like pions or K-mesons to muons or electrons, with neutrinos and perhaps neutral pions to take away the unseen energy. It is interesting that a very similar decay process for charmed particles could explain the neutrino-induced events with pairs of muons in the final state, reported at last year's conference by the Harvard–Pennsylvania–Wisconsin–Fermilab group, and confirmed this summer by the Caltech group, also working at Fermilab near Chicago. It is beginning to look as if the charm lovers may be right, but none of the evidence is really firm yet and physicists like to be sure before they pay out on a bet.

As for the problem of seeing quarks, theoretical physicists now tell us that we should not even try. Quarks exist, they say, but they can never be seen. They explain many of the properties of all strongly-interacting particles. They carry most of the mass, as well as the charge, strangeness and charm quantum numbers, but they can never be shaken free from the groupings of three quarks, or quark and antiquark, out of which particles are built. A group at the Massachusetts Institute of Technology has invented a model in which the quarks are permanently confined in "bags" about 10^{-15} m across. Other groups, including one at Cornell University, have models in which the quarks are tied on strings. Until recently these models were regarded as purely phenomenological; just rigged up to fit the data. But at Palermo, and afterwards at the Erice summer-school, near Palermo, it has become clear that fundamental field theories of elementary particles might provide very natural and attractive schemes in which quark-confinement could be achieved. This would be very exciting, since it could lead to a unified theory in which the strong, weak and electromagnetic interactions could be explained at the same time. At the moment some of the leaders in this effort, such as Coleman from Harvard or 't Hooft from Utrecht, are still proving beautiful theorems about two-dimensional space–time. K. Wilson of Cornell works in four dimensions, but his space and time form a quantised lattice. It may take a few years to get to the four-dimensional space–time continuum that physics actually happens in, but many theorists are very optimistic; although nobody is placing any bets.

review article

Did Chinese cosmology anticipate relativity?

John Gribbin*

Recent interest in historic novae and supernovae, stimulated by the discovery of pulsars, has shown the value of ancient Chinese astronomical observations. But the Chinese also have a long record of "cosmological" theorising; in some cases their old concepts regarding the Universe are remarkably similar to those developed in the West during the twentieth century.

ANY discussion of astronomy and cosmology in China in historic times must inevitably draw on Needham's work[1]; it is therefore appropriate to begin such a discussion in what for an astronomer is the sobering light of the quotation from Franz Kühnert, made in Vienna in 1888 and which graces the title page of ref. 1: "Probably another reason why many Europeans consider the Chinese such barbarians is on account of the support they give to their Astronomers—people regarded by our cultivated Western mortals as completely useless. Yet there they rank with Heads of Departments and Secretaries of State. What frightful barbarism!"

Those "barbarians" were, however, thinking about the nature of the Universe, and producing some remarkably modern concepts, at least two thousand years ago. The earliest concept, of the heavens as a hemispherical dome closing over the Earth, and the slightly later concept of a celestial sphere surrounding the spherical Earth are familiar enough; it is possible that the earliest ideas can be traced back to Babylonian concepts of the world, and that the theories migrated both westward to Greece and eastward to China, where they developed independently. But it is particularly striking that one school of thought does not seem to have displaced the other in China. Followers of either theory could be found from the fourth century BC onwards, and there were also other schools. In terms of modern cosmology, the most striking of these ideas was not, it seems, the most popular some 2,000 years ago—but it was taught, and it is this system that most resembles modern ideas.

Infinite empty space

The Hsüan Yeh theory of the Universe was a later development and little is known about it before the Later Han (AD 25–AD 220). A little later, Ko Hung wrote (see ref. 1 p. 219): "The books of the Hsüan Yeh school were all lost, but Chi Mêng, one of the librarians, remembered what its masters before his time had taught concerning it. They said that the heavens were empty and void of substance . . .

"The sun the moon and the company of stars float freely in the empty space, moving or standing still. All are condensed vapour."

And in AD 336 Yü Hsi, the Chinese discoverer of the precession of the equinoxes, wrote: "I think that the heavens are

*Address: *Nature*, 4 Little Essex Street, London WC2R 3LF, UK.

infinitely high, and that the space below the earth is unfathomably deep."

These ideas were some 1,300 years ahead of western thought (as far as there was any western thought about the nature of the Universe in the fourth century), and it is particularly interesting that western cosmology only broke the bounds imposed by the concept of the "crystal spheres" at about the time that reliable news of Chinese philosophy, mathematics and astronomy was beginning to reach the West. Not that the new ideas were broadcast as a great revelation by the Jesuits who visited China at the end of the sixteenth and beginning of the seventeenth centuries: they were held up to ridicule as examples of the stupidity of Chinese philosophers. Matteo Ricci listed several "absurdities" in Chinese astronomical thought in letters written in 1595 (see ref. 1 p. 438) including: "They say that there is only one sky and not ten skies; that it is empty and not solid. The stars are supposed to move in the void, instead of being attached to the firmament . . . Where we say there is air between the spheres, they affirm there is a void".

But these "absurdities" found a receptive audience in some western thinkers, at least. This was the time when western astronomy began to develop as a science, rather than as a branch of religion, and this development has led, 300 years later, to the present picture of an infinite Universe dotted with island galaxies. It is ironic that just when astronomy was making the crucial break with religion, orthodox western religious views were imposing a barrier on the further development of Chinese astronomy. The Jesuits persistently failed to broadcast new ideas such as those of Copernicus in China, and the centre of development of the science had definitely shifted to the West by the end of the seventeenth century. Even more ironically, a further 300 years of development in the west has only, it seems, brought cosmology to a level reached in China well before the time of the Jesuit mission. Even in the thirteenth century the concept of the plurality of worlds was well established, and Têngu Mu wrote (see ref. 1 p. 221): "Heaven and Earth are large, yet in the whole of empty space they are but as a small grain of rice . . . Empty space is like a kingdom and Heaven and Earth no more than a single individual person in that kingdom. How unreasonable it would be to suppose that besides the Heaven and Earth we can see there are no other heavens and no other earths."

To make that a modern statement, it is necessary only to replace "heavens" by "galaxies"; and if that concept had reached western cosmologists such as Thomas Wright, who

published a remarkable theory of the structure of our Galaxy in 1750 (ref. 2), who knows what the consequences for the development of cosmology might have been.

Space and time

Perhaps the most important difference between the ancient Chinese thinkers and their western contemporaries was openness of mind. The Chinese were always, it seems, prepared to consider different theories of the Universe, rather than subscribing to

Fig. 1 Chinese oracle bone dating from about 1300 BC with the oldest existing written record of a nova (from Needham[1]).

rigid doctrine. They also had a rather better grasp of the size of the Universe, both in space and time. Buddhist ideas of a cyclical Universe may have helped with the development of ideas about time; certainly the eighth century Chinese estimate of the time elapsed since the last "conjunction" (96,961,740 yr; see ref. 3 p. 45) was, while perhaps 100 times too small by modern estimates, still a lot more realistic than a European bishop's notorious eighteenth century estimate that the Earth was created on a certain day in 4004 BC, at six o'clock in the evening.

This grasp of space and time extended even to more abstract ideas. In a text of 120 BC quoted by Needham (ref. 3 p. 219) we find the following definition: "All the time that has passed from antiquity until now is called chou; all the space in every

direction, above and below, is called yü." Thus, the Chinese expression yü–chou, commonly translated as "The Universe", means more literally "space–time"—a concept which only gained respectability in the West a few decades ago. This is not the only example of how the great philosophers of China seemed to foreshadow ideas now firmly attributed to Einstein. As early as 300 BC the Mohists taught (ref. 3 p. 221): "Movement in space requires duration . . . In movement, the motion of an observer must first be from what is nearer, and afterwards to what is further. The near and far constitute space. The earlier and later constitute duration. A person who moves in space requires duration." Although these ideas were so advanced, they have never, it seems, directly influenced the development of western ideas. That cannot be said of Chinese observational astronomy, however, which is even now providing vital fundamental information used by the most modern astronomers of all, the high energy astrophysicists.
Guest stars and Uhuru

Although it was the discovery of pulsars which first stirred renewed interest in Chinese records of guest stars, the most fruitful development recently has stemmed from observations of X-ray stars, made from the satellite Uhuru. The importance of the Chinese observations is that they provide accurate dates for the supernova explosions in which, it is generally believed, pulsars and X-ray stars are born. These sources are evolving so rapidly that information about their ages, and thus of their development over the past 2,000 yr or so, is of great importance.

The most famous Chinese guest star is, of course, the event recorded in June of AD 1054, which gave birth to the Crab Nebula, with its associated pulsar and X-ray source. But Cowley and MacConnell have identified six other X-ray stars with six guest stars dating from AD 1690, AD 1203, AD 902, AD 827, AD 722 and 48 BC (ref. 4). Some of these identifications are tentative, because the Chinese records are not always as accurate as modern astronomers would like (see Fig. 1). But if they are correct, they also provide a new insight into those ancient observations. Assuming that the X-ray stars have not moved far since they were created in the supernova explosions, the combination of modern positional information and the old records provides an accurate calibration of the Chinese unit of angular measure, and this in turn makes other old Chinese records more valuable.

There is still further interaction between modern astronomy and the Chinese records. Kiang, for example, has calculated the orbit of Halley's comet over the millenia[5], and compared the calculated dates with dates of the appearance of comets (also referred to as guest stars) in the Chinese literature. That provides a new calibration of the Chinese calendars, and helps both historians and astronomers to make best use of the wealth of information available about China.

Perhaps there are still unsuspected ways in which this information might contribute to modern astronomy and cosmology; certainly the ideas are worthy of more than passing mention in teaching the subjects, and it would do no harm to students to draw their attention to such theories as the idea noted in a first century BC book (see ref. 1 p. 224): "The Earth is constantly in motion, never stopping, but men do not know it; they are like people sitting in a huge boat with the windows closed; the boat moves but those inside feel nothing."

Similarity of genes *argF* and *argI*

Akihiko Kikuchi & Luigi Gorini

Department of Microbiology and Molecular Genetics, Harvard Medical School, Boston, Massachusetts 02115

Two genes, at different positions on the Escherichia coli *genetic map but producing two enzymes which catalyse the same reaction, have a structure so similar that their DNAs anneal with each other in a heteroduplex mapping test.*

COMPARED with eukaryotes, bacteria rarely have multiple copies of a gene. In some cases the duplicated gene is located very close to the original copy, usually in tandem as in the case of certain transfer RNAs[1]. In other cases they are scattered without unique orientation, as in the case of the genes of rRNA, of which there are 5–7 copies[2]. A need to increase gene dosage may account for these situations. The apparent lack of such a requirement makes the case of ornithine transcarbamylase

(OTC) more intriguing. This enzyme of the arginine synthetic pathway which converts ornithine to citrulline, is coded for by gene *argI* in all strains of *Escherichia coli* and *Salmonella* and is located at 85 min on the *E. coli* linkage map. In *E. coli* strain K12, however, an additional gene copy for the same enzyme, gene *argF*, exists and is located at 7.5 min of the *E. coli* map[3]. Why strain K12 should possess two OTC genes is not clear. The products of each of these two genes, *argI* and *argF*, have been studied biochemically. It has been found that four types of a trimeric enzyme molecule are formed by the random combination of two slightly different subunits coded for by each gene. The difference of each gene product is detected by ion exchange chromatography but not by size and shape of the subunits[4]. In addition the trimeric molecule formed by the *argI* product, is considerably more heat resistant than that consisting of the *argF* product (Glansdorff, personal com-

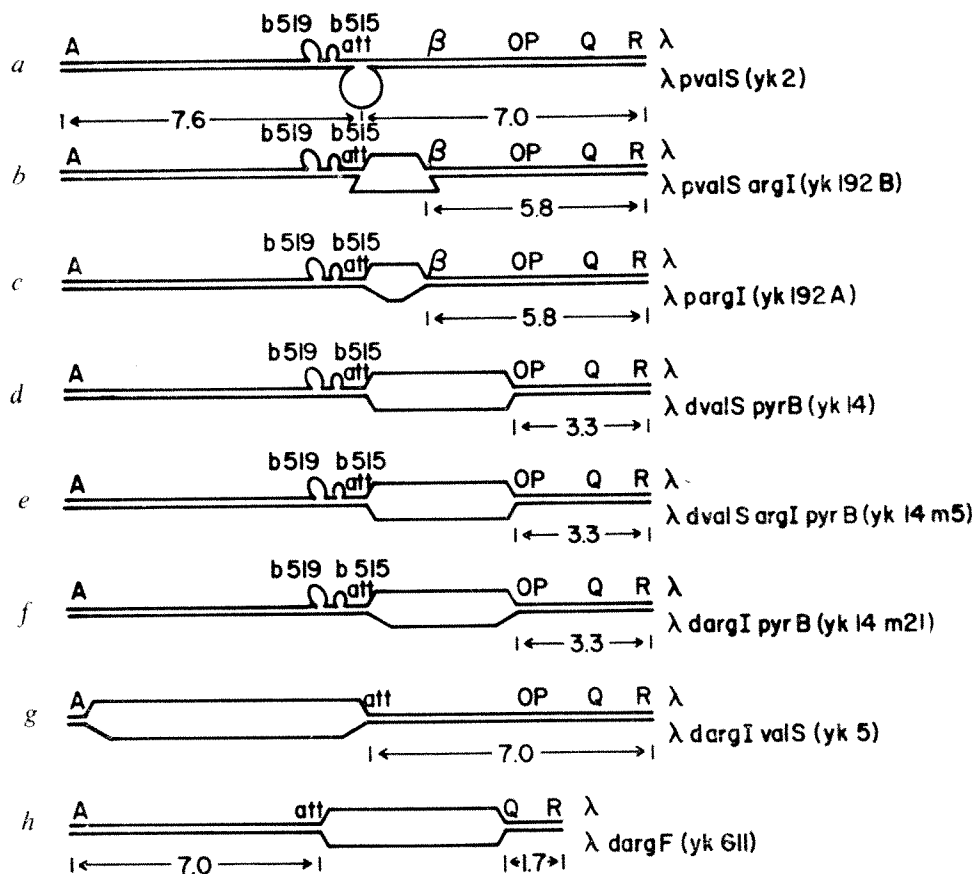
Fig. 1 Heteroduplex structure of λ specialised transducing phages. Heteroduplexes of DNA between λ*c1857 S7* phage and each λ transducing phage are represented in the linear drawings. The double strand regions are represented proportionally while single strand loops are not. The double strand portion was measured by a map-measurer from a suitable enlargement and average values obtained from 10–20 heteroduplex molecules were normalised using *b519*, *b515* deletion loops as internal markers[10]. Total λ*c1857 S7* phage DNA is 16.4 μm long whereas λ*y*199 (carrying the two deletions *b519*, *b515*) is 14.6 μm long using this type of measurement (error 5%). The distances indicated in the drawings are in μm. All material including bacterial and phage strains and methods has already been described[5] except for the heteroduplex mapping technique. After some failures encountered by using the recommended technique for the DNA of φ80 phage particles[8], we modified the technique for λ phage particles as follows: 1–5 μl of the λ phage (10^{10} ml^{-1}) in CsCl solution ($\rho = 1.5$ g cm^{-3}) is added to 5 μl of 0.4 M EDTA-Na$_3$ and left at room temperature for 10 min. The phage solution was then diluted to a final volume of 25 μl by double-distilled water and mixed with 25 μl of another phage solution processed in the same way. The mixture of the two phages (50 μl) is diluted to 400 μl by adding 10 mM Tris-HCl *p*H 8.8, then denatured by 10 μl of 5 N NaOH for 30 min at room temperature and then neutralised by 60 μl of fresh 1:1 mixture of 2 M Tris-HCl *p*H 7.4 and 1.8 M HCl. The renaturation was started by the addition of 0.47 ml of 99% formamide and continued for 36 h at room temperature. During the renaturation a 60 μl of Tris-HCl *p*H 8.8 was added to prevent the lowering of the *p*H.


Fig. 2 Heteroduplex structure of λ specialised transducing phages carrying the *valS argI pyrB* region. The linear drawing represents heteroduplexes between each λ transducing phage. Details are described in the legend of Fig. 1.

munication). All other kinetic and affinity constants of the two enzymes are indistinguishable as well as the regulation pattern of the two operons, both being controlled to the same extent by the same repressor molecule, the *argR* product. Thus, the bulk of the two operons, *argF* and *argI*, which include promoters, operators and structural genes, might be so similar that the two DNA sequences could be able to anneal to a large extent if not completely.

Heteroduplex structure of the transducing phages

To demonstrate this hypothetical DNA homology, we first constructed several specialised transducing phages in the *argI* and *argF* regions of *E. coli* K12 chromosome. The structure of their heteroduplexes with the corresponding wild-type phages is presented in Fig. 1. In the *argI* region, because of two well defined markers, *pyrB* and *valS*, closely located at either side of the *argI* gene and 97% cotransducible with *argI* by phage P1, we could easily isolate λ specialised transducing phages of different sizes in that region of the chromosome. In addition to the previously isolated and described[5] phages λp*valS2* (yk2), λd*argI valS* (yk5) and λd*valS pyrB* (yk14), we have obtained the following phages. λp*valS argI* (yk192B) and λp*argI* (yk192A) were isolated from the HFT lysate obtained from strain RW420 (*proA/B argF lac*)ᵛ (*gal attλ uvrB*)ᵛ lysogenised with λp*valS2* (yk2) phage using the *valS* gene homology. LFT transductants Arg⁺ were selected using the strain AD1 (*proA/B argF lac*)ᵛ *argI*ᵛ as recipient. On heat induction they produced HFT lysates of two types of phages, λp*valS argI* (yk192B) and λp*argI* (yk192A). The lytic growth of yk192B always gives rise to a mixture of yk192B and yk192A (distinguishable by CsCl density gradient centrifugation) in different ratios depending on the conditions of the culture. The heteroduplex mapping shown in Fig. 1b and c, reveals that the λp*argI* phage arises from λp*valS argI* by losing the *valS* portion. In a similar way the phage λp*valS2* (Fig. 1a)

tends to lose *valS* and return to the parental phage λy199 during lytic infection.

Phages λd*valS argI pyrB* (yk14m5) and λd*argI pyrB* (yk14m21) (Fig. 1e and f) were selected from the lysate of strain BC22 *argI⁺ pyrB⁻*, lysogenised with phage λd*valS argI*ᵛ *pyrB⁺* (yk14). In this way rare recombinants with the host chromosome appear which are Arg⁺. As seen in Fig. 1, there is no visible increase in DNA size in yk14m5, while there is a definite decrease in yk14m21 when they are compared with yk14 (Fig. 1d). The DNA length lost is of the order of 1.5 μm, which corresponds to the size of *valS* insertion in λp*valS2* phage (Fig. 1a). In the *argF* chromosomal region we obtained the phage λd*argF* (yk611) (Fig. 1h) as already described[5].

Physical mapping of the *argI* region

To demonstrate the exact location of *argI* genes in the transducing phages, we made a heteroduplex analysis between transducing phages themselves. Figure 2 summarises the heteroduplex map of combinations of phages λp*valS*, λp*valS argI*, and λd*valS argI pyrB*. The gene order can be qualitatively recognised as *valS→ argI→ pyrB* starting from the attachment site, by the estimation of the length of double strand DNA and the size of single strand loop. For example, the double strand region at the left side of Figure 2a and b is the same and that at the right side of Fig. 2a is longer than that of Fig. 2b, indicating that *valS* gene is located at the left of *argI*. An analogous comparison between Fig. 2b and c permits the conclusion that *argI* is at the left side of *pyrB*. In addition, the short single strand loop in Fig. 2a should contain the *argI* gene, while the longer loop in Fig. 2b must contain *argI* and *pyrB* genes. The loop in Fig. 2c should contain at least the *pyrB* gene and probably something more at the right side. Figure 3 gives a clear view of the region because the heteroduplex between λp*argI* and λd*valS argI pyrB* phages directly shows the *valS* size as an insertion loop at the attach-

Fig. 3 Electron micrograph of heteroduplex DNA between λd*valS argI pyrB* (yk14m5) and λp*argI* (yk192A). A drawing is shown at the bottom in the same way described in Fig. 1. Black bars represent 1 μm. The specimen for electron microscopy was prepared and examined as described[5]. We did not expect any heteroduplex between *l* and *l* strands (or *r* and *r* strands) because if any homology exists in the homologous strands of two genes oriented in opposite directions this will be too small to stabilise such a heteroduplex unless each strand is separated and then mixed with the corresponding strand[9]. Therefore, if we did not see any homology among a number of heteroduplexes (*l* × *r*) we concluded that either there is no homology between the corresponding parts of the gene or that the two genes in question are oriented in opposite directions.
Table 1 The size and order of the *valS argI pyrB* gene

Genetic marker	— *valS* —	— *argI* —	— *pyrB* —
P1 cotransducing frequency	←——— 97% ———→←	——— 97% ———→	
	←——————— 85% ——————→		
DNA base pairs calculated from P1 transduction	←——————— 4,500 bp ———————→		
EM observation from Fig. 3	←——— 1.5 μm ———→←	— 0.6 μm —→←	—— 2.0 μm ——→
EM observation for *argF/argI* duplex from Fig. 4		◄0.4 μm►	
DNA base pairs calculated from EM	←——— 5,000 bp ———→←	— 2,000 bp —→←	—— 6,600 bp ——→
		◄1,200bp►	
Molecular weight of the protein	110,000	35,000	33,000+17,000
DNA base pairs expected from the molecular weight	3,300 bp	1,050 bp	1,000 bp+500 bp

The following conversion indexes are used: 1 μm DNA length = 3,300 base pairs; 0.1 min map distance = 4,500 bp; 1,000 bp correspond to a protein of molecular weight 33,000.

ment site, *argI* as a small successive double strand section and *pyrB* as a single stranded loop after *argI* at the right end.

The maximum size of each gene can be calculated as follows. The *valS* insertion is about 1.5 μm which corresponds to about 5,000 base pairs (bp), the *valS* gene itself requiring only 3,000 bp. The *argI* portion is 0.6 μm corresponding to 2,000 bp, but the *argI* gene itself should require only 1,000 bp. There is therefore a considerable space between *valS* and *argI* (about 1,000 bp at least) unaccounted for, which could indicate either another unknown gene or a mere spacer sequence. Finally *pyrB* has a length of 6,600 bp which is certainly too long for the *pyrB* gene. Since we do not have any marker after *pyrB* closer than *fdp* (which is separated by 15,000 bp calculated by P1 transduction frequency[6]), we could not obtain any phage for *pyrB* substitution enabling us to be more precise about the size of the *pyrB* gene. As it may be seen from Table 1, the overall distance of the three genes, *valS*, *argI* and *pyrB* is coincident with the P1 transducing frequency data.

argI, argF gene homology

From the physical mapping of the *argI* region we confirm the conclusion reached previously[5] about the orientation of the *argI* gene in the λ phage. Since it is known that the operator of *argI* is located between *valS* and *argI* (ref. 7), we conclude that the *argI* gene is transcribed from left to right in the phage λd*valS argI pyrB*. The same must be true for the phages λp*valS argI* and λp*argI* on the basis of the heteroduplex mapping results. By contrast, in the case of phage λp*argI valS* (yk5), the orientation of *argI* must be the opposite since we could not detect homology between *valS argI* of λp*valS argI* and *valS argI* of λd*argI valS*. If there is considerable homology detectable by electron microscopy between *argF* and *argI* then we should see the *argF–argI* duplex in the heteroduplex either between λd*argF* and λd*valS argI pyrB* or between λd*argF* and λd*argI valS* (yk5). If there is no homology at all between the two OTC genes, we would not obtain a duplex in either combination. Figure 4*a* and *b* shows that duplex *argF–argI* is obtained

Table 2 Orientation of *E. coli* chromosomal markers on the λ transducing phage
The phage genes are represented at the bottom of the figure by a straight line with A end at the left and R end at the right. The *E. coli* chromosome is shown as a broken line and relative places of genes are shown on the top. The letter orders of each genetic marker are kept as it is in Taylor's map[11] to demonstrate the way in which the chromosomal portion was inserted into the λ genome. The assignment of gene order of λ*pvalS*, λ*pvalS argI*, λ*pargI*, λ*dargI pyrB*, λ*dvalS argI pyrB* and λ*dargI valS* are described in the text. The arrow on the *argI* represents the transcription direction from the operator mapping data of G. Jacoby[7]. The open arrow on the *argF* is determined from the fact that *argF* gene is annealed with the *argI* gene of λ*dvalS argI pyrB* phage.

with the combination λ*dargF* and λ*dvalS argI pyrB* or λ*pargI*. The location of duplex DNA between two single strand loops is exactly where *argI* gene is expected from the physical mapping data so that we believe that the duplex is between *argF* and *argI* although we could not confirm as yet whether the side opposite *argI* is indeed *argF* itself. The determined length of 0.4 μm (1,200 bp) is in agreement with the size of 1,050 bp for

an OTC subunit (molecular weight, 35,000). We could not observe any heterogeneity within this duplex region although some minor base difference should be expected between the two OTC genes. Also we could not demonstrate any evidence for or against the operator–promoter homology. The size of 1,200 bp could accommodate such a region.

This result shows that the DNA sequences of *argI* and *argF* are extensively similar. Moreover, since the annealing extends for about 0.4 μm which is the maximal length for the *argI* (or *argF*) gene, we can conclude that the homology extends over the entire length of the two genes. We do not expect that it should cover more because the surrounding genes at 85 and 7.5 min in the *E. coli* chromosome are completely different. Concerning orientation, our results only show that in this particular phage, yk611, the reading of *argF* is from left to right, the same as in phages λ*pvalS argI pyrB* or λ*pvalS argI* with which it anneals. The actual orientation of *argF* in the bacterial chromosome can only be assessed if we know in which way the *argF* has been inserted in the λ genome. According to considerations developed previously[5] this insertion in yk611 is inverted in respect to the bacterial chromosome. If this conclusion is correct, then the *argF* gene orientation in the bacterial chromosome is counterclockwise as it is for the *argI* gene. These results are summarised in Table 2.

Nucleotide sequence of a viral RNA fragment that binds to eukaryotic ribosomes

Ranjit Dasgupta, Ding S. Shih, Chris Saris & Paul Kaesberg

Biophysics Laboratory of the Graduate School, and Biochemistry Department of the College of Agricultural and Life Sciences, University of Wisconsin, Madison, Wisconsin 53706

The nucleotide sequence has been determined for the first 53 bases of brome mosaic virus RNA4, the monocistronic messenger for brome mosaic virus coat protein. The sequence includes the binding site for wheat embryo ribosomes. The 5'-terminal base is a modified guanosine attached to the penultimate base through a 5' p-p-p 5' link. The initiating AUG codon is only 10 nucleotides from the 5'-terminus. The 13 triplets following the AUG codon correspond to the known sequence of brome mosaic virus coat protein.

IN the past few years, studies of nucleotide sequences of bacteriophage RNAs[1-8] have provided valuable information regarding the structure of initiation sites for protein synthesis in prokaryotes, but how ribosomes are able to select such initiator regions is still an open question. No sequences are known for the binding site of any eukaryotic RNA although recent progress with *in vitro* translating systems[9] utilising such messengers has made sequence investigations both feasible and interesting. We report here the ribosome binding site of brome mosaic virus (BMV) RNA4 (Russian strain). BMV RNA4 is the smallest of the 4 RNAs contained in the virions of BMV, a multicomponent plant virus[10,11] infectious to wheat. BMV RNA4 has been

shown to be an efficient, monocistronic messenger for BMV coat protein synthesis in a cell-free protein synthesising system derived from wheat embryo[12].

Isolation of fragments containing ribosome binding site

A number of workers[4-8] have isolated ribosomal binding sites of bacteriophage RNAs, taking advantage of the fact that regions of RNA can be protected from nuclease digestion by their association with ribosomes. When we tried to isolate a ribosome–mRNA complex in this way with BMV RNA4 and wheat embryo ribosomes, we obtained a series of ribosome-protected fragments which appeared on polyacrylamide gels as closely stacked bands. Fingerprint analyses showed that these fragments contain initiation sequences, but it proved difficult to purify any one fragment in an amount sufficient for detailed analysis.

Rather than using ribosomes to protect binding sites from nuclease digestion, we found it preferable to use ribosomes to select mRNA fragments that contain binding sites. Wheat embryo ribosomes will bind certain BMV RNA4 fragments selectively. Among them are fragments that contain the codons for the N-terminal region of BMV coat protein, and these could be obtained in relatively pure form by choosing appropriate fractions from polyacrylamide gels.

The selection and purification of the binding site fragment were as follows. ^{32}P-labelled BMV RNA4 was digested under very mild conditions with ribonuclease T_1 and a part of the digest was subjected to polyacrylamide gel electrophoresis to examine the extent of degradation. The gel pattern is quite reproducible, indicating the introduction of cleavages at specific sites of the RNA. It contains one major band and many minor bands corresponding to fragments of various lengths. (Analysis of the major band showed that it is a fragment about 150 nucleotides long. It comes from the 3′-end of the RNA molecule and does not contain the ribosome binding site. Its characteristics will be reported elsewhere.) For ribosome binding, the partial digest was added to wheat embryo extracts under conditions that allow initiation of protein synthesis. Elongation of nascent peptide chains was inhibited by the addition of the antibiotic anisomycin[13]. Following incubation, the mixture of ribosomes and RNA fragments was centrifuged through a sucrose density gradient (Fig. 1). About 5% of the total radioactivity sedimented in the region of 80S, indicating a binding of some of the fragments to 80S ribosomes. Fractions containing the ribosome–fragments complex were combined and were extracted with phenol. RNA, consisting of unlabelled rRNA and radioactive RNA fragments, was precipitated from the aqueous layer with ethanol. The resuspended RNA was heated in 6 M urea at 60 °C, followed by a sucrose gradient sedimentation in the presence of urea. All the radioactive RNA was thus dissociated from the bulk of the rRNA and remained near the top of the gradient. Fractions containing radioactivity were pooled and the RNA was precipitated with ethanol. Figure 2a shows the gel electrophoresis pattern of this RNA. Its appearance is different from that of the unbound digest both in distribution and absolute amount of radioactivity. The pattern of Fig. 2a consists of two bands (bands I and II), corresponding to RNA fragments of relatively small size, along with bands corresponding to larger fragments of a variety of lengths. Sequence analysis (see below) showed that the fragments of bands I and II were indeed ribosome binding sites, and the most prominent bands (for example, bands *i*, *ii* and *iii*) corresponding to the larger fragments also contained all of the binding site oligonucleotides. Since the fragments corresponding to bands I and II are short, exist in high molar amount and can be obtained readily in pure form, they were chosen for detailed sequence studies. It may be mentioned here, for example, that although band *iii* exists in Fig. 2a in almost the same radioactive amount as band I, its molar amount is an order of magnitude smaller because it contains a factor of 10 more bases.

For some experiments, fragments were eluted from crushed,

fractionated gels and were studied without further purification. We found that band I and band II materials could, however, be obtained in purer form if the separation of the RNA fragments from rRNA was carried out in two stages.

The RNA obtained from the phenol extraction procedure was first fractionated on a sucrose density gradient without urea treatment. After centrifugation, about half of the radioactivity remained near the top of the gradient while the other half sedimented with the rRNA. Gel electrophoretic analyses showed that fractions from the top of the gradient contained mostly the larger fragments exhibited in Fig. 2a but relatively small amounts of band I and band II material. The 18S RNA fractions contained band I and very little else. The 28S RNA fractions contained band I and band II materials in roughly equal amounts, together with some heterogeneous larger material. Generally, we combined the 18S and 28S fractions, subjected them to gel electrophoresis, and eluted bands I and II for purposes of sequence analysis. Figure 2b shows the gel electrophoresis pattern of RNA fragments obtained in this way. About 0.2% of the radioactivity used for binding was recovered in
Fig. 1　Binding of the RNA4 fragments to ribosomes. BMV RNA labelled with ^{32}P was prepared as described previously[12,29]. Samples (120 μg; specfiic activity 0.5 μCi per μg RNA) were digested with 0.12 μg of RNase T_1 (enzyme: substrate = 1:1,000) for 15–20 min at 0 °C in 100 μl of buffer consisting of 0.1 M NaCl, 0.01 M magnesium acetate and 0.025 M Tris-HCl (*p*H 7.5). After incubation, the reaction mixture was diluted to 0.5 ml with the above buffer, extracted with an equal volume of phenol at 0–4 °C and precipitated twice with 2 volumes of ethanol. The final precipitate was dissolved in 50 μl of distilled water. Binding of the RNA fragments was carried out in a wheat embryo cell-free extract. A procedure, modified from Davies and Kaesberg[30], was used to prepare a cell-free extract. After homogenisation the 23,000*g* supernatant was made 4 mM in magnesium acetate and preincubated with 20 mM Tris-acetate, 1 mM ATP, 0.06 mM GTP, 10 mM creatine phosphate, 75 μg ml⁻¹ creatine phosphokinase (from Calbiochem, containing 58% protein) and 1 mM dithiothreitol at 30 °C for 20 min. Ten millilitres of the preincubated extract was then passed through a Sephadex G-25 column (2 × 41 cm) equilibrated with 10 mM Tris-acetate, *p*H 7.6, 95 mM potassium acetate, 1 mM magnesium acetate and 1 mM dithiothreitol. Fractions with A_{260} between 40 and 220 were pooled and stored at −90 °C in small aliquots. Binding was performed in a 2 ml reaction mixture containing 100 μg (5 × 10⁷ c.p.m.) of the RNA partial digest, 1 ml S23, 20 mM HEPES, *p*H 7.6, 2.5 mM ATP, 0.38 mM GTP, 10 mM creatine phosphate, 250 μg creatine phosphokinase, 0.04 mM each of the 20 amino acids and 25 μg of anisomycin. The reaction mixture was made 4 mM in magnesium acetate and 95 mM potassium acetate and incubated at 30 °C for 20 min. The mixture was quickly cooled on ice and applied to three 10–40% sucrose density gradients prepared in 50 mM Tris, *p*H 7.6, 50 mM KCl and 4 mM magnesium acetate. The gradients were centrifuged at 4 °C in a Spinco SW27 rotor for 4 h at 27,000 r.p.m. Half millilitre fractions of the gradients were collected manually by puncturing the bottom of the tube and counted. The absorbance at 260 nm was measured in a Cary spectrophotometer. Radioactivity was measured as Cerenkov radiation in a Beckman LS300 scintillation counter.

bands I and II. The band I and band II fragments can be rebound to ribosomes but we have not found conditions to bind them to purified rRNA.

Sequence analysis of the initiator fragments

T_1 and pancreatic RNase fingerprints of the RNA fragments isolated from band I and band II are shown in Fig. 3. The yields and the molar ratios of the oligonucleotides were very consistent from one experiment to another, as would be expected for reproducible binding of a specific BMV RNA4 fragment. The fingerprints of band II RNA contain all the oligonucleotides of those of band I, suggesting that band I contains a BMV RNA4 fragment consisting of a part of that of the band II fragment. The primary sequences of most of the oligonucleotides in the fingerprints were determined by standard methods[14-16]. The sequence of the large oligonucleotide UAUUAAUAAUG at the top of the T_1 fingerprint was determined by two dimensional homochromatography after partial spleen[16] and partial pancreatic RNase digestion followed by base composition analysis of the products. The sequence of the T_1 oligonucleotide XG (corresponding to pancreatic oligonucleotide XGU) requires special comment. Its structure has been determined in collaboration with Dr Fumio Harada. It was found to be m⁷G⁵′ppp⁵′Gp.The evidence for this structure will be described in detail elsewhere but can be summarised as follows: (1) the oligonucleotide XG is completely resistant to digestion with T_2 RNase and pancreatic RNase; (2) treatment with alkaline phosphatase released only 25% of its radioactivity as inorganic phosphate; (3) limited digestion with snake venom phosphodiesterase released 7-methylguanosine-5′-phosphate and ppGp by the scission m⁷G⁵′p/pp⁵′Gp. The products were identified by two dimensional thin layer chromatography[17] and by coelectrophoresis with authentic markers; (4) complete digestion with snake venom phosphodiesterase converted the oligonucleotide into the products: pm⁷G, pGp and P_i, that is, by the scission m⁷G⁵′p/p/p⁵′Gp. This indicates that the m⁷G has a free 3′ hydroxyl and is linked through its 5′-phosphate; (5) nucleotide pyrophosphatase, which can cleave pyrophosphate linkages, cleaved 7-methylguanosine-5′-phosphate from the oligonucleotide, giving the same products as above.

This oligomer is the only T_1 product having a 5′-phosphate and it has been detected as such in the T_1 fingerprint of the BMV RNA4 molecule itself. Periodate oxidation and β-elimination of BMV RNA4 removed the m⁷G, giving rise to a new T_1 product pppGp. All of this evidence indicates that m⁷G has a 3′ hydroxyl group and that the structure m⁷G⁵′ppp⁵′Gp must be present at the 5′-end of the RNA molecule. Thus, the 5′-end of the ribosome-bound fragments comes from the 5′-end of RNA4.

The complete nucleotide sequence of the band II RNA is shown in Fig. 4 as achieved from overlapping sequences in T_1 and pancreatic oligonucleotides, partial T_1 RNase digestion and base analysis of the products. Band I contains the first 22 nucleotides of band II. We have determined the sequence of the first 10 amino acids of *in vitro* synthesised BMV coat protein (Russian strain) by use of an Edman Begg automatic sequencer and in the same manner described for the determination of other parts of the BMV coat protein sequence[18]. The sequence is Ser-Thr-Ser-Gly-Thr-Gly-Lys-Met-Thr-Arg. This sequence is in agreement with that reported for the first 25 amino acids of the wild-type BMV coat protein[19]. The sequence of the first 14 amino acids, together with the nucleotide sequence of band II, is shown in Fig. 4. According to the genetic code, the protein sequence corresponds precisely to the nucleotide sequence following the initiation codon AUG at position 10.

Features of the sequence

In the preceding section we have presented the nucleotide sequence of the portion of BMV RNA4 specifically recognised by wheat embryo ribosomes. Its most distinctive feature is the location of the initiation codon only 10 nucleotides from the 5′- terminus. This is in marked contrast to the situation for the

sequences of bacteriophage RNAs. The initiation codons of the first cistron (A-protein cistron) of phage R17 and phage MS2 RNA are located 130 nucleotides from the 5′-terminus[3,4,20] and those of Qβ RNA are 61 nucleotides from the
Fig. 2 Gel electrophoresis of RNA fragments isolated from the ribosome binding complex. The fractions from the 80S ribosome region in Fig. 1 were pooled and precipitated with two volumes of ethanol. The pellet was resuspended in 1 ml of 0.2 M Tris-HCl (pH 7.4), 0.2% sodium dodecyl sulphate and extracted with an equal volume of phenol. The RNA was then precipitated with ethanol. *a*, The precipitate was dissolved in 0.5 ml of a suspension buffer containing 0.02 M NaCl, 0.005 M Tris-HCl (pH 8.3) and 6 M urea and the solution was heated at 60 °C for 10 min to dissociate ³²P-labelled RNA from the unlabelled RNA. The solution was cooled to 0 °C and diluted with an equal volume of the suspension buffer without urea. The solution was then applied to a 5–20% sucrose gradient prepared in the suspension buffer containing 3 M urea. The gradient was centrifuged at 4 °C in a Spinco SW27 rotor for 20 h at 26,000 r.p.m. The fractionation of the gradient and the measurement of the absorbance and the radioactivity of each fraction was done as described in Fig. 1. The first 10 fractions from the top were pooled, the RNA was precipitated with ethanol, and dissolved in 50 μl of the TEB buffer of Peacock and Dingman[31] and 5 μl of a solution containing 50% sucrose and 0.1% bromophenol blue was added to it. The sample was then loaded on a 10% polyacrylamide gel and subjected to electrophoresis at a constant current of 3 mA per gel for 2.5 h at room temperature. The gel was crushed in an automatic Gilson gel crusher which crushed gels into fractions corresponding to gel slices 1 mm thick. Electrophoresis was from right to left. *b*, After phenol extraction and ethanol precipitation, the ribosome-bound RNA was dissolved in 0.5 ml of 0.2 M NaCl, 0.05 M Tris-HCl (pH 8.0), and then applied to a 5–20% sucrose gradient made in the same buffer. Centrifugation and fractionation of the gradients were done as described above. The RNA from the 18S and 28S regions was pooled, combined and precipitated with ethanol. The precipitate was dissolved in 0.5 ml of the suspension buffer containing 6 M urea, heated at 60 °C for 10 min and then subjected to sucrose gradient containing 3 M urea as described in (*a*). The ³²P-labelled RNA was isolated and subjected to gel electrophoresis.

5'-terminus[1]. BMV RNA4 has an estimated chain length of approximately 900 bases. Roughly 600 of these bases are assignable to the coat protein cistron[12]. This suggests that one-third of the BMV RNA4 sequence, adjacent to the 3'-end, has an unknown function other than that of encoding a protein sequence.

BMV RNA4 is unusual in another respect. Although it is a monocistronic messenger for the BMV coat protein, this RNA is not required for infectivity. BMV RNAs 1, 2 and 3 are needed for infectivity; RNA4 is regenerated in the infection process and is present in progeny virions. The sequence of RNA4 is a part of the sequence of RNA3 and complementation studies verify that RNA3 contains the coat protein cistron. The coat protein cistron, however, is translated *in vitro* to only a small extent from RNA3, although a second protein, designated protein 3a, is well translated. We infer that *in vivo*, some

Fig. 4 Nucleotide sequence of the ribosome-binding fragment of band II shown with the N-terminal amino acid sequence of the coat protein. T_1 partial products which helped to deduce the sequence are shown by solid lines. These were obtained by a limited digestion of the band I and band II material with an enzyme: substrate ratio of 1:500 for 15 min at 4 °C. The products were fractionated in two dimensions by homochromatography and identified by fingerprint analysis after complete digestion with T_1 RNase. Palindromes are shown by dotted lines.

Fig. 3 RNase fingerprints of ribosome binding fragments of BMV RNA. *a*, T_1 RNase digest of band II; *b*, T_1 RNase digest of band I; *c*, pancreatic RNase digest of band II; *d*, pancreatic RNase digest of band I. Fractions corresponding to band I and band II shown in Fig. 2*b* were pooled and RNA was eluted by shaking the gel particles in 2 ml of 0.25 M NaCl for 3 h at room temperature. Gel particles were removed by Millipore filters and 50 μg of unlabelled yeast RNA was added to the filtrate. RNA was recovered by ethanol precipitation. After one additional ethanol precipitation, each sample was divided into two parts and subjected to fingerprint analysis following standard procedures[14]. For determining the sequence UAUUAAUAAUG, the T_1 oligomer was divided in to two parts and subjected to limited digestion with 2 μl of a solution of spleen phosphodi-esterase (5 mg ml⁻¹; 2 min at room temperature) and pancreatic RNase (50 μg ml⁻¹ containing 5 mg ml⁻¹ unlabelled yeast RNA; 15 min at 4 °C). The products were separated by two-dimensional homochromatography and identified by complete digestion with pancreatic RNase. XG is m⁷G 5' p-p-p 5' Gp. Oligonucleotide AG in the pancreatic fingerprint of band I (*d*) comes from the 3'-end of the fragment

of RNA3 is processed—presumably by nucleolytic cleavage, replication and 5'-terminal modification, to yield RNA4. Thus, a pre-translational cleavage is necessary for expression of the coat protein cistron. It may be mentioned that RNA3 also has a m⁷G 5' p-p-p 5' Gp terminus and it is probably implicated in the effective translation of protein 3a.

The presence of 7-methylguanosine and the pyrophosphate linkage has been recently reported to occur in viral messenger RNA from reovirus[21], vaccinia virus[22,23] and cytoplasmic polyhedrosis virus[24]. It is also present in Novikoff hepatoma cell nuclear RNA[25], and the reovirus genome RNA[26]. Our fingerprint analysis of BMV RNA4 shows that about 50 to 75% of it contains this structure whereas the BMV RNA4 binding fragments contain a quantitative amount. This differ-ence could mean that some of BMV RNA4 lacks part or all of the distinctive 5'-terminus. Possibly ribosomes select those fragments containing it. We find, however, that the oligomer m⁷G 5' p-p-p 5' Gp does not bind significantly to wheat embryo ribosomes so that this structure alone, cannot be responsible for the binding of ribosomes. Our binding results show that the fragment of band I can bind ribosomes as efficiently as the band II fragment. This implies that the ribosome binding signal resides within the first 22 nucleotides. The binding site sequence does not form a stable secondary structure as evaluated accord-ing to Tinoco *et al.*[27]. The association of the initiation fragments with rRNA implies a sequence complementarity between messenger and rRNA[28]. We suggest that the unique 5'-terminus, the short sequence of As and Us, and the AUG codon constitute a simple and efficient ribosome recognition and binding site.

Observations of a transient X-ray source with a period of 104 s

DURING routine observations of the Crab Nebula by Ariel V, experiment A, the rotation modulation collimator (RMC), discovered a new X-ray source A0535+26. The source was just detectable during the first observation on April 13, and during the 16 d of observation was seen to brighten to nearly twice the Crab's intensity (in the 3–7 keV range). The source varies periodically, with a period of 104 s, and has a very flat spectrum in the 3–7 keV range.

Figure 1 shows the observed count rate from A0535+26 as a function of time in units of counts s^{-1} in the 3–7 keV range corrected for the collimator response. Intensities before April 21 were obtained by overlaying several orbits of data together. An approximate ratio between Uhuru counts and the RMC counts is 13:1. The source was definitely present at a low irregular level several days before the main increase started, and it returned to a low level or turned off for short periods during the early stages of increase. This behaviour is reminiscent of that shown by A1118−61 (refs 1, 2) which returned to a low level twice in the period immediately before the main

increase in intensity. But the smaller deviations from a smooth curve during the latter part of the observations are probably a result of interference from the Crab X-ray source which was close to the spin axis at the time and are probably not significant. Thus the later behaviour differs from the continued irregular behaviour of A1118−61. Data from another experiment[3] on Ariel V indicate that the source reached a peak within a few days after our observations ceased. Though the rise time is slow compared with optical novae and supernovae, it is comparable with other X-ray transients.

The position of A0535+26 has been measured to be 05h35min47s±2s +26°16'52"±45" (1950.0) (90% confidence) which differs from our previously announced position[4] by 2'. The RMC determines positions relative to the spin axis pointing position of the spacecraft. Using the relative position of the Crab Nebula from our data, and its position on the sky taken to be 15" NW of the radio pulsar[5], the attitude of the spin axis was determined independently of the crude spacecraft attitude data. One additional parameter is necessary from the spacecraft, the azimuth angle of the arbitrary starting point of its rotation. At the beginning of the Crab Nebula observations new spacecraft alignment parameters were used to correct for

Fig. 1 Light curve of A0535+26. Bars indicate periods of integration (where these exceed one orbit) and ±1σ errors. Upper limits are 3σ.
previously large (~0.5°) systematic errors in the spacecraft attitude solutions. But it was not until after the Crab Nebula observations (in the Cygnus region using Cyg X-1 and Cyg X-3 as benchmarks) that it was found that the new alignment parameters caused a change in azimuth angle (zero sector angle) of 20'. This in turn caused a change in right ascension at the position of A0535+26 of 2'.

During four orbits on April 28, 1975, data were collected in the experiment's "time" mode. In this mode data are integrated for 32 s and stored. Each orbit yielded about 45 min of useful data, which were collected starting at 4.21695, 5.80538, 7.390116 and 8.99238 h UT. The average count in 32 s was 6,000, made up by a 40% contribution due to A0535+26, and 30% each due to the Crab and to total particle and diffuse X-ray background in the 17° FWHM field of view. The sum of the power spectra for all four orbits of time mode data is shown in Fig. 2. This power spectrum differs from that expected from a constant signal with statistical noise fluctuations in three ways: (1) an excess low frequency component; (2) excess power at all frequencies as compared to expected statistical fluctuations; and (3) marked sinusoidal features at 0.960×10^{-2} Hz (104.1 s) and 1.20×10^{-2} Hz (83.3 s).

The low frequency component is a result of a combination of slow drift in the intensity of the source and background, and
Fig. 2 Sum of power spectra of the four orbits in TIME mode. Only the mean has been removed. The height of the 104.1-s peak corresponds to a 25% modulation of the source, and its width is that expected for a pure sine wave. *a*, 104.1 s; *b*, 83.3 s.

Table 1 Possible periods which would be aliased to 104.14 s with a sampling time of 32 s

Period (s)	Frequency (Hz)	Attenuation factor
104.14	0.96×10^{-2}	0.852
46.1	2.17	0.376
24.4	4.09	−0.201
18.9	5.29	−0.154
13.9	7.21	0.112
11.9	8.42	0.098
9.7	10.34	−0.078
8 7	11.54	−0.073
7.4	13.46	0 063
6.8	14,66	0.054

The attenuation factor caused by the finite sampling is also shown.

to the finite sampling time (45 min). Removing a quadratic trend in the data, from each orbit independently, reduces the low frequency component. The excess power over all frequencies indicates that the source is randomly fluctuating over all periods between several seconds to minutes at least.

The periodic feature at 0.960×10^{-2} Hz must be accepted as real, and not an artefact of some type of beating phenomenon between the modulation caused by the rotating grids and the sampling frequency. Since the rotation rate of the spacecraft is nominally 10 r.p.m. the 32-s integration time represents an integration over more than 10 half-rotations of the RMC. Analysis of time mode data from the region of the galactic centre and Cyg X-1 taken before and after the observations reported here do not show any periodic components, nor any comparable power over the measured range of frequencies.

But it is not necessary that the 104.1 and 83.3 s periods are the true incident periods. Because of the integration time of 32 s any frequency above the Nyquist frequency 1/64 s⁻¹ would be aliased to a measured period greater than 64 s. Indeed the 83.3 s period is explained as the 52 s harmonic of the 104 s fundamental aliased to 83.3 s. Furthermore, the 104 and 52 s periodicities could also be aliases of shorter period oscillations. Table 1 lists the first 10 possible higher periods which could be aliased to 104 s with a sampling rate of 32 s. The second harmonic of any of these frequencies would be aliased to produce an apparent period of 83.3 s.

But there is a means of differentiating between some of the possible different frequencies. Since data are integrated for 32 s

the observed periodic signal will have been attenuated by a factor depending on its frequency. The attenuation factors for the possible fundamental frequencies are shown in Table 1. The observed modulation of the signal was 25% of the mean. The shorter periods (24.4 s and less) are precluded because they would imply a modulation depth of the incident signal greater than 100%.

An epoch-folding analysis yields the best estimate for the period of 104.14 ± 0.16 s (1σ). Figure 3 shows the observed light curve for the 104.14 s periodicity, folded into 10 bins for all 340 32-s samples over the four orbits. The third harmonic, if it exists, is aliased near the DC level and is masked by any slow trends in the data. The fourth harmonic is too weak to be seen above the noise. Because of the relatively long sampling time, and thus the low sensitivity to the higher harmonics, no attempt has been made to deconvolve the measured light curve with the instrumental response.

The light curve of the source (Fig. 1) shows no sign of eclipses; the time mode data are insufficient to measure a change in period of the dwarf in its orbit.

Fig. 3 The light curve of the 104.14-s period folded into 10 bins, shown over two cycles. The error shown is statistical. ———, 32-s sample time.
Crude three channel energy resolution (3–7.5 keV) shows that around its peak the spectrum of this source is very similar to the transient A1118–61 (ref. 2). There are indications that during the growth phase the absorption increased to this value from a low level.

Hard X-ray measurements of nova A0535+26 in Taurus

MEASUREMENTS of high energy X rays in the region of the Crab Nebula were made with the Imperial College detector on Ariel V between April 13 and April 29, 1975. During that time the X-ray nova A0535+26 was first detected and observed to rise to its maximum intensity[1,2]. At 30 keV this nova reached an intensity considerably brighter than the Crab Nebula, making it the brightest known source in the sky.

Our experiment uses an actively shielded crystal scintillator, and operated in the energy range 26 keV–1.2 MeV, making
Fig. 1 Light curve of nova A0535+26 obtained from channel 1 of the high energy experiment, with an 8-h time resolution. Data have been normalised to 26 keV. Errors are ±1σ counting statistics. a–e, Five spectra obtained during this period; the data collection period for each spectrum is indicated.

spectral measurements in 16 logarithmically spaced energy channels. It has a sensitive area of 8 cm² and an opening angle of 8° FWHM which is offset from the spacecraft spin axis by 3°. A source a few degrees from the spin axis direction can be detected by determining the modulation in the counting rate accumulated in four equal angle spin sectors. Since a spurious modulation is induced in the apparatus by cosmic rays, a separate measurement is required to subtract this background. This is normally achieved by making observations at offsets on either side of the source; however, in the case of the nova discussed here, data for background subtraction were taken from a period before the nova had reached a significant intensity as measured by the low energy experiments.

For most of the observations reported here, the spin axis was pointing to within 0.5° of the Crab Nebula which does not give any significant modulation for this offset angle. Data for
Fig. 2 Photon flux ratios at various energies plotted to indicate any spectral changes during the rise of the event. a–c, Ratio of the fluxes observed in channels 1–3, respectively, to those measured by the RMC experiment, d, the ratio of the flux in channel 4 to that in channel 1 of the high energy experiment. Error bars indicate ±1σ in counting statistics. Energy intervals: RMC experiment, 2.95–7.60 keV; our experiment: channel 1, 26–33 keV; channel 2, 33–43 keV; channel 3, 43–56 keV; channel 4, 56–73 keV.

background subtraction were obtained on April 20, 1975, and it is assumed that the nova source had not reached a detectable level for this experiment on that day. The position of the nova[1] places it 4° from the spin axis which happens to be the offset giving maximum modulation and therefore maximum sensitivity for this experiment. For the last day of the observation the spin axis was offset 1.4° from the Crab Nebula towards the nova and corrections had to be applied, first for the signal now produced by the Crab Nebula and second for the slight reduction in efficiency because of the reduced offset from the nova. Data from previous measurements on the Crab Nebula were used to make these corrections.

Figure 1 shows the light curve obtained from the lowest energy channel with an 8-h time resolution starting when the first statistically significant signal was observed. The flux has

been corrected to the lower threshold of this channel (26 keV). The phase of the spin modulation for this data corresponds to the stated position of the nova; any spurious signal originating from the Crab Nebula would change this phase, which is kept as a free parameter in the analysis.

The light curve has been divided into five sections and data from each section used to obtain energy spectra. (Fig. 1a–e). Upper limits are shown at a 2σ significance level. The spectra show some evidence of steepening as the nova brightens.

Further information on the spectral development is given in Fig. 2 where results from this experiment are plotted as a ratio to the low energy measurements made with the rotation modulation collimator (RMC) experiment described in ref. 1.

Whereas the channel 1: RMC ratio (Fig. 2a) indicates some initial hardening of the spectrum the channel 4 : channel 1 ratio (Fig. 2d) shows a gradual softening. The latter may also be noted in Fig. 1a–e where, after the initial section, the flux at 56 keV remains essentially constant whereas at 26 keV it increases by a factor of 3. But though the low energy intensity increases by a factor of 10 during the period covered, the results do not indicate any dramatic change in the spectrum.

In Fig. 3 we have combined the spectrum from the high energy experiment taken in period d (see Fig. 1) with three low energy points from the RMC experiment taken in the same period. A simple power law will not fit the data in the range shown. The results can be interpreted in terms of accretion of material from a normal star on to a compact object like a neutron star. Suppose that the X-ray flare-up is caused by a large change in the amount of accretion material available.

Fig. 3 Spectrum obtained by combining data from the high energy experiment (lower five points) with those from the RMC experiment (upper three points) measured during the same period (Fig. 1d). Errors are $\pm\, 1\sigma$ and 2σ for the upper limit based on counting statistics. a, 3 keV black body curve; b, 8 keV modified black body curve.
The outer layers of the accretion disk may be expected to emit low energy X rays according to a black body photon spectrum:

$$(dN/dE)_{BB} \propto E^2/[\exp(E/kT)-1]$$

More energetic photons produced in the deeper layers will emerge after scattering by electrons in a finite skin depth. The photon spectrum expected for this situation is [3,4]:

$$(dN/dE)_M \propto (dN/dE)_{BB}\{g[1-\exp(-E/kT)]/E^3\}^{\frac{1}{2}}$$

with a Gaunt factor $g \propto E^{-0.4}$.

The deepest layers, which correspond to the greatest gravitational energy, may radiate according to a thermal bremsstrahlung law, but the overlaying layers will only be transparent to the high energy tail.

Whereas a black body curve with $kT = 3\pm0.5$ keV fits the low energy data, a modified black body curve with $kT = 8\pm1$ keV is required for the high energy data. No simple single parameter curve will fit all the data. Our results therefore point to a multilayer, multitemperature source model.

Suppose that the increase in source intensity is attributable to an increasing flux, F, of material accreting on to a compact object. Then, for black body radiation, a consequence of Stefan's Law and the transfer of gravitational energy to thermal energy in a constant accretion disk geometry implies that

$$T_{BB} \propto F^{\frac{1}{4}}$$

and thus the spectral shape will only be weakly dependent on T_{BB}. Pringle and Rees have also found[4] a weak dependence on F of both the modified black body temperature and the point of transition between the two laws. The relatively constant shape of the spectrum during the flare-up of the source is thus consistent with an accretion model in a binary system.

We thank the groups at the Mullard Space Science Laboratory and the University of Birmingham for making results from the RMC experiment available to us.

Observations of A0535+26 with the Leicester sky survey experiment

THE Leicester University Sky Survey instrument with its field of view perpendicular to the spin axis was able to continue the study of A0535+26 after the spin axis experiments (see accompanying papers) were manoeuvred away on April 29. The source was close to the centre of our field of view on May 2, May 19 and June 1. On the first occasion the instrument was in a single channel mode (no spectral information) but eight-channel spectra between 2 and 18 keV were obtained on the second and third observations.

In addition to these three direct observations a measurable signal was obtained continuously from May 3 to May 31 while the source was outside the normal field of view of the instrument (FWHM 10°). This resulted from the brightness of the source at the higher energies; the detector efficiency combined
Fig. 1 The light curve of A0535+26 obtained with the Leicester University Sky Survey instrument. Points are mean daily intensities, errors are one sigma poissonian. The offsets at which the data were collected are indicated in degrees.

Table 1 Spectral parameters for $I = CE^{-\alpha}$ photons $(cm^2\ s\ keV)^{-1}$

Date	Nova Coefficient C	Index α	Crab Nebula Coefficient C	Index α
May 19	1.62	−0.8	12.0	−2.1
June 1	0.67	−1.1	10.2	−1.95

Statistical error in index is 0.1.

across a manoeuvre. The resulting light curve, consisting of daily averages, is shown in Fig. 1. On May 2, we find the intensity (3–18 keV) to be three times that of the Crab Nebula. Direct comparison with the pre-maximum light curve of the MSSL/Birmingham Modulation Collimator experiment (accompanying paper) must take account of the spectral hardness of the A0535+26 source since in the energy band of that experiment (2–8 keV) the relative strength of the transient source is less pronounced.

The peak intensity of A0535+26 seems to lie between the periods covered by the two light curves, occurring between April 29 and May 2. The main features are an initial slow fall, to May 16, followed by a sharper decrease in intensity, which is apparently close to exponential, over the following 15 d.

with the transmission through the wall of the collimator gives a mean response of ~1% at 12° offset decreasing to ~0.3% at 28° offset, for the observed spectrum of A0535+26. In this way, it has been possible to extend the Ariel V measurements of intensity to cover the whole period from the appearance of the source to June 1, leaving a gap of two days from April 29 to May 2.

The data from the various large offset observations were combined to give a continuous light curve. The method used was to correct those large angle measurements with adjacent direct measurements so that they fitted smoothly. For the data obtained between May 9 and May 17 no direct comparison was available and these data have therefore been adjusted so that the intensity changes smoothly from one offset to the next

Fig. 2 The two sets of eight-channel spectral data from A0535+26, together with predicted counts for the best fit power law spectrum. +, Observation with 1σ error; − − −, best fit prediction.

Fig. 3 The best fit input spectra with the deduced input photon spectrum. The May 19 spectrum is shown with (dashed) the effect of a low energy cutoff at 1.2 keV. *a*, May 19 with $E^{-0.8}$; *b*, June 1 with $E^{-1.1}$.

Thirty seconds of exposure to A0535+26 were obtained on May 19 in PHA mode, and 40 s on June 1. Both observations were timed to coincide with balloon observations of the source with high energy X-ray instruments (of Southampton University and MIT).

Spectral data for the two observations are plotted in Fig. 2, and Table 1 lists the optimum spectral parameters, together with those for the Crab Nebula measured simultaneously. The best fitting input spectra of A0535+26 are also shown in Fig. 3, here the relative measured intensities are given for each energy

channel, determined by comparing the observations with the input spectra folded through the detector response.

The spectrum obtained on May 19 is best characterised by a power law index of -0.8 with no absorption. The upper limit for the cutoff energy (1.2 keV) corresponds to a hydrogen column density of less than 10^{22} atom cm^{-2}. It must be emphasised that the power law fit over such a restricted energy range does not imply a non-thermal source mechanism and is used only to allow a convenient description of the spectral parameters. The June 1 spectrum is best fitted with a somewhat steeper power law of index 1.1, again with no measurable low energy attenuation. Thus if the spectrum is thermal it seems that the emission region has cooled significantly over a thirteen day period. Spectral data from the MSSL proportional counter viewing along the satellite spin axis is reported (J. Ives and J. Burnell, private communication) to show strong low energy attenuation during the rising part of the light curve, indicating that in this respect also the spectrum has changed significantly during the evolution of A0535+26.

Decay of X-ray source A0535+26

THE All-Sky Monitor (ASM) aboard Ariel V is a pinhole camera sensitive to X rays in the energy range 3–6 keV. It has an effective area of 0.6 cm² with a duty cycle of $\sim 1\%$ for a given source, and monitors more than 3π of the celestial sphere each orbit[1]. It is important to note that the regions of sky inaccessible to the ASM include the spacecraft spin axis and a band about the spacecraft equator, so that its field of view and those of the other five Ariel V experiments are mutually exclusive.

The transient source A0535+26 was first detected by another Ariel V experiment[2] during an extended spin axis hold in Taurus between days 103 and 119 of 1975, during which time a threefold increase in the emission from Cyg X-1 was observed[3,4]. When the spin axis was moved toward Cyg X-1, the Taurus region became accessible to the ASM, enabling us to study the decay of the transient source. When Cyg X-1 was next observed by the ASM from day 136, it had returned to its usual intensity of $\sim 1/3$ the Crab Nebula in the energy band 3–6 keV.

Figure 1 is the overall 3–6 keV light curve of A0535+26 when it was in the field of view of the ASM. Before spin axis hold in Taurus, the new source was not observable at a 2σ upper limit of $\sim 10\%$ of the Crab Nebula intensity (the latter was simultaneously measured at its stationary value of 1.4 cm⁻² s⁻¹). When first observable by the ASM on day 119, (April 29) the new source was $\sim 15\%$ more intense than the Crab Nebula, and stayed at this level for approximately one week. The source then decayed with an e-folding time of ~ 19 d until the Sun was too close to the source for unambiguous separation. When the Sun moved sufficiently far to allow the intensity of the source to again be interrogated, it was found to be unobservable (at $<10\%$ of the Crab Nebula).

The plateau region of the decay measured before day 126 is not unusual for transient X-ray sources. Similar plateau

effects in the decay just after maximum have been observed in the older transient sources Cen X-4 (ref. 5) and 2U1543–47 (ref. 6), as well as in the Ariel V transient source A1524–62 (ref. 7). Unlike these sources, however, the e-folding time for the Taurus source is considerably shorter than the $\gtrsim 2$ months which is typical of the others. The only other transient sources previously reported with comparably short lifetimes are 3U1735 −28 and A1118−61, with which the Taurus source shares spectral and temporal (pulsing) similarities (see accompanying papers and ref. 8). No temporal resolution finer than 100 min is possible with the ASM, nor is there any spectral resolution obtainable in the 3–6 keV acceptance window. The window is, however, insensitive to input spectral form[1], so that the light curve displayed for this band in Fig. 1 does not suffer from any spectrum-dependent systematic offset.
Fig. 1 Intensity measured from A0535+26 over approximately half-day accumulation times. The source is not in the usable field of view of the ASM where the abscissa is shaded. The 2σ upper limits before and after the measured points are determined primarily by the statistical accuracy in the measurement of the Crab Nebula, with which A0535+26 may be confused in the ASM data.

Finally, we note that the short-lived transients typified by 3U1735−28, A1118−61 and A0535+26 may be as much as an order of magnitude more frequent than longer-lived transients. The proximity to the galactic plane argues that these sources have a Population I distribution, and are >1 kpc distant. As discussed in ref. 7, their short lifetimes (and appearances in relatively congested regions of the plane) make them less easily detectable than the longer-lived transients. With an average luminosity at maximum of $\sim 10^{37}$ erg s⁻¹, their frequency may approach 100 yr⁻¹ in the Galaxy without conflicting with existing source or galactic ridge measurements. L. J. Dynamo generation in Mercury

OBSERVATIONS during the most recent encounter of the planet Mercury by Mariner 10 seem to have confirmed the existence of a small but intrinsic magnetic dipole of about 3×10^{-3} gauss $R_M{}^3$, where R_M is the radius of Mercury[1]. This field may be small enough to have a non-dynamo explanation[1,2], but it is nevertheless of interest to examine whether dynamo generation is possible for the present Mercury.

Siegfried and Solomon[3] have calculated models for the interior and thermal evolution of Mercury. In these models, the cosmochemical calculations of Lewis[4] were used to constrain the composition. They concluded that Mercury is most likely differentiated[5], with a Fe–Ni core extending out to about $0.7R_M$, and a silicate mantle. I have tested their models for four necessary (but possibly not sufficient) conditions for magnetohydrodynamic dynamo generation.

First, dynamo generation requires that the interior be at least partially fluid, since solid-state convection is too slow for dynamo generation. In the models of Siegfried and Solomon, radioactive heat sources in the silicate mantle may be sufficient for fluidity in a region extending from about 200 km to about 800 km below the planet surface. The metallic core is either partly or entirely solid, depending on when differentiation took place.

Second, dynamo generation requires an energy source that drives a flow of the fluid relative to a rigidly rotating planet. Thermal convection seems to be the only plausible energy source, since precession is insignificant[2], and the other possible sources are just as unsatisfactory for Mercury as they are for the Earth[6]. The Siegfried and Solomon models assume that all the radioactive heat sources are in the mantle, so that thermal convection occurs in a 600 km thick silicate layer, but not in the stably stratified metallic core. Other heat sources in the core (latent heat, gravitation) seem to be insufficient to drive the temperature gradient superadiabatic and initiate convection. The thermal conductivity of the metallic core is sufficiently high that convection would only occur if about half of the radioactive heat sources reside in the core. One possiblity is that Mercury has a similar fraction of ^{40}K as Lewis[4] proposes for the Earth's core. This would violate Lewis's cosmochemical arguments, since potassium compounds are too volatile to condense from the primitive solar nebula at Mercury's distance from the Sun.

Third, dynamo generation requires that the magnetic field diffusion time, τ_M, exceeds the characteristic fluid flow (convective) time scale τ_C. The ratio of τ_M to τ_C is known as the magnetic Reynold's number. In the convecting silicate layer, simple mixing length theory[7] predicts a convective velocity of 0.1 cm s^{-1} for the expected heat flux[3] of about 50 erg cm^{-2} s^{-1}. A similar estimate applies to the Earth's outer core[8] and is unlikely to be incorrect by more than an order of magnitude. The corresponding convective time scale is $\tau_C \sim$ 1–10 yr. The magnetic field diffusion time is given by[2]

$$\tau_M \approx 10^{-9} \sigma l^2 \text{ s} \tag{1}$$

where σ is the electrical conductivity in Ω^{-1} cm^{-1} and l is the smallest dimension of the convection region. The requirement $\tau_M > \tau_C$ implies $\sigma > 10$–100 Ω^{-1} cm^{-1}. This would be easily satisfied in the core ($\sigma \sim 10^3$ or 10^4 Ω^{-1} cm^{-1}) but not in the semiconducting silicates. In the Siegfried and Solomon models,

the temperature is at most about 2,100 K in the mantle. At this temperature, the conductivity in the Earth is probably less than 0.1 Ω^{-1} cm^{-1} (ref. 9). Cosmochemical arguments[4] indicate that the Mercurian mantle should be somewhat different from the Earth, with MgSiO$_3$ prominent, but a generous extrapolation of high temperature laboratory experiments on enstatite[10], indicates that a conductivity in excess of 1 Ω^{-1} cm^{-1} is very unlikely. This figure is for solid materials, but these minerals (unlike pure germanium or silicon) are not likely to change their short range order or conductivity dramatically upon melting[11]. (The conductivity may increase by as much as an order of magnitude, but certainly not several orders of magnitude.) I conclude that the liquid silicate conductivity is probably inadequate for dynamo generation. I note that generation in a thin silicate layer near the surface of the planet is likely to lead to a substantially non-dipolar field at the planetary surface.

Fourth, dynamo generation requires a fluid flow of sufficient complexity to satisfy Cowling's theorem[12]. In particular, the requirement of a non-axisymmetric field is usually interpreted to imply a need for "rapid rotation" of the planet (although other alternatives may exist[13]). Actually, "rapid rotation" only means that the Coriolis force has an important effect on convective flow. A measure of this is the ratio of inertial to Coriolis forces, $v/\Omega l$, where $v \sim 0.1$ cm s^{-1} is a typical convective velocity in the absence of rotation, and $\Omega \sim 1 \times 10^{-6}$ s^{-1} is the planetary angular velocity. For $l \lesssim 10^5$ cm, this ratio (which is a nominal Rossby number for the flow) is less than unity, and the Coriolis force is important. For the largest scale convective flows in Mercury, $l \approx 10^7$ cm, so that in this respect Mercury is a rapidly rotating planet. The requirements of Cowling's theorem may then be satisfied because of the effect of planetary rotation alone.

In a more complete theory, such as that attempted by Parker[14], and more recently in rigorous work by Busse (unpublished), the criterion for dynamo generation is generally more stringent than the simple ones we have discussed. A complete theory would also make a prediction for the field magnitude. A feature of the Busse theory is that if the core is convecting, then the small field of Mercury would be a consequence of the slow planetary rotation. Unlike the Earth, the ohmic dissipation in Mercury is likely to be completely insignificant compared with any important energy source such as radioactivity.

I conclude that a literal interpretation of the cosmochemical calculations of Lewis[4] implies that dynamo generation in Mercury is improbable. Generation would be possible if the metallic core were contaminated with substantial amounts of radioactive material. It would then follow that not all the material that comprises Mercury condensed from the solar nebula at the present distance of Mercury from the Sun. The magnitude of the field and any future multipolar analysis (such as might be achieved by an orbiter) will be important in determining the field source.

Fracture mechanism of Henbury meteorite by separation along surfaces of shear faulting

THE smallest Henbury meteorite crater contained[1] a massive iron that had broken into four pieces weighing 132.7, 54.4, 10.9 and 2.3 kg, respectively. When these four pieces were excavated from the depths of the crater they were found to be still juxtaposed to one another. We have studied a 5 kg, 20×40 cm slice (BM 1932, 1359) taken from the largest of these pieces. We have also prepared and studied sections cut from a number of pieces of 'shrapnel' from a Henbury crater, weighing about 100 g and purchased from the American Meteorite Laboratory.

The macrosection BM 1932, 1359 is traversed by a number of fault displacements, most of which are continuous across the whole section and lie approximately parallel to an outer edge of the section. This suggests that, in this instance, the fracture surfaces could represent the extreme situation in which limited shear displacement gives way to physical separation along the fault surface. This macrosection is too large for satisfactory microscopic examination, and, consequently, the fracture mechanism was explored using the smaller shrapnel fragments. In each instance slip-fault displacements were encountered within the shrapnel pieces, and in one instance an internal crack was found to merge continuously into a pronounced displacement fault. The most convincing evidence for fracture by separation along the surfaces of shear faults, however, comes from those pieces of shrapnel that were not reheated significantly during break-up. In those cases, the bulk of the kamacite (αFe–Ni) is shock hardened but not recrystallised. Shear-displacement surfaces within these specimens were revealed (by Nital etch) as continuous traces of fine grained (1–5 μm) recrystallisation in the kamacite, similar to geological mylonitisation zones. The 'throw' of the fault varies from a few micrometres to several millimetres and is best seen where particles of taenite (γFe–Ni) are cut and displaced. The Nital etch did not reveal recrystallisation in the taenite and, consequently, the metallographically visible 'thickness' of the shear effect in taenite was limited to the apparently sharp geometrical surface of displacement. But the heat that is generated during the rapid propagation of the displacement fault causes the shock-hardened kamacite to recrystallise within a zone of finite thickness on either side of the surface of displacement. The visible width of this recrystallised zone varies from 1 to 20 μm according to the energy input at the particular fault.

We have examined a number of sections of Henbury 'shrapnel' in which relics of this 'mylonitised' kamacite are present at the outer fracture surfaces. To identify these relics of heat effect with shear mylonitisation, it is necessary to eliminate the possibility that the surface heating was produced by ablative friction during high-velocity flight through the atmosphere[2]. It is possible to do this since an ablative heat alteration zone[3] is composed of coarse ragged α_2 (martensitic) product that indicates reheating above 850 °C, whereas, by contrast, the effect observed at the surface of Henbury shrapnel is a fine-grained, recrystallised α (non-martensitic): the product of a much milder heating of shock-hardened kamacite.

The presence of shocked kamacite in Henbury shrapnel indicates that the fragmentation took place under conditions of shock loading with a shock pressure of at least 130 kbar. The shear faults seem to be superimposed upon the shock-hardened structure and, therefore, seem to have formed subsequently.

Once the fault has commenced to move on a selected surface it is likely to continue to do so because of the local generation of heat and the superplastic lubrication of the small kamacite grains in the mylonitised zone. The factors that cause a particular surface to be selected for shear faulting are, however, more difficult to specify, but, in general terms, they must arise from unbalanced shear forces as the projectile adjusts itself rapidly to the complex array of shock waves that accompany high-velocity impact with the Earth.

Mechanism of the oxidation of ethylene by palladium(II)

THE oxidation of ethylene to acetaldehyde by aqueous palladium chloride forms the basis of the Wacker process. The kinetics and mechanism of this reaction have been extensively studied for ethylene and other olefins, and most authors assume that the formation of a *cis* hydroxoethylene-palladium complex is an essential step in the reaction[1–4]. We propose here a new mechanism by which the *trans* intermediate, $[C_2H_4Pd(OH)Cl_2]^-$, may directly yield the palladium σ-hydroxyalkyl species without the necessity of *trans–cis* isomerisation or the attachment of a fifth ligand.

It is widely accepted that the first steps of the reaction are the formation of a π-ethylene complex, $[C_2H_4PdCl_3]^-$ (Fig. 1a) the palladium analogue of Zeise's salt, followed by the aquation and dissociation of the *trans* aquo complex to give $trans[C_2H_4Pd(OH)Cl_2]^-$ (Fig. 1b). A *trans* to *cis* isomerisation is then assumed with the subsequent insertion of the ethylene into the palladium–hydroxide bond (a *cis*-migration rearrangement) giving a palladium σ-hydroxyalkyl molecule $[PdCl_2CH_2CH_2CH_2OH]^-$ (Fig. 1c) which yields acetaldehyde by a palladium assisted hydride shift. Little attention[5,6] has been focused on the isomerisation of $[C_2H_4Pd(OH)Cl_2]^-$ although it has been suggested[1,7] that a dihydroxo species is involved as an intermediate. An alternative view[4,8,9] is that a five-coordinate palladium(II) species is involved, thus avoiding the requirement of the *cis* configuration. The kinetic evidence for these latter proposals has been obtained at low chloride and acid concentrations and is somewhat unconvincing in the normal concentration range so that the isomerisation of $[C_2H_4Pd(OH)Cl_2]^-$ remains controversial.

We have already suggested[10] a model for catalysis by nickel (II) complexes, which was based upon the facilitation of certain molecular vibrations by the vibronic coupling of the highest filled molecular orbital with vacant molecular orbitals derived

Fig. 1 Compounds occurring during the oxidation of ethylene by palladium(II): *a*, π-ethylene complex; *b*, $trans[C_2H_4Pd(OH)Cl_2]^-$; *c*, the palladium σ-hydroxyalkyl molecule $[PdCl_2CH_2CH_2OH]^-$.
from ligand π-acceptor orbitals. Application of that model to the Wacker process is straightforward. The *trans* complex $[C_2H_4Pd(OH)Cl_2]^-$ is a planar molecule with C_{2v} molecular symmetry. The out-of-plane YMZ bending vibration of a MX_2YZ molecule of C_{2v} symmetry with the coordinate axes as shown in Fig. 1 has b_2 symmetry. If this vibration is facilitated in $[C_2H_4Pd(OH)Cl_2]^-$ then the C_2H_4 and OH^- ligands will move closer together as the molecule distorts towards a pseudo-tetrahedral structure allowing a ready path for the insertion of ethylene into the Pd–OH bond. Molecular orbital calculations are available[11,12] for Zeise's salt, $[C_2H_4PtCl_3]^-$, and because of the marked similarity of the electronic structures of $PtCl_4{}^{2-}$ and $PdCl_4{}^{2-}$ (ref. 13) we assume that the general qualitative features of the Zeise's salt calculations will be applicable to $[C_2H_4Pd(OH)Cl_2]^-$. Both calculations agree that the highest filled molecular orbital is of b_1 symmetry, although the exact nature of the orbital is debatable. Facilitation of the b_2 vibration may occur by the vibronic coupling mechanism if a vacant molecular orbital of a_2 symmetry ($b_1 \times b_2$) lies close enough to the filled b_1 orbital to lead at least to a reduction in the force constant of the b_1 vibration. Such an orbital is available: it is largely a non-bonding orbital of the metal complex derived from the molecular orbitals of the ethylene ligand. Symmetry considerations are thus consistent with the possible facilitation of the b_2 molecular vibration and the ethylene and hydroxide ligands may approach each other by the out-of-plane bending of the $[C_3H_4–Pd–OH]$ unit. Attack by the hydroxide on the π* orbitals of ethylene may occur either in an approximately end-on situation with the carbon atoms and the oxygen atom lying in the *zy* plane or, if the ethylene molecule is allowed to rotate about the palladium–ethylene axis, at the centre of the double bond. If, as suggested by Hartley[14], the palladium–olefin bonding is weaker than the platinum–olefin bond then attack on the largely vacant π* orbitals may be more likely leading to *cis*-insertion through a four membered metallocycle.

This mechanism provides an alternative to the *trans–cis* isomerisation which, together with rotation of the olefin, is a prerequisite for the *cis*-insertion reaction which is generally accepted at present.

Mechanisms of reactions at square planar metal centres

SQUARE-PLANAR platinum(II) complexes have in the past been found to react by associative mechanisms (see refs 1 and 2). This has been of some comfort to the proponents[3] of the '16 and 18 electron rules', which state that all stable transition metal complexes and intermediates in the reactions of such complexes should have either 16 or 18 electrons in the transition metal's valence shell. We point out here that though substitution reactions at platinum(II) occur by an associative route, reactions between ligands coordinated to platinum(II)—here called combination reactions—occur by a dissociative route that violates the '16 and 18 electron rules'.

Substitution reactions involve a trigonal bipyramidal transition state (reaction 1) and not a square pyramidal one, and in the trigonal bipyramidal transition state the leaving group

$$A_T - M - L + E \rightleftharpoons A_T - M \begin{smallmatrix} L \\ E \end{smallmatrix} \rightleftharpoons A_T - M - E + L \quad (1)$$
(L), the entering group (E) and the *trans*-ligand (A_T) all lie in the trigonal plane with angles of about 120° separating them.

Combination reactions, such as that involved in the insertion of olefins into platinum(II) hydride bonds to give platinum(II)-alkyls[4,5] and that involved in the insertion of carbon monoxide into platinum(II)-alkyl bonds to give acyl complexes[6,7], occur by a dissociative route (reaction 2) in which insertion occurs

$$L_2Pt(A)(B) \xrightarrow{+E} [L_2Pt(AB)] \rightarrow [L_2Pt(AB)E] \quad (2)$$
first to give an intermediate that is either 3-coordinate or 4-coordinate with the fourth coordination site occupied by a solvent molecule.

A similar mechanism has been suggested for the insertion of isocyanides into platinum(II)-alkyl and aryl bonds[8], and
Fig. 1 Platinum(II) (methyl) acetylene complexes (see text).

it is likely that the insertion of olefins and acetylenes into platinum(II)-alkyl bonds follows the same route since an essential prerequisite for reaction is a 4-coordinate complex in which the alkyl and olefin groups are *cis* with respect to each other[9]. It is noteworthy in this connection that 5-coordinate complexes in which the alkyl and acetylene groups are *cis* with respect to each other are reluctant to undergo insertion. Thus the five-coordinate complexes in Fig. 1*a*, in which the Me–Pt–acetylene bond angle equals 88.5° (ref. 10), and in Fig. 1*b*, where L = PMe₂Ph, do not give insertion, whereas the five-coordinate complex in which L = AsMe₂Ph (Fig. 1*b*), and the four-coordinate complex shown in Fig. 1*c*, do give insertion.

Nucleophilic attack on olefins coordinated to platinum(II) and palladium(II) can occur either on the same side as the

metal (cis-attack; Fig. 2a) or on the side remote from the metal (trans-attack; Fig. 2b). Cis-attack will almost invariably involve prior coordination of the nucleophile to the metal. This coordination can, in principle, occur in two ways: first, by displacement of one of the ligands bound in the square-plane cis to the olefin giving a 4-coordinate intermediate; second, at one of the two axial sites giving a 5-coordinate intermediate. Analysis of the available evidence would suggest that cis-attack always involves the first of these two possible mechanisms. Thus cis-attack has been shown by stereo-chemical analysis of the products to occur when phenyl[12,13], carboxymethyl[12], chloride (sometimes)[14,15] and acetate (in the absence of chloride)[16] are the attacking nucleophiles. Kinetic investigations of the chloride[14] and acetate[16] reactions have shown that cis-attack involves reaction of a ligand originally bound to a site in the square-plane and does not involve an extra ligand coordinated to an axial site. Thus, cis-nucleophilic attack on olefins involves a mechanism essentially similar to that given in reaction 2 for the insertion type of combination reaction.
Fig. 2 Possible modes of nucleophilic attack on metal–olefin complexes: a, cis-attack, b, trans-attack.

Clearly, it is of interest to ask why substitution reactions involve a trigonal bipyramidal intermediate whereas combination reactions apparently involve reaction between two ligands bound in the square-plane. Though no definitive answer can be given two salient points can be made:

First, ligands bound in the square-plane lie closer to one another (~90° apart) than ligands in a trigonal bipyramidal intermediate where the incoming ligand and the ligand being attacked would presumably lie in the trigonal plane (~120° apart) by analogy with their geometry in substitution reactions. The fact that the methyl and acetylenic ligands in the trigonal bipyramidal complex (Fig. 1a) do not combine is of interest in this connection as they lie at almost 90° to each other. It is, however, possible that in this case reaction is not favoured electronically.

Second, coordination of ligands in the square-plane clearly involves a much stronger interaction between the ligand and the metal than does axial coordination. This facilitates combination reactions since coordination weakens the multiple bonds in unsaturated ligands such as carbon monoxide, olefins and acetylenes, because of the π-back donation of electron density to the ligand antibonding orbitals. That this bond-weakening is important is demonstrated by the stability of [(Et₂B(pz)₂)Pt(Me)(ac)] (Fig. 1c), where ac is PhC≡CMe or PhC≡CPh, compared with the rapid insertion that occurs when attempts are made to prepare the analogous complex with the strongly π-accepting acetylene, CF₃C≡CCF₃ (ref. 9).

It is far from clear why both substitution and combination reactions, on the basis of current experimental evidence, seem to spurn the square-pyramidal intermediate, particularly in view of the low energy barrier separating it from the trigonal bipyramidal configuration[17].

Nucleophilic attack on olefins coordinated to metal ions

occurs most readily when palladium(II) is the activating metal ion; other metal ions such as platinum(II) are much less active as promotors. A number of reasons have been advanced[18] to account for this.

First, palladium(II)–olefin complexes may be formed more rapidly than platinum(II)–olefin complexes.

Second, π-back donation from metal to olefin is likely to be less in the palladium(II)–olefin complex than in the platinum-(II)–olefin complexes because of the higher ionisation potentials of the valence shell electrons of palladium(II). Thus, the electron density around the olefinic double-bond would be less when it was coordinated to palladium(II) than to platinum(II), and so olefins coordinated to palladium(II) would be more susceptible to nucleophilic attack.

Third, the palladium(II)–olefin bond is weaker than the platinum(II)–olefin bond so that the activation energy of any rearrangement process that may be necessary during the course of the reaction will be lower for palladium(II)–olefin complexes than for platinum(II)–olefin complexes.

Fourth, palladium(II) can more readily expand its coordination sphere to accept a fifth and sixth ligand than can platinum(II). This would allow the incoming nucleophile to coordinate to palladium(II) before attacking the olefin, thus lowering the activation energy of the nucleophilic attack.

The fact that palladium(II)–olefin complexes such as [(C₂H₄)PdCl₂]₂ (ref. 19) and [Pd(CH₂=CH-CH₂NH₃)Cl₃] (ref. 20) are hydrolysed instantaneously, whereas their platinum(II) analogues[21,22] are hydrolysed, respectively, only on heating and not at all, suggests that though the first of those reasons may be important, it is by no means the limiting factor. Kinetic and stereochemical evidence suggests that the last reason is irrelevant because coordination of the attacking nucleophile to a fifth position out of the square-plane is abortive and does not precede the combination reaction between olefin and nucleophile.

We have recently carried out experiments to distinguish between the remaining reasons using methoxide as the nucleophile, as it is known to attack olefin complexes trans with respect to the metal[23], thus eliminating any complications caused by the greater preference of this nucleophile for coordination to one or other metal.

1. When platinum(II)–olefin complexes such as [(PPhEt₂)-PtCl₂(C₂H₄)] are treated with methoxide ion, the principle reactions involve displacement of ethylene from the platinum(II) complex to yield either [(PPhEt₂)PtCl₂]₂, or [(PPhEt₂)-PtCl₂(OMe)], which subsequently decomposes with the elimination of formaldehyde; nucleophilic attack on the olefin to yield methylvinylether is only a minor reaction[24].

2. Treatment of [(C₂H₄)MCl₂]₂ with methanolic sodium carbonate gave a 70% yield of CH₃CH(OMe)₂ and no detectable C₂H₄, CH₂=CHOMe or HCHO when M was palladium; but when M was platinum only C₂H₄ and HCHO (formed by decomposition of the initially formed platinum(II)–methoxy complex) were detectable. [CH₃CH(OMe)₂ is formed by nucleophilic attack by MeO⁻ at the β-carbon atom of -Pd-CH₂-CH₂OMe formed by nucleophilic attack on the co-ordinated ethylene.] Both experiments indicate that platinum(II)–olefin complexes readily undergo substitution reactions with methoxide ion, which suggests that the third reason outlined cannot be of major importance in determining the relatively low susceptibility of platinum(II)–olefin complexes to nucleophilic attack. It thus seems that palladium(II)–olefin complexes are highly susceptible to nucleophilic attack because the correct balance is achieved between the loss of electron density from the olefin pπ-bonding orbital through the olefin to the metal σ-bond, and the gain of electron density in the olefin pπ*-antibonding orbital through the metal to the olefin π-bond. Too much π-back donation prevents nucleophilic attack, as shown by platinum(II) and even more effectively by platinum(0), and too little π-back donation is equally effective in preventing nucleophilic attack as shown by silver(I).

Search for isotope effects in heavy-ion diffusion in liquids

THERE is some controversy as to the existence of isotope effects in liquid diffusion in which isotopically labelled molecules diffuse in the same liquid medium. Friedman[1] has predicted from the standpoint of the correlation-function theory of diffusion that there should be little or no effect and certainly nothing approaching the inverse square mass relationship and this has been shown[2,3] to be true for organic liquids. Miller[4] claims, however, that uranyl ions diffusing in aqueous solution do show an isotope effect and also that heavier ions diffuse faster than lighter ions. He attributed the phenomenon to kinetic effects in the molecular diffusion process; in particular, to persistence of velocities and backscattering. The effects should apply generally to heavy ions diffusing in light

solvents, and in view of the reported separation factors the difference in diffusion coefficients may be expected to be measurable. I report here the results of experiments designed to test this supposition.

The heavy ions chosen for study were the pairs $^{125}I^-$, $^{131}I^-$ and $^{134}Cs^+$, $^{137}Cs^+$; in the former case the absolute mass difference is double that in the uranyl ion case. Both these ionic species are considered to be unhydrated so that their effective masses in aqueous solution are known fairly reliably. Diffusion coefficients for these ions were measured using the magnetically stirred diaphragm cell method[5]. The conditions which were varied in the course of these experiments were temperature, concentration and the type of diffusion. One set of tracer-diffusion results is shown in Table 1. In this first type of experiment, the solutions were uniform throughout the cell and there was a gradient in the trace radioactive components only.

Two further sets of binary diffusion experiments were also carried out. In these experiments there was a gradient in the salt concentration as well as in the radioactive component. In one case, 0.5 M KCl was allowed to diffuse into water and radioactive Cs^+ ions were added as tracer; in the other, 2.0 M KI diffused into water accompanied by radioactive I^- ions. It will be appreciated that the conditions of these two sets of experiments approach more closely those used by Miller[4] than do the tracer-diffusion set used in the earlier experiments. The results are shown in Table 2.

The results (Tables 1 and 2) indicate that within the 'average error' of about 0.2% there is no detectable isotope effect for these heavy ions under a variety of conditions. Each experiment in which both KCl and trace Cs^+ ions were diffusing into water could be internally calibrated since the diffusion coefficients of the system KCl-water were accurately known[5]. This refinement allows diffusion coefficients to be specified to within ±0.1% for this system.

The high separation factors reported in Miller's original paper[4], particularly those recorded when agar gel was used as the diffusion medium, were caused by transient diffusion effects and were not related directly to the steady state diffusion coefficients (L. Miller, personal communication). Miller[6] has

Table 2 Coefficients of isotopic ions in binary diffusion at 25 °C

Diffusing isotope	Medium	Mean $D \times 10^9$ ($m^2 s^{-1}$)	No. of expts	Average deviation from mean
$^{134}Cs^+$	0.5 KCl diffusing into water	1.871	3	±0.002
$^{137}Cs^+$		1.872	3	±0.003
$^{125}I^-$	2.0 M KI diffusing into water	2.062	3	±0.003
$^{131}I^-$		2.064	4	±0.002

Table 1 Tracer-diffusion coefficients of isotopic heavy ions in aqueous solution

Diffusing isotope	Medium	Temperature (°C)	Concentration (mol l^{-1})	Mean $D^*_i \times 10^9$ ($m^2 s^{-1}$)	No. of experiments	Average deviation from mean
$^{125}I^-$	KI	10	0.5	1.381	3	±0.004
$^{131}I^-$	KI	10	0.5	1.377	3	±0.006
$^{125}I^-$	KI	10	3.0	1.393	5	±0.002
$^{131}I^-$	KI	10	3.0	1.394	5	±0.002
$^{125}I^-$	KI	25	0.5	1.992	4	±0.005
$^{131}I^-$	KI	25	0.5	1.985	5	±0.007
$^{125}I^-$	KI	25	2.0	1.952	6	±0.004
$^{131}I^-$	KI	25	2.0	1.950	5	±0.004
$^{125}I^-$	KI	45	0.5	2.899	4	±0.010
$^{131}I^-$	KI	45	0.5	2.900	3	±0.003
^{134}Cs	KCl	25	0.5	1.935	5	±0.003
^{137}Cs	KCl	25	0.5	1.930	4	±0.002

derived from the transient separation data the difference between the diffusion mobilities of $^{235}UO_2^{2+}$ and $^{238}UO_2^{2+}$ ions and found it to be of the order of 0.25%. This latter result is compatible with those reported here because were a persistence mechanism responsible, it would affect less those ions which have a mass considerably below that of the uranyl ion. In any event, both studies show that isotopic effects in the diffusion of heavy ions in light solvents are either nonexistent or very small.

Stereoillusion based on visual persistence

IF a moving vertical line is stroboscopically lit, it seems to undergo a multiplication, so that at any instant of time it is perceived as a series of lines, spread out in the direction of motion[1-3]. If the illumination going to the eye is reduced, the apparent multiplication increases[3], suggesting possibly that the effect is a function of sensory integration time or "persistence" as it is affected by adaptation state of the eye[2]. Since the adaptation conditions of the two eyes are substantially independent[4], it is interesting to ask what we should see if a stroboscopically moving target were viewed with a filter over one eye only, and the different numbers of apparent bars stereoscopically fused. In these conditions more bars should be signalled by the filtered than by the unfiltered eye, and it is not obvious what the fused percept will be.

To investigate this problem I used a haploscopic display in which the number of bars presented separately to the two eyes was controlled on an oscilloscope (CRO) display by a digital computer. One eye was presented with a single vertical bar (5° high) that moved in discrete steps of 0.67° every 40 ms. The bar can be thought of as a target moving at 1.0 Hz, peak-to-peak amplitude 9.5°, and stroboscopically illuminated at 25 Hz. The other eye was presented with two bars, one of which corresponded in spatial position with the bar in the first eye, and the second with the preceding position of that bar (Fig. 1). Fusion of the left and right eye displays was aided by means of a stereoscope positioned in front of the CRO. Observers were instructed not to "track" the apparently moving targets, and to aid steady fixation a vertical white (0.4 log foot lambert) line was provided in the optical plane of the CRO screen.

The appearance of the fused display was that of several bars travelling in an orbit around the fixation line. The number of lines was difficult to count accurately, but it was certainly often in excess of two. These bars moved as a unit, giving an impression of a picket fence in motion. There was a convincing impression of depth to the motion, the "fence" appearing to rotate in a clockwise orbit (as if viewed from above) with the extra bar in the left eye, and anticlockwise with the extra bar in the right eye. To demonstrate this, a random series of trials was programmed in which the extra bar appeared in the left and right eye, and observers (colleagues and undergraduates in the laboratory) pressed a button on each trial to indicate whether they saw clockwise or anticlockwise motion. The experimenter was not in the room. Responses of the observers very seldom varied from the rule that an extra left-eye bar produced clockwise motion, and an extra right-eye bar anticlockwise motion.

The direction of this effect is the same as that of the "Pulfrich"
Fig. 1 Schematic representation of the display at successive times ($t_0, t_1 \ldots t_9$). In the actual display the left and right halves were presented separately to the left and right eyes and fused to give a single percept. In this particular representation the right eye has an extra bar, which is in a "trailing" position.

effect"[5], in which a continuously visible target seems to move in a clockwise orbit when viewed with a left-eye filter. If we recall that a reduction in illumination produces greater visual persistence, the facts are strongly suggestive of a common mechanism for the Pulfrich stereophenomenon and the new illusion reported here. To support this hypothesis, a neutral density filter in front of one eye was added to the display described above. With a suitably chosen filter (1.0 log units) in front of the left eye we expect depth to be enhanced when the extra bar is in the left eye, and reduced when it is in the right eye; conversely with the filter over the right eye. Observers were given a random mixture of trials with extra bar in the left and right eyes, first with the filter in front of one eye (40 trials) and then with the other eye filtered (40 trials). On each trial they were asked to say whether they saw clear depth (and in which direction) or whether the effect was weak. Since all observers had previously seen the strong effect without a filter, and since it was very quickly obvious to them that depth was absent or much reduced on a proportion of the trials, these judgments were accomplished without difficulty. The results, shown in Fig. 2, were as expected; clear depth was seen only when the Pulfrich, (filter) and persistence (extra bar) effects reinforced one another; when they were in opposition the depth effect was much reduced or absent.

Although these considerations favour a relationship between

Fig. 2 Mean data for three observers who saw displays like those illustrated in Fig. 1, but with a 1.0 log unit filter over one eye. When the filter was over the eye that had the extra bar, the percentage of trials on which the observer reported a clear depth effect (ordinate) was large. When the filter and the extra bar were in opposite eyes, there were many fewer confident depth judgments.
the Pulfrich effect and the effect reported here, the latter is not to be explained either by existing knowledge of static stereopsis, or by the conventional explanation of the Pulfrich effect itself. The most nearly related stereoscopic effect is that of "Panum's limiting case". in which a single bar in one eye is fused with a pair of bars in the other eye, to yield an impression of two bars at different distances. This is what will be seen if the two halves of Fig. 1 are fused in a stereoscope. In my display, however, there was not an impression of lines at different distances, but rather of a set of lines moving in the same orbit. It seems, then, that there is an important difference between the dynamic and static versions of the "limiting case". Similarly, Fertsch's classical explanation[5] of the Pulfrich effect in terms of latencies will not apply here. Fertsch proposed that the filtered eye signalled the actual position of the target at some later time than the unfiltered eye. In my experiments, however, the most advanced (leading) edge of the left and right-eye targets was identical, and differed only in one eye having a longer "trailing" edge. This reinforces other objections that have been advanced against the latency interpretation of the Pulfrich phenomenon[5]. The alternative explanation of filter-induced depth suggested by the present experiment is that the filter causes a trailing edge disparity between the two eyes, and that depth is determined, either by fusion of trailing edges of the signals, or after some spatial averaging has taken place. The possible importance of trailing edge information was realised long ago by Edmund[6]: "Of a movable object, the one eye particularly sees the posterior contour trailing behind, and that is the reason why one thinks that the image of the one eye really succeeds that of the other eye and thus, as Pulfrich's observation shows, receives a false stereoscopic impression."

I thank J. Mollon for discussions and Professor Zangwill for facilities.

Preferential inactivation of the paternally derived X chromosome in the extraembryonic membranes of the mouse

RANDOM X inactivation makes the female mammal a natural mosaic for clones of cells having either the maternally derived X (X^m) or paternally derived one (X^p) which is genetically inactive[1]. There are, however, instances in which inactivation is obviously not random[2–7]. Non-randomness was inferred from studies made on differentiated cells remote from early embryonic cells in which inactivation occurred. Thus it is not clear whether the randomness of the X inactivation process was influenced or whether cell selection occurring after random inactivation was responsible for the ultimate non-random appearance[4–9]. In an effort to determine the embryonic stage at which the X chromosome initiates differentiation in famale mouse embryos heterozygous for Cattanach's translocaton[10], we found that the mosaic composition was consistently biased in extraembryonic membranes, whereas it was not necessarily so in the embryonic body.

Cattanach's translocation comprises an insertion of a segment from chromosome 7 into an X (refs 11 and 12), making the X (X^t) the longest element in the cell[13]. In somatic cells from female heterozygotes, either X^t or the normal X (X^n) replicates asynchronously with the remaining chromosomes of the complement[14,15]. This is consistent with the c-variegation in their coats[10]. Since asynchronous replication of one X chromosome is a cytological manifestation of genetic inactivity[16,17], we used this criterion to ascertain the inactive X in the present study.

The allocyclic X chromosome of the mouse usually becomes late replicating by 8.5 d of gestation[18]. Before this stage the same chromosome initiates DNA replication later and finishes it earlier than the rest of the complement[18], which renders replication in the middle of the S phase more active in the former than in the latter. We expected, therefore, that the acridine orange (AO) fluorescence technique after the incorporation of 5-bromodeoxyuridine (BrdU)[19,20], for an appropriate period before fixation may allow not only the identification of every autosomal pair but also the distinguishing of the allocyclic X chromosome from the isocyclic one Preliminary tests, in fact, proved the technique satisfactory; the allocyclic X was identified in more than 80% of metaphases from 7.5-d embryos as the palest red (Fig. 1) or the brightest green element in the complement depending primarily upon the amount of incorporated BrdU[20].

The 6.5-d-old embryo consists of two germ layers with minimal mesodermal elements, and the proamniotic cavity and the exocoel join to form an elongated narrow lumen. The whole embryo, being small at this stage, provided just enough material for a single slide Either X^t or X^n showed differential staining (Fig. 2) in the heterozygous females from reciprocal crosses between the chromosomally normal (A/He) mice and the animals bearing a translocation. Surprisingly, however, the allocyclic X was predominantly paternal (Table 1). The proportion of cells with an allocyclic X^p closely agreed in heterozygous females from both types of crosses. This may imply that the decision of X inactivation was not necessarily random, otherwise the random decision was hidden by the overgrowth of cells having the isocyclic X^m. Before this point is made clear, it seems essential to know the distribution of two types of cells with either the allocyclic X^p or X^m in the embryo. If both cell types distribute unevenly, certain recognisably large areas consisting of a single cell type could be expected. We looked for such specific embryonic regions in embryos at 7.5 and 8.5 d of gestation.

The 7.5-d embryo, at late egg cylinder stage, is divided by the amnion into the embryonic and extraembryonic areas, which were studied separately. The mosaic constitution of both regions proved outstandingly different. The allocyclic X^p was found in less than 70% of cells from the embryonic area, whereas it was found in more than 90% of cells from the extraembryonic area. The decreased overall frequency of cells with the allocyclic X^p at this stage might be attributed to the increase of the embryonic elements relative to the extraembryonic ones in comparison with the earlier stage.

Mosaic composition was studied in five well-defined regions isolated from 8.5-d embryos, the anterior and posterior halves of the embryonic body, the allantois, the yolk sac, and the chorion. Cells with the allocyclic X^p were found to outnumber those with the allocyclic X^m in extraembryonic membranes, whereas the former was only slightly in excess of the latter in the embryonic body as such. The extreme instance was the chorion where the X^p seemed allocyclic in more than 95% of the constituent cells. Since intermingling of cells from different embryonic structures could not be rigorously excluded by the present dissection procedures, it is possible that the chorion is composed exclusively of cells in which X^m is active.

It therefore seems probable that X^p is mostly inactive in the chorion and the yolk sac of embryos heterozygous for Cattanach's translocation. Evidently, we are not dealing with the O^{hv} type mutation which makes the inactivation
Fig. 1 Verification of the BrdU–AO technique in ascertaining the allocyclic X chromosome in the mouse (T6 heterozygote in this photograph). The brightest (allocyclic) X chromosome after QM technique (*a*) corresponds to the palest element in the complement after BrdU–AO technique (*b*). Embryos 7.5 d after fertilistion were taken out of the uterine cavity, incubated at 37 °C for 8 h in Eagle's medium supplemented with foetal calf serum (20%) and BrdU (100μg ml^{-1}). Colcemide (1 μg ml^{-1}) was added 2 h before collection. Air-dried slides were prepared accordingly to a modified method of Wroblewska and Dyban[21] as described by Takagi and Oshimura[22].

process nonrandom[23,24] since both cell types were nearly equally represented in the embryonic body as a whole. The slight excess of cells with an allocyclic X^p in the embryonic body seems to be at variance with the lower levels of the c-variegation when X^t is inherited from the father rather than from the mother[25]. Of particular interest are the mechanisms responsible for accomplishing divergent mosaic compositions in different regions of a single embryo. Our finding is apparently incompatible with random inactivation followed by random sampling of primordial cells for the extraembryonic structures or random inactivation after the divergence of the embryonic from the extraembryonic anlage, unless reversal of inactivation or extensive cell selection is advocated.

It is tempting to postulate that the preferential paternal X inactivation in the extraembryonic membranes is not restricted to Cattanach's translocation, but is common in the laboratory mouse and possibly in some other mam-

malian species. The eutherian type random X inactivation system of gene dosage compensation is considered to have evolved from the marsupial type paternal X inactivation system[26,27]. If so, does the peculiar feature represent a character directly inherited from the paternal X inactivation system? Or, has it been evolved after the establishment of random inactivation? In either case, it seems highly unlikely that the specific pattern of inactivation has been retained without any advantages for embryogenesis. Thus an assumption could be made that the active X^m in the extraembryonic membranes is favourable, though not indispensable to embryonic development. We did in fact find an exceptional case of a grossly retarded 8.5-d embryo whose yolk sac was composed predominantly of cells with an allocyclic X^p, but further studies are essential for testing the validity of our tentative hypothesis. Investigations along these lines might also prove significant in man. ·

Table 1 Parental influence on X-inactivation mosaic compoistion in 6.5–8.5-d-old female embryos carrying Cattanach's translocation

Area examined	Age (d)	Mating type	No. of embryos examined	No. of cells examined	% Cells with allocyclic X^p(range)
Whole embryo	6.5	I*	19	789	87(71–98)

Evidence derived from sister chromatid exchanges of restricted rejoining of chromatid subunits

SISTER chromatid exchanges (SCE) were first described by Taylor *et al.*[1] using autoradiographic techniques. After DNA replication in the presence of tritiated thymidine and subsequent replication in the absence of this radioisotope, two types of SCE were observed in colchicine-induced tetraploid cells. Twin exchanges represented events occurring in the second division cycle whereas single exchanges represented events occurring in the first division cycle.

If SCE rejoining occurs randomly between chromatid subunits, the ratio of twin to single SCE should theoretically be 1:10 (ref. 2). Alternatively, if SCE rejoining is restricted due to inherent polarity, this ratio should theoretically be 1:2 (ref. 2). Experimental support for these alternatives through the use of tritiated thymidine and autoradiography has been inconclusive, with ratios of twin to single SCE varying from 2.4:1 to 1:10 (refs 3 and 4). As an alternative method to examining tetraploid cells, the frequencies of SCE have been compared in metaphase cells one and two division cycles after tritiated thymidine labelling[5,6]. Again, results have been inconsistent, providing no clear evidence for either random or restricted rejoining of chromatid subunits. This variability is probably related to the use of tritiated thymidine, an agent known to induce SCE[7].

Recently, techniques have been developed which make possible the examination of SCE without radioactive labelling. These techniques are based on the differential staining of sister chromatids by fluorescent compounds[8,9] or Giesma[10] after a minimum of two division cycles in the presence of bromodeoxyuridine (BrdU). It was, therefore, decided to use these new techniques to re-examine whether SCE rejoining is random or restricted by comparing the frequency of SCE occurring in the first two division cycles with SCE occurring in the third division cycle.

Lymphocyte cultures from ten male subjects were incubated at 37 °C for 72 h in total darkness using culture media containing phytohaemagglutinin-M (Gibco) and 0.9 µg ml^{-1} BrdU. Colcemid (Gibco) was added to a final concentration of 0.1 µg ml^{-1} for the final 3 h of incubation. The cells were collected, fixed and slides prepared.

Metaphase chromosomes from cells having passed through one division cycle in the presence of BrdU exhibit no differential sister chromatid staining with acridine orange. Consequently, SCE cannot be detected (Fig. 1*a*). After two BrdU cell cycle divisions (Fig. 1*b*), SCE can be clearly observed since acridine orange stained chromatids unifilarly substituted with BrdU fluoresce more intensely than bifilarly substituted chromatids[9]. Mitotic cells after three BrdU cell cycle divisions can be easily distinguished from cells having undergone two replications in the presence of BrdU since only one-fourth of total sister chromatid length retains thymidine and fluoresces brightly (Fig. 1*c*).

In the examination of SCE frequency, previous investigators[5,12] have avoided the inclusion of SCE which seem to involve the centromeric region. Assumed difficulty in distinguishing centromeric SCE from chromosomal twists in this region was the basis for this exclusion. Centromeric SCE occurring in the first two division cycles, however, can be unequivocally determined in third division metaphase cells where they appear as chromosomes with only one arm brightly fluorescent (Fig. 1*c*). Examination of centromeric SCE fre-
Fig. 1 Fluorescence photomicrographs of metaphase chromosomes. *a*, Cell after one division cycle in BrdU with all chromatids unifilarly substituted with BrdU and therefore no differential fluorescence; *b*, cell after two division cycles in BrdU with one-half of all sister chromatid regions bifilarly substituted with BrdU. These regions fluoresce less intensely than unifilarly substituted sister chromatid regions; *c*, cell after three division cycles in BrdU with only one-fourth of all chromatid regions still unifilarly substituted with BrdU. Arrows with (CENT.) denote centromeric SCE, arrows with (SCE (1, 2)) denote SCE which had occurred within the first two division cycles, arrows with (SCE (3)) denote SCE occurring in the third division cycle. Heparinised whole blood was cultured in Eagles MEM with Earle's salts, non-essential amino acids, 2 mM L-glutamine, penicillin (10,000 U ml⁻¹), streptomycin (10,000 μg ml⁻¹) (Gibco), and 10% heat-inactivated foetal bovine serum (Flow). Cultures were incubated at 37 °C for 72 h in total darkness in the presence of phytohaemagglutinin-M (Gibco) and 0.9 μg ml⁻¹ BrdU. Colcemid (Gibco) was added to a final concentration of 0.1 μg ml⁻¹ for the final 3 h of incubation. The cells were collected, fixed, and slides prepared[11]. Slides were stained for 5 min in 0.125 mg ml⁻¹ acridine orange[9] dissolved in phosphate buffer (*p*H 7.4), rinsed briefly with distilled water, incubated for 10 min in phosphate buffer (*p*H 7.4) and mounted in the same phosphate buffer. Chromosome fluorescence was observed in a Leitz Orthopian microscope equipped with epi-illumination from a 200 W mercury light source, BG12 and TK510 dichroic excitor filters, K515 and K510 suppressor filters. Photographs were taken using a ×54 objective.

quency in these cells showed them to occur as a relatively high proportion of all SCE. Consequently, in any comparison of SCE frequencies, it was decided that centromeric exchanges should be included. To assess our ability to distinguish centromeric SCE from chromosomal twists, we examined both second and third division metaphase cells for the proportion of centromeric SCE which occurred in the first two division cycles. Unequivocal centromeric SCE measured in third division metaphase cells accounted for 18% of all SCE occurring in the first two division cycles, whereas centromeric exchanges measured in second division metaphase cells accounted for 21% of all SCE. Therefore, it seems possible to distinguish true centromeric SCE occurring during any cell cycle from apparent chromosomal twists. These values for the proportion of SCE which occurs in the centromeric region are comparable with previously reported estimates[5,13].

The total SCE frequencies occurring in the first two division cycles are listed in Table 1. No significant difference was observed between measurements made in second or third division metaphase cells. Therefore, these data were combined and the ratio of SCE occurring in the first two division cycles to SCE occurring in the third division cycle was calculated. If SCE occur with equal frequency in each division cycle, the expected frequency of SCE occurring in the first two division cycles should be twice the frequency of SCE occurring in the third division cycle. Since only half of the SCE occurring in the third division cycle can be detected (half of the SCE occur in chromo-

somal regions completely substituted with BrdU), the expected ratio of the first two division cycle SCE to third division cycle SCE becomes 4 : 1. The derived ratio of 4.05 : 1 is clearly consistent with restricted rejoining of sister chromatid subunits. The ability to attain such a close approximation to the predicted ratio is most likely a result of the use of this new non-radioactive technique.

It has not been completely resolved whether the SCE observed with this technique are spontaneous or induced by BrdU. High concentrations of BrdU[10], or low concentrations of BrdU in the presence of light[14], have been shown to induce SCE. It is not clear whether BrdU at the low concentration we used in the absence of light induces SCE[10,15]. Irrespective of whether the observed SCE were induced or spontaneous, our results indicate that the observed SCE clearly involved both chromatid subunits with restrictions on rejoining due to subunit polarity. This does not exclude the possibility that in radiation or chemically treated systems, a proportion of induced SCE could be the result of exchange between single chromatid subunits.

Although our data strongly support a mononeme structure for eukaryotic chromosomes (that is, composed of one DNA duplex with chromatid subunits being single polynucleotide strands), it is also possible to devise a model by which SCE can occur with polarity restrictions on rejoining between sister chromatids composed of more than one DNA duplex. Such a polyneme model for SCE rejoining would, however, be several orders of magnitude more complex than a mononeme model.

Table 1 Mean SCE frequency

Division cycles in BrdU	(a) Frequency of SCE occurring in the first two division cycles (mean ± s.e.)	(b) Frequency of SCE occurring in the third division cycle (mean ± s.e.)	Derived ratio a/b	Expected* ratio a/b
2	10.50 ± 0.31 (165)	—	—	—
3	10.05 ± 0.33 (165)	2.54 ± 0.15 (165)	3.96	4.00
2 and 3	10.28 ± 0.23 (330)	2.54 ± 0.15 (165)	4.05	4.00

Thirty or more metaphase cells per individual (one-half second metaphase cells, one-half third metaphase cells) were optically examined by two observers for SCE frequency. Number of cells examined are shown in parentheses.
* Expected ratio based on restricted rejoining of chromatid subunits would be 2 : 1. Since only half of all SCE occurring in the third division cell cycle can be detected, however, the expected ratio becomes 4 : 1.
Fig. 2 Progression of cells through three division cycles in the presence of BrdU based on the unineme model of eukaryote chromosome structure. *a–d*, Appearance of chromosomes during three division cycles with: *a*, no SCE occurring; *b*, SCE occurring in the first division cycle; *c*, SCE occurring in the second division cycle; *d*, SCE occurring in the third division cycle. ———, Thymidine – – – –, BrdU-bearing DNA strand. Direction of arrow indicates polarity of chromatid subunits. Black chromosomal regions indicate regions which fluoresce less intensely with acridine orange. White chromosomal regions indicate regions which fluoresce more intensely with acridine orange.

Figure 2 is a schematic representation of the results of SCE occurring in each of the three successive replication cycles in the presence of BrdU based on the mononeme model of eukaryotic chromosome structure.

Genes for immunoglobulin heavy chain and serum prealbumin protein are linked in mouse

Several cases of allelic variation have been reported in the mouse that are presumably determined by genes for the variable region of the heavy chain of immunoglobulins[1–8]. These genes control qualitative and/or quantitative differences in the immune response to particular antigens, and exhibit close linkage to the cluster of genes (*Ig-1, Ig-2, Ig-3, Ig-4*) that determine the allotypic differences residing in the constant portion of the heavy chains of several immunoglobulin classes[9–11]. (No

recombinants have been observed among the latter in over 2,000 backcross mice.) Significantly, several presumptive recombinants have been recovered that seem to separate some variable region genes from the allotype loci, and some variable region genes from each other [1,12]. Outside genetic markers would be very valuable in identifying and interpreting these presumptive recombinants. Unfortunately, efforts to place the heavy chain allotype locus in the mouse linkage map have been unsuccessful [9,10,13]. We report here the discovery of close linkage between *Ig-1* and the serum prealbumin locus of the mouse.

The autosomal prealbumin locus (*Pre*) determines the presence or absence of a minor serum protein band that migrates ahead of the albumin band on electrophoresis[14]. Density of the band is hormone dependent, and is greatest in sexually mature males. The *Pre*ᵃ allele determines the presence of the band in both homozygotes and heterozygotes, whereas *Preᵒ/Preᵒ* homozygotes lack the prealbumin band. The absence of a detectable prealbumin band in *Preᵒ/Preᵒ* mice may reflect an altered mobility that coincides with the albumin fraction. The nature, function, and origin of the prealbumin protein is unknown[14,15]. The *Pre* locus has not been located in the linkage map[14].

Evidence favouring linkage of *Ig-1* and *Pre* came initially from observing the joint segregation of these loci in recombinant inbred (RI) lines. Three different sets of RI lines were studied. CXB lines developed by Bailey were derived by brother–sister mating from the F₂ generation of the cross of C57BL/6By and BALB/cBy (ref. 16). AKXL and BXD sets were similarly produced by Taylor from the crosses of AKR/J × C57L/J (ref. 17) and C57BL/6J × DBA/2J (ref. 18) respectively. It is clear that unlinked genes will be randomised in the F₂ generation, whereas closely linked genes will tend to become fixed in the same combinations as they entered the cross.

The results of typing the three sets of RI lines for *Ig-1* and *Pre* are presented in Table 1 with the genotypes of the progenitor strains. A preponderance of parental genotypes with respect to *Ig-1* and *Pre* was observed. Out of 54 independently derived RI lines, only 14 exhibited recombinant phenotypes ($P < 0.001$). If the loci were unlinked, a 1:1 ratio of parental to recombinant genotypes would be expected.

To confirm the linkage, sexually mature males from the C57L/J × (AKR/J × C57L/J)F₁ backcross were typed both for the presence of the prealbumin band and the AKR/J allotype. The numbers of mice in each of the four classes were as follows: *Pre*ᵃ/*Pre*ᵒ, *Ig-1*ᵈ/*Ig-1*ᵃ (51); *Pre*ᵒ/*Pre*ᵒ, *Ig-1*ᵃ/*Ig-1*ᵃ (54);

Pre^a/Pre^o, $Ig-1^a/Ig-1^a$ (9); Pre^o/Pre^o, $Ig-1^d/Ig-1^a$ (5). These results differ significantly from the expected 1:1:1:1 ratio in favour of linkage ($P<0.0001$). The estimated recombination fraction from the backcross data is 0.118 ± 0.034.

During the successive generations of inbreeding in the formation of an RI line, there are multiple opportunities for recombination between linked loci. The probability of fixing a recombinant genotype (R) is $4r/(1 + 6r)$, where r is the probability of recombination in a single meiosis[19]. Substituting 14/54 for R provides an estimate for r of 0.106 ± 0.040. The authors thank Dr E. L. Green for pointing out that r is equal to $R/(4-6R)$ and that the large sample variance of r estimated this way is $r(1 + 2r)(1 + 6r)^2/4N$, where N is the number of RI lines. The estimate obtained in this way is very similar to the estimate obtained in the backcross. The combined estimate of r is 0.114 ± 0.024. As this is a relatively short distance, we are probably justified in equating recombination frequency with map distance. The estimated map distance between Pre and $Ig-1$ is 11.4 ± 2.4 centimorgans (cM). Note that the estimate from the RI lines reflects the average recombination frequency in the two sexes, whereas the backcross data reflect recombination in males only.

Shreffler place the Pre^a allele of CBA/J on to the C57BL/10JSf genetic background by 10 backcrosses followed by brother–sister mating. The strain is designated B10.PRE. The allotype of the line proved to be that of the background strain ($Ig-1^b$) rather than that of the donor strain ($Ig-1^a$), indicating that a crossover in the $Ig-1–Pre$ region had occurred at some stage. This congenic strian may prove to be useful for crossing with Pre^o strains, when the C57BL background, the $Ig-1^b$ allele, and the Pre^a allele are all desired. It should also be useful in studies aimed at characterising the prealbumin protein as to site of synthesis, turnover rate and function.

The results of typing five $Ig-1$ congenic strains[1,10,11,20] in which the $Ig-1$ alleles from strains C57BL/Ka and AL/N (both Pre^o) were placed on the BALB/c (Pre^a) background are shown in Table 2. The BAB/14, C.B17, and C.B26 strains are all Pre^o type like the donor C57BL/Ka strain, indicating that no crossover has occurred between $Ig-1$ and Pre during the backcrossing and inbreeding process. This provides further confirmation of the linkage between $Ig-1$ and Pre. The C.AL9 and the C.AL20 strains are both Pre^a type unlike the donor AL/N strain, indicating that a crossover occurred between $Ig-1$ and Pre during their development. These results plus the finding of crossing over in the B10.PRE congenic strain, provide a basis for a third estimate of the recombination frequency between $Ig-1$ and Pre. The likelihood of obtaining recombination in the B10.PRE and C.AL series, without recombination in the C.B series is maximised by a recombination frequency of about 0.05, a value similar to the estimates obtained from the RI lines and backcross data. Note that the BAB/14 strain is an apparent recombinant between $Ig-1$ and the closely linked gene that determines an idiotype specific immune responsiveness to α-1,3 dextran[1]. This implies the gene order: $Pre–Ig-1–V_H–DEX$, unless a double crossover is postulated.

Extensive typing of the three sets of RI lines at other loci has not revealed the chromosomal location of Pre and $Ig-1$. The mapped loci with their respective chromosome numbers in parentheses, for which there exists at least partial typing in the CXB, AKXL, and BXD RI lines, are as follows: CXB: a (2), $Mup-1$ b $H-15$ $H-16$ $Gpd-1$ (4) $H(go)$ (5), $H-22$ $Gpi-1$ c Hbb $H-1$ (7), $Es-1$ $H-19$ (8), $Mod-1$ $H-7$ $Fv-2$ Bgs (9), Hba (11), and $H-2$ (17); AKXL: ln $Dip-1$ ald (1), $H-3$ Svp (2), $Mup-1$ b $Gpd-1$ (4), Gus (5), $Ly-2$ (6), c Hbb (7), $Es-1$ (8), $Thy-1$ $Fv-2$ (9), $Es-3$ (11), $H-2$ (17); BXD: $Id-1$ $Dip-1$ (1), Svp (2), $Mup-1$ b $Gpd-1$ $Fv-1$ (4), $Pgm-1$ (5), $Ly-2$ (6), $Gpi-1$ Hbb (7), $Es-1$ (8), d $Mod-1$ $Fv-2$ Bgs (9), $Es-3$ (11), and $H-2$ (17).

We have typed for prealbumin a number of inbred strains maintained by the Jackson Laboratory. Knowledge of this typing may be helpful in planning linkage studies of this region. To the list of Pre^a-bearing strains reported by Shreffler[14] (AKR/J, BALB/cJ, CBA/J, DBA/1J, DBA/2J, RF/J, and WB/Re),

*CXB RI strains were sib-mated more than 30 generations before testing. AKXL and BXD RI lines were tested at a time when they were incompletely inbred ($F> 0.83$). Lines that were known to be segregating at either $Ig-1$ or Pre are not included. Certain deviations from continuous sib-mating occurred in AKXL lines 6, 11 and 16, the net effect being to slightly increase the probability of fixing C57L/J alleles. Several of the AKXL and BXD RI lines are now extinct, and other lines will likely become extinct.

†CXB RI strains were $Ig-1$ typed by Dr M. Potter[23]. AKXL and BXD RI lines were tested for the presence of the $Ig-1^d$ and $Ig-1^b$ alleles, respectively. Thus, from a d (or b) designation of RI lines for $Ig-1$, it should be interpreted that the $Ig-1^d$ (or $Ig-1^b$) allele was present in the line at the time it was tested. (Requisite antisera to test for the presence of $Ig-1^a$ and $Ig-1^c$ alleles were not available.) Allotyping was carried out using immunodiffusion with antisera made in BALB/c mice against conjugates of *Bacillus pertussis* and anti-pertussis antibodies made in NZB ($Ig-1^e$, cross reactive with $Ig-1^d$) and BAB/14 ($Ig-1^b$, otherwise congenic to BALB/c) mice, respectively. These allotyping sera precipitated only with immunoglobulins of appropriate strains[9-11].

Serum samples from two to six sexually mature males of each RI line were tested for the presence of prealbumin protein. Electrophoresis of fresh or frozen sera was carried out using a vertical gel electrophoresis cell (EC470, EC Apparatus, St Petersburg, Florida). A 5% Cyanogum 41 acrylamide gel was prepared as described by the manufacturer. Buffer was 0.09 M Tris, 0.09 M borate, 2.5 mM EDTA, pH 8.4 Electrophoresis of 10–20 μl serum samples was carried out for 2 h at a potential of 250 V. Gels were stained for 1h with 1% Amido Black in 5:5:1 methanol–water–acetic acid solution, and destained in the same solvent.

Table 2 Prealbumin types of several congenic strains in which different *Ig-1* alleles have been placed on the BALB/c (*Ig-1*ᵃ, *Pre*ᵃ) background by serial backcrossing*

Congenic strain	Donor strain	Generations of backcrossing	Crossover?
BAB/14 (*Ig-1*ᵇ, *Pre*ᵒ)	C57BL/Ka (*Ig-1*ᵇ, *Pre*ᵒ)	14	No
C.B17 (*Ig-1*ᵇ, *Pre*ᵒ)	C57BL/Ka (*Ig-1*ᵇ, *Pre*ᵒ)	17	No
C.B26 (*Ig-1*ᵇ, *Pre*ᵒ)	C57BL/Ka (*Ig-1*ᵇ, *Pre*ᵒ)	26	No
C.AL9 (*Ig-1*ᵈ, *Pre*ᵃ)	AL/N (*Ig-1*ᵈ, *Pre*ᵒ)	9	Yes
C.AL20 (*Ig-1*ᵈ, *Pre*ᵃ)	AL/N (*Ig-1*ᵈ, *Pre*ᵒ)	20	Yes

*The *Ig-1* congenic strains described here as well as the AL/N strain are maintained at the Institute for Cancer Research. The BAB/14 and C.B17 congenic strains were separated at the 13th backcross generation. Brother–sister inbreeding was instituted after one and four additional backcrosses in the BAB/14 and C.B17, respectively. The C.B26 congenic strain was separated from the C.B17 strain at the 17th generation. The C.B26 strain was backcrossed nine additional generations before inbreeding. The first 13 backcrosses were to the BALB/cAn strain. Subsequent backcrossing in the C.B17 and C.B26 strains was to the BALB/cAnNIcr subline. The C.AL9 and C.AL20 strains are related to each other in the same way that C.B17 and C.B26 are related. In the C.AL series all backcrosses were to the BALB/cAn strain. The designations used to represent these congenic strains varies between publications and do not follow the rules for standardised nomenclature. The designations used here are intended to be descriptive rather than definitive.

the following strains may be added: BDP/J, BUB/BnJ, CE/J, I/LnJ, LT/Re, NZB/BINJ, P/J, RIII/2J, SEA/GnJ, SEC/1ReJ, SJL/J, ST/bJ, and 129/J. To the list of *Pre*ᵒ-bearing strains reported by Shreffler (A/HeJ, A/J, C57BL/6J, C57BL/10J, C3H/HeJ, and WC/Re), the following strains may be added: AU/SsJ, CBA/CaJ, C3HeB/FeJ, C57BL/KsJ, C57BL/10Sn, C57BR/cdJ, C57L/J, C58/J, HRS/J, LG/J, LP/J, MA/J, MWT/Ww, SM/J, SWR/J, and WK/Re. The difference between the CBA/J and CBA/CaJ sublines explains a discrepancy in the reports of Shreffler[14] and Reuter *et al*[15]. The latter apparently typed a CBA subline related to CBA/CaJ. These two sublines exhibit multiple differences[21], indicating that they were either incompletely inbred at the time of separation or that contamination occurred. We have been unable to confirm Shreffler's *Pre*ᵃ typing of the WB/Re strain.

The *Pre* locus described by Shreffler and considered here should not be confused with another prealbumin electrophoretic variant designated *Pre-1* described by Claxton *et al*[22] that segregates independently of Shreffler's *Pre* locus. The close linkage of the *Pre-1* locus to the brown (*b*) locus in chromosome 4 suggests that it is identical to the *Mup-1* locus[23] that determines an electrophoretic variant in major urinary protein which is also detectable in serum[15].

The *Pre* locus has several merits as a marker for the *Ig-1* region; fresh or frozen serum is used for typing; there is a significant polymorphism among the commonly used inbred strains; typing is relatively easy, inexpensive and reliable. The weak and variable expression of the prealbumin gene in females and the inability to reliably distinguish between *Pre*ᵃ/*Pre*ᵃ and *Pre*ᵃ/*Pre*ᵒ mice limits the usefulness of this marker[14,15]. Both of these limitations may be removed by refinements in the typing procedure.

In man the heavy chain allotype locus (*Gm*) is linked to the protease inhibitor locus (*Pi*) with a map distance of about 25 centimorgans[24]. The *Pi* locus comprises an allelic series of electrophoretic variants of the serum glycoprotein α_1-antitrypsin[25]. Although murine α_1-anti-trypsin seems to share some chemicophysical characteristics with prealbumin[15,26], the former is electrophoretically monomorphic among inbred strains[26]. Further biochemical and biological characterisation of the prealbumin protein is in progress.

Chemotaxis of lymphoblasts

LYMPHOCYTES are motile cells whose movement *in vivo* seems to be directed, yet investigators over many years have repeatedly failed to show chemotaxis of lymphocytes *in vitro*. There have been some recent reports that lymphocytes migrate into micropore filters towards substances placed below the filter[1-3], but this migration was not found to be chemotactic[3]. It seemed to us that our and other people's failure to demonstrate lymphocyte chemotaxis might be because we were using the wrong population of cells. The lymphocytes which can be shown most clearly to migrate into inflammatory lesions *in vivo* are blast-transformed cells [4-6], and we therefore examined the migration in Boyden chambers of lymphoblasts from two sources; firstly cloned human lymphoblast cell lines maintained in continuous culture[7]; and secondly blast cells from the lymph nodes of CBA mice, either without deliberate sensitisation with antigen, or following exposure to the contact sensitising agent, oxazolone. Both human and mouse lymphoblasts were shown to migrate into filters towards chemoattractants. The nature of this migration is discussed below.

Locomotion and chemotaxis of blast-transformed lymphocytes were measured using the micropore filter technique as described previously[8]. For mouse lymphoblasts a filter of 8 μm pore size was used. Because the human blasts were larger, filters of 12 μm pore size (Sartorius, Göttingen, Germany) were used. The distance migrated by the leading front of cells was measured as described by Zigmond and Hirsch[9] after 3 h. At this time, the leading-front cells in a population of lymphoblasts migrating towards a strong chemoattractant have
Fig. 1 Human lymphoblasts (line SMI_4) migrating in a micropore filter and showing locomotor morphology. The picture is take from above and the cells are at a depth of 60 μm in the filter. ($\times 900$)

migrated deeply into the filter but not reached the lower surface. This compares with 2 h for human blood monocytes migrating the same distance in the same filters. The cells did not require to be incubated in CO_2 (refs 1, 2) nor was prolonged incubation (18 h) necessary as has been suggested previously[1]. Table 1 shows the migration of lymphocytes from seven human lymphoblast cell lines in Gey's solution alone and in the presence, below the filter, of substances previously shown to be chemotactic for monocytes or neutrophils. The cell lines varied considerably in their random unstimulated migration and in their response to chemoattractants. Cells from all of the lines migrated further in the presence of endotoxin-activated plasma than in its absence and most of them also showed an enhanced response to casein. The migrating cells showed a typical locomotor morphology with a broadened leading edge and a narrow tail which occasionally became very elongated (Fig. 1).

To test whether the migration was chemotactic, experiments were set up in which the absolute concentration and the gradient of the chemoattractant were varied above and below the filter. The influence of chemoattractants on either rate of locomotion or on its orientation has been distinguished in this way[9]. Table 2 shows that the rate of locomotion of lymphocytes in the absence of a gradient (figures along the diagonal from upper left to lower right) varies with chemoattractant concentration, that is the cells show chemokinesis under these conditions. Furthermore, lymphocytes migrating in a positive gradient penetrated deeper into the filter than would be expected on the basis of concentration-dependent random migration alone; conversely,

lymphocytes migrating in a negative gradient did not penetrate as deeply as would be expected by random migration alone. These results support the conclusion that the locomotor response of human lymphoblasts to activated plasma depends not only on the absolute concentration of the plasma but also on the concentration gradient and is, therefore, chemotactic. Similar results were obtained with three other human lymphoblast lines. Table 2b shows the effects of colchicine on the migration of the same cells. Colchicine enhances concentration-dependent random migration in the absence of a gradient (figures on the diagonal), but colchicine-treated cells lose the capacity to detect and respond to a gradient. Similar results were obtained with vinblastine (10^{-5} M). These results resemble our unpublished data on the effects of colchicine and vinblastine on neutrophil and monocyte locomotion. They support the hypothesis[10-12] that the integrity of microtubules is required for the orientation of locomotion of these cell types but not for locomotion itself.

The lymphocytes from the auricular nodes of unsensitised mice are mostly small cells and the type of filter used was not suitable for the study of the migration of such cells. The small number of blast cells present in suspensions from normal mouse lymph nodes were, however, shown to migrate into filters and gave a dose response to chemoattractants which resembled that of human lymphoblasts (Fig. 2). Cell suspensions made from the draining nodes of mice 72 h after contact sensitisation by painting the ears with oxazolone contained many more blast cells (30%) than suspensions from unsensitised
Fig. 2 Migration towards varying doses of casein of lymphoblasts from normal mouse auricular lymph nodes (●) and auricular lymph nodes 72 h after sensitisation with oxazolone (□)

Table 1 Migration of cultured monoclonal human lymphoblasts

Cell line	Source (refs 7, 13, 14, 15)	Ig release into supernatant (ref. 15)	Migration (μm in 3 h) towards

The cell lines were obtained from Dr Judith Evans, MRC Clinical and Population Genetics Unit, Western General Hospital, Edinburgh. They were established and maintained in tissue culture as described by Steel[7]. For studies of locomotion they were maintained in Eagle's medium +10% foetal calf serum and HEPES buffer (3% of a molar solution) changed every 4 d. They were incubated in 5% CO_2 at 37 °C until required for use when they were washed twice in serum-free Gey's solution before being placed in chemotaxis chambers at 2×10^6 ml⁻¹. Normal human plasma was activated by incubation at 37 °C for 30 min with *Shigella flexneri* lipopolysaccharide.

Table 2 The effect of varying concentration gradient and absolute concentration of chemoattractant on locomotion of human lymphoblasts (line F_{89} 9489)

Figures along the diagonal from upper left to lower right indicate distance migrated (μm) in increasing concentrations of the activated plasma but in the absence of a concentration gradient. Above the diagonal, the cells were moving in a positive gradient, below, in a negative one. The figures in brackets are estimates of what migration would have been in each of the tests assuming that the cells detected only the absolute concentration of the chemoattractant but not the gradient. They were calculated after Zigmond and Hirsch[9]. P for gradient effect on migration of cells without colchicine < 0.0005: with colchicine, > 0.1.

nodes (3%) and these cells were much more motile than those from the unsensitised nodes. They usually, but not always, showed considerable random motility in the absence of any chemoattractant (Fig. 2). This was also true of the blast cells from such nodes which did not adhere to nylon wool. Their response to chemoattractants was variable. Typically those which showed high unstimulated motility showed little further increase in motility when placed in the presence of a chemoattractant (Fig. 2). Experiments on the lines of Table 2 were done to test whether oxazolone-stimulated blast cells show a chemotactic response. In two out of three such experiments—the third gave an equivocal result—lymphoblasts from oxazolone-sensitised lymph nodes failed to show evidence of chemotaxis when tested under varying gradient conditions as in Table 2. These cells also consistently showed little or no change in the rate or the direction of their migration after treatment with colchicine. This might suggest that the blast cell population obtained after contact sensitisation shows a form of locomotion which is not directed or restrained by the action of microtubules.

These preliminary results suggest that populations of blast-transformed lymphocytes vary considerably in their locomotor response to chemoattractants, more so indeed than neutrophil or macrophage populations. The majority of cultured human lymphoblastoid B cell lines show low unstimulated motility, move faster in the presence of a chemoattractant, and show variations in their migration when the concentration gradient is varied which are consistent with a chemotactic response. This should be confirmed by time-lapse studies of the migration of single cells and the demonstration of oriented movement in a gradient by direct observation. Oxazolone-sensitised mouse lymphoblasts, however, show considerable unstimulated migration, and although they also respond to chemoattractants, this response does not seem to be chemotactic. It remains to be established whether these variations in locomotor behaviour reflect fundamental differences between B and T cell populations. It seems likely that the migration of lymphoblasts which we have observed *in vitro* is related to the migration of similar cells *in vivo* into sites of inflammation, especially since activated plasma is similar to attractants found *in vivo* in inflammatory tissue. Whether other examples of apparently directed lymphocyte migration *in vivo* are mediated by chemoattractants remains to be seen.

Ultrastructural evidence for ectoglycosyltransferase systems

CONSIDERABLE biochemical evidence suggests that glycosyltransferases, in addition to being present in the Golgi apparatus[1], are also located on the outer surface of the plasma membrane of a variety of normal and malignant cell types[2-9]. The enzymes catalyse the transfer of specific monosaccharide units from nucleotide sugar donors to appropriate glycoprotein or glycolipid acceptors. Presumably those in the Golgi play a major role in the biosynthesis of glycoproteins and glycolipids[1] while those at the plasma membrane (ectoglycosyltransferases) have been implicated in mechanisms for cell to cell adhesion, recognition and communication[2-7]; cell surface repair[8] and for binding circulating oligosaccharides or glycoconjugates[9]. Although the biochemical evidence for the existence of ectoglycosyltransferases is compelling, it is not definitive. In this report, we use electron microscope (EM) autoradiography to demonstrate the plasma membrane localisation of a N-acetylneuraminic acid ectoenzyme system (ectosialyltransferase, EC 2.4.99.1; the enzyme together with cell surface acceptor molecules constitute the ectoenzyme system[8]). The results provide the first ultrastructural evidence for the presence of such a glycosyltransferase system at a cell surface.

Murine leukaemic L-1210 cells, shown previously in our laboratory[8] by biochemical methodology to possess galactosyl- and sialyltransferase activities at their external cell surface were again used in this study. The cells were obtained from the ascites fluid of DBA/2 female mice, washed twice in ice-cold phosphate buffered saline (PBS, Dulbecco's), pH 7.4,

adjusted to 10^8 cells ml^{-1} and incubated in PBS containing 10 µM CMP-^{3}H-N-acetylneuraminic acid (CMP-^{3}H-NANA) for 15 or 60 min at 37 °C. It was assumed that under these conditions whole nucleotide monosaccharides do not enter the cell. When the cells were incubated with CMP-^{3}H-NANA in the presence of a 100-fold higher concentration of free unlabelled N-acetylneuraminic acid, N-acetylmannosamine, mannosamine or mannose (all competitors of possible labelled degradation products of CMP-^{3}H-NANA), there was no decrease in incorporation levels (Table 1, experiments 1 and 2). Apparently, extracellular degradation, enzymic[10] or otherwise, of CMP-^{3}H-NANA with subsequent uptake and incorporation of labelled products was not responsible for the cell labelling. In addition, paper chromatography[8] of the cell medium following incubation with CMP-^{3}H-NANA revealed that less than 1% of the total radioactivity was present as free ^{3}H-NANA. It was concluded, on the basis of the above, that incorporation of ^{3}H-NANA from CMP-^{3}H-NANA into glycoconjugate must be taking place at the cell surface. We attempted to confirm this autoradiographically.

To attain sufficient incorporation levels of ^{3}H-NANA for EM autoradiography to be feasible, L-1210 cells were treated with *Vibrio cholerae* neuraminidase (VCN) for

Fig. 1 Electron microscope autoradiographs of labelled L-1210 cells incubated 15 min with CMP-^{3}H-NANA (*a*) or ^{3}H-galactose (*b*). The autoradiographic methods of Salpeter and Bachmann[11] were applied as described previously[12]. Ultramicrotome sections (1,000 Å thick) were mounted on collodionised slides, stained with 2% uranyl acetate, carbon coated and overlaid with a monolayer of Ilford L-4 emulsion. The preparations were exposed 25–55 d, developed in D-19 (Kodak) for 2 min at 24 °C and photographed with a Siemens Elmiskop 101. Note that for cells labelled with CMP-^{3}H-NANA, the grains lie mainly over the plasma membrane or within the range of radiation scatter from it while for cells labelled with ^{3}H-galactose, the grains are concentrated over the Golgi apparatus ($\times 2,772$).

15 min before incubation with CMP-^{3}H-NANA. The procedure presumably increases the available endogenous acceptor sites at the external cell surface for ectosialyltransferase and provides a sixfold increase in incorporation of label without affecting cell viability (Table 1, experiments 1 and 2). After a 15-min incubation in 10 µM CMP-^{3}H-NANA, cells were washed thoroughly in PBS, pelleted, fixed in 3% buffered glutaraldehyde (*p*H 7.0), postfixed in 1% osmium tetroxide, dehydrated and embedded in Spurr medium. Sections of the cells were processed for EM autoradiography[11,12]. Only the monosaccharide incorporated into glycoprotein, and not that present in the cell as free sugar, nucleotide sugar or glycolipid, is retained after this tissue processing[13,14].

EM autoradiographs of L-1210 cells incubated with CMP-^{3}H-NANA under the above conditions consistently showed grains over the plasma membrane of the cell (Fig. 1*a*). When for comparison, cells were labelled under the same conditions for 15 min with 10 µM ^{3}H-galactose (New England Nuclear, 0.6 Ci mmol^{-1}) in PBS and examined, the grains were concentrated mainly over the Golgi apparatus (Fig. 1*b*). A comparison of the relative grain densities over several cellular compartments (Table 2) clearly defines the organelles where incorporation of either label is taking place. The mode of incorporation of ^{3}H-NANA directly on to external plasma membrane glycoconjugate from its nucleotide monosaccharide represents a definite departure from that of free monosaccharides[13,14] which are ordinarily incorporated by means

Table 1 *In vitro* incorporation of N-acetylneuraminic acid from CMP-^{3}H-NANA by murine leukaemic L-1210 cells

Experiment	Conditions	^{3}H-NANA incorporation (d.p.m. per 10^7 cells)	
		15-min incubation	60-min incubation
1	Cells	3,104	18,109
	Cells+NANA*	3,228	19,423

	VCN-treated cells+NANA	22,248	121,071
3	Cells labelled (21,100 d.p.m. per 10^7 cells) as in experiment 2 and post-treated 15 min with VCN‡	2,069	—
4	VCN-treated cells preincubated§		
	0 min in PBS	19,380	91,062
	30 min in PBS	18,800	92,101
	60 min in PBS	19,100	90,381

5×10^7 L-1210 cells were suspended in 0.5 ml PBS containing 10 µM CMP-^{3}H-NANA (New England Nuclear, 2.33 Ci mmol^{-1}). The cell suspensions were incubated for 15 or 60 min at 37 °C in a Dubnoff metabolic shaker. Viability remained $> 96\%$ throughout the experiments as measured by Trypan blue dye exclusion. Incubations were terminated by the addition of 2 ml of 1% phosphotungstic acid in 0.5 N HCl. Acid-insoluble material was collected by centrifugation (500*g* for 5 min) followed by two washes with 10% trichloroacetic acid. The insoluble material was washed once with ethanol:ether (2:1) and dissolved in 0.2 ml 1 N NaOH. This material was neutralised with 1 N HCl and the radioactivity determined by scintillation counting as previously described[8]. The incubations were performed in duplicate on at least three different occasions. The data are expressed as the means of those experiments.
*During the incubation in CMP-^{3}H-NANA, 1 mM NANA was included in the medium as a competitor of possible CMP-^{3}H-NANA degradation products. N-acetyl-mannosamine, mannosamine and mannose were also separately tested with results similar to those shown for NANA.
†5×10^7 washed cells were treated with 10 units of *Vibrio cholerae* neuraminidase (Behring Diagnostic Company, EC 3.2.1.18) in 0.5 ml PBS for 15 min at 37 °C. The cells were washed three times in 2 ml PBS before incubation with CMP-^{3}H-NANA.
‡Cells labelled as in experiment 2 (−NANA, 15 min) were washed three times in 2 ml PBS, resuspended in 0.5 ml PBS containing 10 units of VCN and incubated for 15 min at 37 °C. Acid-insoluble radioactivity was determined as above.
§5×10^7 washed VCN-treated cells were suspended in PBS and preincubated for 0, 30 or 60 min at 37 °C. CMP-^{3}H-NANA was added to the same medium to a final concentration of 10 µM and the cells were incubated for 15 or 60 min at 37 °C.

of multiple activation steps in the Golgi apparatus as exemplified here with galactose, a known[13] glycoconjugate marker.

To demonstrate that the radioactivity associated with the cells was actually ³H-NANA, labelled cells were exposed to VCN for 15 min. The enzyme released 90% of the bound radioactivity from the cells (Table 1, experiment 3). Paper chromatography[8] revealed that 86% of the radioactivity recovered into the medium was ³H-NANA and 14% CMP-³H-NANA. This latter may be a result of incomplete washings after the labelling period.

It is conceivable that the transfer of ³H-NANA on to the cell surface might have been catalysed by free enzyme in the incubation medium incidentally secreted by Golgi vesicles[15] or otherwise released into the medium by cell surface shedding. To test this possibility, washed VCN-treated cells were preincubated 0, 30 or 60 min in PBS before the addition of CMP-³H-NANA to the cell medium, to allow enzyme accumulating in the cell medium during the preincubation period to then catalyse higher levels of incorporation in the 30 or 60-min preincubation samples. But in fact, the 30 and 60-min preincubation samples resulted in no additional incorporation during subsequent incubation in the presence of CMP-³H-NANA (Table 1, experiment 4). This indicates that labelling of the cell surface is not a result of a sialyltransferase being released into the medium from the cells before or during the labelling period. Further, there was no detectable transfer of ³H-NANA on to cells treated at 56 °C for 60 min (to inactivate endogenous cell surface enzymes) by the medium from a 15-min preincubation with viable cells.

The ultrastructural data reported here, together with those obtained biochemically, are evidence for the presence of an ectosialyltransferase system at the surface of L-1210 cells. We note that the bound radiation demonstrated at this location does not represent the enzyme itself, but macromolecular acceptors that have been glycosylated by the sialyltransferase. As with most EM cytochemical techniques for localising enzymes (with exceptions such as the labelled-inhibitor methodology[16]), it is the product of the enzyme reaction that is demonstrated and not the enzyme itself. The precise role of such enzymes or their acceptors is uncertain. Roseman[2] has postulated that batteries of different glycosyltransferases on the plasma membrane bind to acceptor molecules on opposing cell surfaces in a lock and key fashion to establish cell recognition and/or early adhesion. This postulate has recently gained much experimental support from several biochemical studies[4-7]. A more direct assessment of the role of ectoglycosyltransferases (or the macromolecules they glycosylate) in cell behaviour may now be achieved through the application of the methodology used in this study. In addition, the enzyme(s) may serve as a selective means for physiologically introducing an isotopic label on to specific cell surface glycoconjugates.

Serological identification of HL-A-linked human 'Ia-type' antigens

THE Ir genetic region of the mouse which lies between the H-2K and H-2D loci that control the original serologically detectable H-2 specificities, has also been shown to contain genes controlling a new set of serological specificities called Ia for immune associated. Antisera raised by cross immunisation between H-2 recombinant strains have been shown to recognise the products of several genes within the Ir region (reviewed in ref. 1). Unlike the H-2K and H-2D antigens the Ia antigens have a tissue distribution that often does not include T lymphocytes.

By analogy with the mouse, human Ia antigens have been defined by mixed lymphocyte culture (MLC) inhibition and by serological tests on HL-A identical unrelated individuals[2-5]. We describe here some new approaches to the ready identification of sera against Ia-type antigens in man which make use of lymphoblastoid cell lines derived from B cells[6].

Extra reactions of HL-A-typing sera with lymphoid lines have been described[7,8]. A similar increase in reactivity has been noted when typing chronic lymphocytic leukaemia (CLL) cells derived from B cells[9-11]. Using HL-A-negative variants of lymphoid lines some of these extra reactions have been shown to be caused by antigens other than HL-A[12].

The fact that all these anomalous reactions are with cells presumed to be derived from B lymphocytes suggested that they may be directed against polymorphic antigens specific to B lymphocytes. Furthermore, the suggestion[12] that antibodies to these antigens tended to occur in HL-A-typing sera containing antibodies to particular serologically-defined LA and four locus antigens, indicated an association between the production of these antibodies and particular HL-A antibodies. This could most easily be explained by linkage disequilibrium[13] between the genes determining the corresponding antigens which, together with the evidence for B cell specificity, suggested that the anomalous reactions with lymphoid lines and CLL cells may be directed against human equivalents of the mouse H-2-linked Ia antigens.

In the first systematic screen for such reactions we used the B-cell-derived lymphoid lines T51 (ref. 14) and DAUDI (ref. 15), and our standard fluorochromatic cytotoxicity assay. DAUDI does not express the usual serologically determined

---

Table 2 Grain density distributions for cells incubated with CMP-³H-NANA or ³H-galactose

Compartment	Relative grain density	
	CMP-³H-NANA	³H-galactose
Plasma membrane*	100	16
Cytoplasm	11	14
Osmiophilic vacuoles	0	14
Golgi apparatus	7	100
Nucleus	2	7
Nucleolus	0	5

Photographs of labelled cells were taken at random and enlarged to a final magnification of ×10,000. Grains and points from a superimposed grid (1 point = 9 μm³ at ×10,000) were scored according to the cellular compartment they occupied. Grains per μm² minus background (0.2 grains per 100 μm²) were determined for each compartment and then normalised so that the compartment with the highest grain density was set equal to 100 and all other densities for that label adjusted proportionally. Relative grain densities for cells labelled with CMP-³H-NANA are based on 230 cells, 780 grains and 1,300 grid points. Those for ³H-galactose are based on 175 cells, 850 grains and 1,200 grid points.

*Includes all grains and points within 3,000 Å of the actual membrane to allow for radiation scatter[12].

HL-A antigens of the LA and four loci, nor does it have $\beta_2$microglobulin (β_2m)[16]. Any sera reacting with DAUDI are therefore presumed to have antibodies against Ia-type antigens. Out of 108 pregnancy sera previously characterised as having lymphocytotoxic HL-A antibodies when screened on a cell panel covering all the known LA and four loci antigens, ten were found which reacted with DAUDI or gave reactions with T51 that could not be explained by its HL-A type.

Serum P1530B, a weakly cytotoxic anti-HL-A9 antibody, was selected for further investigation using an indirect immunofluorescence assay[16]. Table 1 suggests that P1530B was reacting preferentially with B cells of some, but not all donors. As further evidence for B cell specificity, the percentage of lymphocytes reacting with P1530B was compared with the percentage reacting with a fluorescent anti-human IgM antibody. The differences were not significant in five cases tested. Furthermore, labelling with anti-human IgM antibody and P1530B failed to increase the percentage of fluorescing cells. B lymphocytes separated from peripheral lymphocytes by 'E' sheep red cell rosetting also showed an increased percentage of positive cells with P1530B, the rosetted T cells being totally unreactive. The positive reactions could not be removed by absorption with HL-A9-positive platelets (4×10^9 ml^{-1}) which did remove the weak cytotoxic HL-A9 antibody.

Two lines of evidence indicate that the P1530B reaction with B lymphocytes is directed against an antigen determined by a gene in the HL-A region, thus supporting the analogy with the mouse Ia antigens. The first is that out of a series of six somatic cell hybrids derived from a cross between the mouse L cell derivative A9 and DAUDI (refs 16 and 17) the only positive clone by immunofluorescence was also the only one containing human chromosome 6, which carries the HL-A region[18,19]. Subclones of this and other similar hybrids are now being studied to confirm this assignment. The second is that the results of a study of the immunofluorescence reactions of

P1530B on peripheral blood lymphocytes of parents and offspring from three families, were consistent with linkage between the HL-A system and the gene determining the antigen recognised by P1530B.

Screening for serum reactions similar to P1530B was extended by testing a panel of HL-A2 antisera for their cytotoxic activity on DAUDI, 8866 and its HL-A2-negative variant 8866 1-2 (ref. 12). Reactions with 8866 1-2 or DAUDI, are indicative of Ia-type reactivity. Out of 13 such sera tested, all of which reacted with 8866, two (5005 and 7155A, Table 2) also reacted with 8866 1-2 and DAUDI, whereas the remaining 11 were negative on these lines. This approach to detecting Ia-type activities, however, is limited by the need for a number of well-characterised HL-A-negative lymphoid line variants. It did

Sera	Origin	BRI8	BRI8 stripped

Rabbit anti-β_2m	Dakopatts	4	1/2

Scores: 4, very strong positive; 3, strong positive; 2, weak, but definitely positive; 1/2, slight reaction, doubtful positive; 1, negative. Stripping of β_2m was carried out essentially according to Bernoco et al.[19] using rabbit anti-human β_2m (Dakopatts, Denmark) followed by a purified horse anti-rabbit IgG antibody, which was absorbed with an equal volume of human red blood cells and 10^8 DAUDI cells per ml serum to remove nonspecific effects. Stripped cells were suspended in a medium containing 10 mM sodium azide and then used in a cytotoxicity assay.

however, suggest another way of screening sera for Ia-type activity, namely to remove HL-A from lymphoid lines or from peripheral blood lymphocytes by 'stripping'[19] with anti-β_2m and anti-immunoglobulin sera.

The removal of β_2m from the surface of peripheral blood lymphocytes in this way also removes the associated allogeneic chain of the HL-A molecule and thus results in a complete loss of HL-A antigenicity. As DAUDI seems to have Ia-type antigens on its cell surface but not β_2m, at least some of these Ia antigens are presumably not normally associated with β_2m on the cell surface and so would not be removed from normal cells by stripping of the β_2m with specific antisera. In this way, therefore, we can turn any line effectively into a completely HL-A-negative variant and then screen for other Ia-type activities not associated with β_2m.

Reactions of the line Bri8 (HL-A1, 2, 8, 13) before and after

Sera (including P1530B) were selected in the course of routine screening of pregnancy sera for HL-A activity because of their reactions with DAUDI. Scoring system as in Table 1.
*Cells from Searle Diagnostics; †see text; ‡cell line initiated by Dr G. Moore; §cells from Searle Diagnostics; ‖cells from Searle Diagnostics; ¶ see text; **P1530B was also found to be positive on the lymphoid lines Ba-13, Des3 and Sha, and negative on the lymphoid lines OR-1 and Bec 11.

stripping with essentially the same set of HL-A2 antisera used on 8866 and its variant, are shown in Table 2. The reactions of HL-A2-positive peripheral lymphocytes with this set of antisera could be completely removed by β_2m stripping. The same two sera (5005 and 7155) that reacted with the HL-A-negative variant of 8866 (and with DAUDI) also reacted with β_2m stripped Bri8. The only other serum to react in this way was 4253A, all the remaining sera, including as a control the anti-β_2m, were negative. These results validate the use of stripped lymphoid line cells for the detection of Ia-type activity. Reaction of 4253A with stripped Bri8 but not 8866 1-2 or DAUDI indicates some complexity in the Ia polymorphism. This is confirmed by more extensive typing of several of the lymphoid lines after β_2m stripping with a total of 20 antisera that have been shown to exhibit these Ia-type activities. A sample of these reactions is shown in Table 3. There is a complex pattern of reactions which is reminiscent of the early days of HL-A typing with unselected pregnancy sera, before the serologically detectable antigens had been properly defined. It seems likely that these initial Ia antisera will be complex mixtures of possibly cross reacting antibodies and further work is now being carried out to define the specificities properly.

Very striking associations between HL-A antigens and specific diseases have been established[20,21]. There are, however, a number of weak associations with the serologically detectable antigens which may simply reflect weak linkage disequilibrium between the genes in the HL-A region controlling disease susceptibility and those controlling the antigens of LA, 4 and AJ series. MLC typing in multiple sclerosis patients[22] has demonstrated that in such cases alleles at other loci in the region may show much stronger associations and so lead to both a better definition of the HL-A association and possibly its cause. Serological Ia typing will undoubtedly prove to be a powerful tool in future disease association studies.

While this paper was being written, Winchester *et al.*[23] reported a somewhat analogous study on B lymphocyte specific human antigens also using lymphoid lines. Details of our investigations will be published elsewhere.

We thank C. Barnstable and J. Brown for discussions, Professor H. Harris for providing the DAUDI xA9 hybrids, Dr A. Williams for the purified horse anti-rabbit IgG antibody, Drs W. Sly, M. Steel and G. Moore for lymphoid lines and many colleagues for exchanges of HL-A typing reagents. This work was supported in part by a grant from the MRC. P.G. and E.J. acknowledge predoctoral studentships from the MRC.

Mouse T-cell surface glycoprotein recognised by heterologous anti-thymocyte sera and its relationship to Thy-1 antigen

CELL surface proteins specific for either T or B lymphocytes probably have a significant role in lymphocyte physiology, and we have therefore been characterising the plasma membrane proteins from mouse lymphocytes to identify such molecules and to determine their function. We have previously detected a high molecular weight T-cell-surface protein (T200, apparent molecular weight 200,000) which could be labelled by lactoperoxidase-catalysed iodination[1] and was recognised by rabbit anti-mouse thymocyte sera (ATS). We have now identified a low molecular weight T-cell-specific molecule present on mouse thymocytes, T lymphomas and peripheral T cells which is also recognised by rabbit antibodies to mouse lymphocytes.

This molecule was recognised during immunoprecipitation studies using labelled thymocytes and both unabsorbed ATS and a preparation of ATS made specific for T cells by absorption. ATS selectively precipitated two major iodinated species from labelled thymocytes—T200 and a low molecular weight component of broad electrophoretic mobility (T25, molecular weight 25,000–30,000; Fig. 1*b*). Several less heavily labelled species were also precipitated by ATS. Qualitatively similar results were obtained with four different preparations of antisera: two raised as described previously[2], one by repeated intravenous immunisation[3], and the fourth was a commercial preparation of antiserum (Microbiological Associates).

Similar gel profiles were observed whether cell lysates were prepared and immunoprecipitations carried out in the presence of either Nonidet P40 or sodium deoxycholate. Rabbit antisera to mouse T lymphomas that express the Thy-1 antigen also precipitate T25 and T200 (for example, anti-BW5147 serum, Fig. 1*e*, and anti-WEH1 22 serum, Fig. 1*f*). A preparation of ATS which was absorbed with neonatal liver cells and spleen cells from thymectomised, irradiated, neonatal liver cell-restored mice and was specific for mouse T lymphocytes as judged by indirect fluorescence and cytotoxicity studies (anti-T serum[4,5]), still contained antibodies which recognised T25 (Fig. 1*c*). This observation indicates that T25 carries antigenic determinants which are specific for T lymphocytes. The amount of radioactivity associated with T25 suggests that it is a major component of the thymocyte cell surface. Almost all the radioactivity precipitated by the anti-T cell serum was associated with T25 and this antiserum precipitated 4.8% of the total acid-insoluble radioactivity in an NP40 extract of labelled thymocytes. In contrast, unabsorbed ATS precipitated 8.5% and normal rabbit serum (NRS) 0.16% of the acid-insoluble radioactivity. T25 is also present on the surface of T lymphomas which express the Thy-1 antigen (for example, WEH1 22, Fig. 1*g*).

Examination of the labelled species precipitated by unabsorbed ATS or anti-T serum from iodinated peripheral lymphocytes of either normal or congenitally athymic (*nu/nu*) mice showed that T25 is present on peripheral T cells but probably in lesser amounts than on thymocytes (Fig. 2). Anti-T serum precipitated T25 from detergent-solubilised extracts of spleen and lymph node cells of normal mice (Fig. 2*c* and *e*) but not from peripheral lymphocytes of athymic mice. Unabsorbed ATS precipitated T25 from spleen and lymph node cells of normal mice, and T200 and the high molecular weight B-cell protein[1] from peripheral lymphocytes of both normal and athymic mice (Fig. 2*b*, *d* and *e*). A comparison of the gel profile of the labelled species precipitated by ATS with that of the labelled proteins precipitated by rabbit anti-mouse immunoglobulin serum (Fig. 2*h*) suggests that this particular preparation of ATS reacts with immunoglobulin.

Thus, T25 is a T-cell-specific molecule present on thymocytes, T lymphomas and peripheral T cells. Biosynthetic labelling studies, sensitivity to proteolytic enzymes and binding to plant

Molecular weight standards: β-Gal, β-galactosidase; BSA, bovine serum albumin; H chain, rabbit IgG heavy chain; OVA, ovalbumin; CA, carbonic anhydrase; L chain, rabbit Ig light chain. A 9% polyacrylamide gel was used. The preparation of viable cell suspensions, lactoperoxidase-catalysed iodination, solubilisation of cells for immunological studies, and polyacrylamide gel electrophoresis in the presence of SDS have been described[1].

lectins suggest that T25 is a glycoprotein (I.S.T. and M.J.B., unpublished). Furthermore, no radioactivity was precipitated from an NP40 lysate of cells labelled with ^{3}H-palmitate using a variety of antisera which precipitate T25 and T200, suggesting neither molecule is associated with lipid in these conditions. Other investigations to be reported in detail elsewhere suggest that T25 is identical with the molecule which carries the mouse Thy-1 alloantigenic determinant[6]. T25 is precipitated by rabbit antisera against mouse brain, rat thymocytes and rat brain; similar cross reactivity has been noted for the Thy-1 molecule on the surface of mouse[7] or rat thymocytes[8]. T25 cannot be detected on the surface of Thy-1-negative variants[9] of mouse T lymphoma cell lines, and has the same properties as those of the rat thymocyte Thy-1 molecule[10] when chromatographed on Sepharose 6B in 1% sodium deoxycholate. T25 is recognised by a rabbit antiserum raised against a purified preparation of rat brain Thy-1. 1 antigen (Fig. 3), also indicating that T25 carries the Thy-1 determinant. This antiserum is specific for the Thy-1 molecule on rat thymocytes (A. N. Barclay, M. Letarte-Muirhead, and A. F. Williams, unpublished). Antibodies present in this antiserum which cross react with T25 from BALB/c thymocytes were removed by absorption with either mouse thymocytes, mouse brain homogenate, or rat thymocytes,

but not by rat lymph node cells which express only low levels of the Thy-1 antigen[11,12]. In contrast to this heterologous antiserum, mouse anti-Thy-1 alloantisera failed to specifically precipitate any iodinated species from thymocytes or T lymphoma cells whether solubilised in NP40 or sodium deoxycholate. This failure is probably a consequence of the low affinity of the anti-Thy-1 alloantibodies present in these sera. The presence of detergent or the abolition of multivalent interactions by disruption of the cell membrane may prevent formation of stable antibody–antigen complexes.

Two other possible explanations, that detergent specifically masks the Thy-1 antigenic determinant, or that the mouse Thy-1 antigenic determinant is a glycolipid[13,14] which is specifically associated with T25 on the T lymphocyte surface but which dissociates from T25 after solubilisation of the cell membrane by detergent can be excluded because an antiserum prepared from the rabbit anti-rat Thy-1 serum by absorption with BALB/c thymocytes or brain tissue precipitated T25 from an NP40 lysate of AKR/J thymocytes but not BALB/c thymocytes. The recognition of T25 by an antiserum apparently specific for the Thy-1. 1 alloantigenic determinant strongly suggests that T25 is identical with the Thy-1 antigen; only the unlikely possibility that BALB/c and AKR/J mice express

Fig. 2 Autoradiographs of iodinated peripheral lymphocytes from normal and congenitally athymic (*nu/nu*) mice: *a–c*, spleen cells; *d* and *e*, lymph node cells from BALB/c mice; *f–i*, mixture of spleen and lymph node cells of mice carrying *nu/nu* character backcrossed on to a BALB/c genetic background. *a*, Total spleen cell NP40 lysate; *b–i*, immunoprecipitates using various antisera; *b*, *d* and *f*, unabsorbed ATS; *c*, *e* and *g*, anti-T serum; *h*, anti-mouse Ig serum; *i*, NRS. different alleles of another alloantigenic determinant with the same tissue distribution and interspecies cross reactivity as Thy-1, prevents these observations from being considered formal proof that T25 is the Thy-1 antigen. If this is the case then earlier reports that the mouse Thy-1 antigen is a glycolipid[13,14] require re-examination. One possibility is that the Thy-1 antigenic determinant may be carbohydrate; the blood group substances provide an example of a carbohydrate antigen present on both glycoprotein and glycolipid[15].

Thymus dependence of viral antigens

AFTER exposure of animals to most antigens, formation of antibody by cells of the B lymphocyte lineage requires helper effects of T lymphocytes[1]. The degree of thymus dependence varies for different antigens, and slowly metabolised immunogens with repeating epitopes, generally polysaccharides or polymerised forms of protein, seem to be the most thymus-independent[2]. Antigens of some viruses, however, may be relatively thymus independent. Inherent in the structures of many viruses is a rigid geometrical array of repeating antigenic determinants which, if the spatial relationships were appropriate, may effectively interact with and trigger B cells without help from T cells. Also, glycoproteins are important antigens in the virions of many viruses[3], and the carbohydrate portions of these molecules may function as thymus-independent immunogens. In addition, repeated immunisation of mice depleted of T cells can sometimes result in antibody production to thymus-dependent antigens[4], and virus infections often result in the sustained production of antigens and thus prolonged exposure of the infected host to the antigens. These antigens may be presented to the immune system in a variety of ways—on the membranes of infected cells, as soluble antigens released from such cells, and as repeating epitopes on virus particles.

The humoral antibody responses of athymic nude (*nu/nu*) mice after virus infection were compared with those of normal littermates (*nu/+* or *+/+*). Lymphocytes from nude mice have no demonstrable functions characteristic of T cells[5], whereas B cell functions such as blastogenic responses to lypopolysaccharide are present, and normal or increased antibody responses are made to thymus-dependent antigens such as type III pneumococcal polysaccharide[6]. The function of dendritic macrophages in nude mice is also normal[7] and nude mice can be rendered immunologically competent by the implantation of thymus grafts[8]. Heterozygous (*nu/+*) mice seem to be immunologically normal[5]. The alternative use of mice which have been depleted of T cells by thymectomy, irradiation, and bone-marrow reconstitution (TXBM) was rejected as such mice have defects in addition to T-cell depletion of T cells[9-11] (W. H. B. and H. C. Morse, unpublished).

Nude mice and their normal littermates were infected intraperitoneally and their sera assayed for antibody to certain antigens (Table 1). Sustained antibody responses to all 12 viruses from nine major virus groups were markedly thymus dependent. Nude mice, however, made early transient responses equal in magnitude to those of normal littermates to the picornaviruses, Coxsackie B1 virus and encephalomyocarditis (EMC) virus, to vesicular stomatitis virus (VSV), and to Sindbis virus. Antibody production in nude mice to the Sindbis antigen(s) that react with neutralising antibody was sustained for 2 weeks and was solely IgM as indicated by its appearance in the IgM fraction after column chromatography of serum on Sephadex G-200 and by its sensitivity to 2-mercaptoethanol (data not shown). Normal littermate mice produced IgG as well as IgM antibody to this antigen and these mice, unlike nude mice, produced large secondary responses (1:10,000) of predominantly IgG antibody. The Sindbis antigen(s) concerned are found on two virion membrane glycoproteins[12,13].

As Kennedy demonstrated that the antigenic determinants of Semliki Forest virus (an alphavirus similar to Sindbis virus) are in the polypeptide portions rather than the carbohydrate portions of the envelope glycoproteins[14], it will be of interest to determine if antibodies produced in the relatively thymus-independent IgM response react with antigenic determinants of Sindbis virus residing in the protein part of the molecule. Neutralising-antibody production by nude mice to Coxsackie B1 virus, EMC virus, and VSV peaked 6–8 d after infection, was sensitive to 2-mercaptoethanol, and thus was probably IgM immunoglobulin. As picornaviruses back lipid and carbohydrates, the neutralising antibody to Coxsackie B1

*NT, neutralising antibody; HI, haemagglutination-inhibiting antibody; CF, complement-fixing antibody.
†Immunising dose of infectious virus given intraperitoneally on day 0 and repeated thereafter as indicated in immunisation schedule.
‡Mice were inoculated on day 0 and on subsequent days as indicated.
§Antibody assays were carried out on indicated day after initial inoculation. Assays were carried out soon after infection to detect transient IgM responses, as well as late in infection and after multiple immunisations. Neutralisation tests were carried out by incubating 0.2 ml virus containing 100 plaque-forming units (PFU) and 0.2 ml diluted sera at 37 °C for 1 h and assaying for residual infectious virus. Complement-fixation (CF) and haemagglutination-inhibiting (HI) tests were carried out on coded serum samples by Microbiological Associates, Bethesda, Maryland. All sera were heated to 56 °C for 30 min before antibody assay. Titres are expressed as the reciprocal of the highest serum dilution that neutralised 50% of the virus and are the average of determinations on two or more animals.

virus and EMC virus must be directed against protein antigenic determinants. The neutralisation antigen(s) of VSV are found on an envelope glycoprotein, but the relative contributions of protein and carbohydrate to the antigenic determinants are not known.

Until availability of the athymic nude mouse, however, neonatal thymectomy or treatment with ALS was used to deplete animals of T lymphocytes and ascertain the thymus independence of viral antigens. Thus, neither neonatal thymectomy[4] nor ALS treatment[15] of mice diminished their production of HI antibody to influenza virus. In CF1 mice neonatally thymectomised, titres of complement-dependent neutralising antibody (probably IgM) to herpes simplex virus (HSV) were similar to those in control mice[16]. Discrepancies between these findings and the present demonstration of the thymus dependence of antibody production to influenza virus and HSV may stem from the use of mice inadequately depleted of T cells in earlier studies. Thymus dependence of HI antibody production to influenza virus has, however, been observed using TXBM[17] and nude[18] mice; the former do not produce neutralising antibody to HSV (W. H. B. and H. C. Morse, unpublished). Also, TXBM mice have been reported to respond well to Coxsackie B3 virus[19].

In conclusion, normal magnitude but transient IgM responses have been observed early after infection of athymic nude mice with several viruses. The antigens concerned are clearly protein in nature (picornaviruses) or are probably protein portions of virion envelope glycoproteins (Sindbis virus and VSV). The switch from IgM to IgG synthesis and the elicitation of secondary (IgG) antibody responses to these viral proteins, as to protein antigens generally, is highly thymus-dependent.

The present study has, however, surveyed the thymus dependence of a small number of viral antigens and utilised mice exclusively; the examination of other antigens of these same viruses, of different viruses, or the use of other animal species may disclose more thymus-independent viral antigens. Also, because of a limited supply of nude mice, dose–response studies were not carried out. Although normal littermates ($nu/+$ or $+/+$) were used in this study for comparisons, a more proper control would be thymus-grafted nude mice using thymuses from congenic mice. As the nude mice available were the result of passing the nu trait in outbred Swiss mice, such experiments were impossible and must await the availability of nude mice congenic with an inbred strain. The use of infectious agents makes difficult the administration of precise amounts of antigens, and the possibility exists that the viral infection itself may be thymus-dependent. Antigenic doses, however, were in some cases sufficient to elicit normal IgM responses in nude mice and the failure to switch to sustained IgG responses is unlikely to be caused by insufficient antigen.

Our findings should be considered in the light of the need for cell-mediated immunity in viral infections. Depletion of T cells may result in deficient antibody production as well as a diminution of effector cells involved in cell-mediated immunity. K-cell activity may also be diminished in those situations in which IgG antibody is not produced[20].

Binding of α-foetoprotein to murine T cells

α-FOETOPROTEIN (AFP), an embryo-specific glycoprotein, is primarily known as a tumour-associated embryonic antigen. Although much is known about the occurrence of AFP in ontogeny and levels of AFP in different diseases, such as hepatocellular carcinoma and other tumours[1-4], little work has been done on its functional significance. Results from our laboratory have shown that AFP exerts an immunosuppressive effect on antibody synthesis when administered *in vivo*[5] and that it is a non-cytotoxic suppressor of both the primary and secondary antibody response to sheep red blood cells (SRBC) *in vitro*[6]. In addition, we found that AFP suppresses certain T-cell-dependent functions in mice such as allogeneic and mitogen-induced lymphocyte transformation[7]. A recent report[8] suggests that bovine foetuin is immunosuppressive for mitogen and allogeneic reactions. Bovine foetuin and AFP have, however, been shown to be different proteins[9]. Moreover, in view of the relatively large amounts of foetuin used to obtain suppression (10,000-fold higher than those required for suppression in our studies using AFP), it is possible that the foetuin preparations were contaminated with suppressive amounts of bovine AFP.

To define the cell type(s) affected by AFP we studied the binding of AFP to the surface of various cells involved in the immune reaction using direct immunofluorescence on preparations of thymus derived lymphochtes (T cells), bone marrow derived lymphocytes (B cells) and macrophages.

Mouse amniotic fluid (MAF) contains three major components: AFP, albumin, and transferrin[6]. MAF was collected from Ha/ICR mice in the late second trimester of pregnancy. Antiserum to MAF was prepared in rabbits by subcutaneous injection of MAF in Freund's complete adjuvant. A globulin fraction of this antiserum (double 18% sodium sulphate precipitation) was conjugated with fluorescein and absorbed with lyophilised normal adult mouse serum, rendering it monospecific for AFP. This antiserum gave a single line on Ouchterlony gel diffusion with MAF, which fused in a reaction of immunological identity with foetal, newborn and pregnant sera and purified AFP. Purified AFP was isolated from MAF as described previously[6]. Briefly, this involves affinity chromatography using an anti-whole adult mouse serum, followed by preparative polyacrylamide gel electrophoresis. The specificity of the AFP was determined by gel diffusion and immunoelectrophoresis using anti-mouse whole serum and anti-mouse MAF. The antisera were shown to be specific by the following: First, the absorbed antiserum gave a single line with whole concentrated MAF. This line fused on Ouchterlony with a single line in cord serum, pregnant serum and a highly purified preparation of AFP. Second, the antiserum was checked against another antiserum from Roswell Park, which is specific for AFP derived from a mouse hepatoma, and was found to form a line of

identity. Third, the fluorescent reaction was blocked by pure AFP and not albumin or transferrin (see ref. 6 for techniques of isolation and purity of preparations and antisera). In addition to the procedures outlined in that reference, we used gel filtration on Sephadex G-200. Finally, at least three other antisera have been produced in this laboratory recently against purified preparations of AFP and have been shown to be identical to the one used in the present study. No significant surface staining occurred with an anti-mouse albumin. (In addition the purity of the AFP was checked by sedimentation ultracentrifugation and polyacrylamide gel electrophoresis in both alkaline and sodium dodecyl sulphate gels.)

All studies were carried out using 6–10-week-old C57BL female mice with the exception of the experiment done with nude mice. We found that after a 90-min incubation in MAF a maximum number of cells stained in whole spleen preparation (approximately 18%) as shown by positive membrane fluorescence when reacted with anti-AFP. Various primary and secondary lymphoid tissues were examined to determine the presence of cells which bound AFP. The results presented in Table 1 show that spleen, lymph node and cortisone resistant thymocytes, but not bone marrow or nude mouse spleen cells, contained AFP binding cells.

Adult mouse spleen cells were treated with either anti-Fab or anti-θ plus complement to produce lymphoid preparations depleted of B and T cells respectively[10]. Spleen cells were passed sequentially over glass and nylon wool columns to enrich for T cells[11]. These preparations contained 88% cells staining with anti-θ and 7% cells staining with anti-Fab (anti-L chain). Peritoneal exudate cells were obtained by injection of thioglycolate to obtain a cell population containing a high proportion of macrophages[12]. Finally, a population of spleen cells was depleted of B cells and macrophages using glass and nylon wool columns and the non-adherent cells (largely T cells) were treated with anti-θ and complement. A summary of the results obtained for AFP binding on these various cell populations is presented in Table 2. AFP binds to cells which are not adherent to nylon wool and are destroyed by anti-θ plus complement. No binding is seen with B-cell enriched populations (spleen treated with anti-θ plus complement) or in the spleens of nude mice. We cannot rule out a small amount of binding to macrophages but the major cell type involved seems to be a T cell. Figure 1 illustrates the surface binding of AFP by spleen cells.

Since only a fraction (about one-third) of the T cells bind AFP, it is possible that a subclass of T cells may be involved in AFP suppression. More sensitive techniques, such as the use of ^{125}I-AFP, will, however, be necessary to determine whether significant numbers of molecules of AFP bind to "negative" T and B cells but are not present in sufficient numbers to be detected by the fluorescence method.

The relatively small numbers of thymocytes ($< 1\%$) and

*15×10^6 viable cells incubated in media, normal mouse serum (NMS) at 2 mg ml^{-1} or mouse amniotic fluid (MAF) at 2 mg ml^{-1}, for 90 min at 37 °C. Cells washed three times in cold media (RPMI 1640), suspended in 100 µl of media plus 50 µl of a fluoresceinated monospecific anti-AFP antiserum and incubated at 4 °C for 30 min. Surface fluorescence examined using a Leitz ortholux microscope. Figures are the average of duplicate experiments.

†Cortisone acetate (125 mg kg^{-1}) was injected intraperitoneally 2 d before the thymocytes were collected.

cortisone resistant thymus cells (6%) demonstrating binding compared with 18% of peripheral spleen T cells, suggest the possibility that AFP binding is detecting surface receptors which require additional maturation after peripheralisation from the thymus.

The binding of AFP to a T-cell population is compatible with the previous data from our laboratory showing that the addition of AFP late in the antibody response does not suppress the synthetic capacity of B cells[6]. We also reported[5,6] that the IgA and IgG responses are more sensitive to the suppressive effects of AFP than are IgM responses. These findings are consistent with AFP exerting its effect on helper T cells since the switch from IgM to IgG and IgA is thought to be T-cell dependent[13,14]. The observations[7] that AFP has a direct effect on certain T cell dependent functions (mitogen and allogeneic stimulation) in mice is consistent with the findings presented here. Finally, preliminary experiments (R.J.D., R. H. Keller, and T.B.T., unpublished) indicate that concanavalin A (con A) and methyl-α-D-glucopyranoside inhibit AFP binding suggesting that the con A and AFP binding sites may be identical or closely spaced on the membrane surface.

Table 2 Percentage surface staining for AFP*

Treatment	Spleen cells	Spleen cells passed over nylon wool†	Peritoneal exudate cells

†Indirect immunofluorescence with anti-θ and anti-Fab showed that these preparations contained 88% θ-positive and 7% immunoglobulin-positive cells whereas the starting spleen cells contained 45% T and 44% B cells.
‡Normal mouse serum (NMS).
ND, Not done.

The mechanism of AFP suppression is unknown. T cells could be "turned off" by AFP binding to their surface, for example by mechanisms involving changes in cellular concentrations of cyclic AMP and cyclic GMP. Alternatively, AFP may activate suppressor cells or promote differentiation of a precursor T cell into a suppressor cell population. Further studies are necessary to define the mechanism(s) involved in AFP induced suppression.

Hormonal regulation of α₁ foetoprotein

THE clinical usefulness of α_1 foetoprotein (AFP) is extensively documented[1] but the biological significance of this protein and the mechanisms regulating its synthesis remain unknown. We have investigated the effect of various hormonal, nutritional and haematological conditions on AFP metabolism in newborn and adult rats and mice. We present our results and some conclusions on regulation and function of AFP.

Different types of hormones markedly suppressed serum AFP levels in newborn rats. Among them, glucocorticoids (prednisolone 3 µg g^{-1} d^{-1}, dexamethazone 2 µg g^{-1} d^{-1}, hydrocortisone 15 µg g^{-1} d^{-1}) all induced a dramatic decrease in blood AFP (Fig. 1) together with an increase in albumin and total protein levels; this effect was partly reversible on cessation of treatment. Adrenocorticotrophic hormone (ACTH) (10 U d^{-1}), levothyroxine (3 µg d^{-1}), adrenaline (1:10,000, 2 µl g^{-1} d^{-1}) and db-cyclic AMP (10 µg g^{-1} d^{-1}) also produced significant decreases in AFP levels without depleting albumin and total protein levels. Inconsistent or non-significant effects were observed with desoxycorticosterone (0.025 µg g^{-1}d^{-1}), insulin (semilente 0.03 U g^{-1}d^{-1}), glucagon (0.1 µg g^{-1} d^{-1}), 17-β-oestradiol (3 µg g^{-1} twice a week), testosterone (3 µg g^{-1} twice a week) and progesterone (5 µg g^{-1} three times a week). Neonatal adrenalectomy, ovariectomy, orchidectomy, radiothyroidectomy or thymectomy did not modify the normal physiological disappearance curve of AFP. Adrenalectomy suppressed the effect of ACTH and reduced the effect of thyroxine but did not modify the effects of prednisolone and db-cyclic AMP. Thyroidectomy did not modify the effects of prednisolone, db-cyclic AMP or thyroxine.

Metabolic studies were carried out on prednisolone-, thyroxine- and adrenaline-treated rats. These three hormones did not significantly alter the serum clearance of radiolabelled AFP (half life 23 h), although they all decreased incorporation of ^{14}C-leucine in to AFP at a rate proportional to serum levels (Fig. 2). Liver tissue AFP content was also drastically decreased by prednisolone. These results indicate that prednisolone and probably adrenaline and thyroxine depress AFP levels through a selective blockade of its synthesis.

Attempts to correlate AFP levels with liver DNA synthesis activity of rats during uninterrupted prednisolone treatment disclosed the following facts. Prednisolone injection is rapidly followed by a marked depression of ^{3}H-thymidine incorporation in liver parenchymal cells. This negative phase, however, is always followed by a burst of labelling activity 8 d after injections are started (Fig. 1). The newly labelled cells are typical hepatocytes uniformly dispersed throughout the lobule.
Fig. 1 Effect of prednisolone (3 μg g^{-1} d^{-1} from days 9 to 21) on serum AFP levels (●, ○) and ^{3}H-thymidine incorporation in liver cells of newborn rats (▲, △). Mean ±s.d. (4–6 rats). ●, ▲, Controls; ○, △, prednisolone. AFP-suppressive action of prednisolone was effective throughout the postnatal period (0–21 d) and also before birth (injection into amniotic sac of 16-d pregnant rats). The experiments were carried out on Sprague–Dawley rats and C3H/HeB mice. Hormones injected were current pharmaceutical products; usually, intraperitoneal injections were used, control animals receiving equivalent amounts of carrier. In neonatal experiments, half of every litter was used as control. Albumin and α$_1$ foetoprotein were quantitated by electroimmunodiffusion. The hepatic DNA synthesis activity was measured by autoradiography of liver tissue taken 1 h after intraperitoneal injection of ^{3}H-thymidine (2 μCi g^{-1}). Protein synthesis activity was evaluated by measuring the amount of radioactivity incorporated in serum AFP and total proteins 15–240 min after intravenous or intraperitoneal injection of ^{14}C-leucine (1.5 μCi per 100 g). The AFP catabolic rate was determined by measuring the serum clearance of ^{125}I-labelled antigen (purified by the method of Nishi[2]) between 6 and 168 h after injection of radioactive material (1 μCi per animal.)

This wave of DNA synthesis is never accompanied or followed by a resurgence of AFP secretion. It is in turn followed by another phase of suppression of ^{3}H-thymidine incorporation. Although the blocking action of glucocorticoids on liver DNA synthesis of newborn rats is a well known phenomenon[3], to our knowledge, such a biphasic effect of prednisolone has not been reported so far.

Our data thus indicate that adrenal and thyroid hormones may have an important function in the physiological regulation of AFP metabolism. Further, assuming that AFP is produced by a liver parenchymal cell and considering the association of AFP synthesis with cell division[4], the following conclusions may be reached. The secondary hepatocyte proliferation wave which appears during prednisolone treatment (Fig. 1) infers

Fig. 2 Effect of prednisolone (3 μg g^{-1} d^{-1} for 3 d) on ^{14}C-leucine incorporation in total serum proteins (*a*) and serum AFP (*b*) of 8-d-old rats. Radioactivity recovered from 5% TCA precipitates and from AFP–anti-AFP precipitates. Mean and limit values for 4–6 animals.
that AFP synthesis is not a prerequisite for hepatocyte proliferation; moreover, it shows that AFP is not produced indifferently by any type of mitotic hepatocyte. The rapid labelling of circulating AFP after ^{14}C-leucine administration (Fig. 2) indicates that AFP is rapidly secreted into the blood following its synthesis. Therefore, that AFP is synthesised before mitosis and released after mitosis[4–5] may be excluded; furthermore, injecting 4-d-old rats with colchicine (25 ng g^{-1}d^{-1} for 6 d) did not modify serum AFP levels (although it lowered by 47% the number of ^{3}H-thymidine-labelled liver cells).

In contrast to newborn rats (and mice), glucocorticoids usually have an enhancing effect on AFP levels in adult animals submitted to AFP-inducing conditions. This is best illustrated using mice intoxicated with CCl$_4$ (Fig. 3). In such animals, prednisolone markedly reduces the regenerative hepatocyte proliferation, but strikingly increases serum AFP levels; furthermore, the peaks of cellular proliferation and AFP secretion are shifted respectively from 40 to 72 h and from 3–4 to 6 d in control compared with hormone-treated animals (Fig. 3). Although prednisolone aggravates liver damage (as evidenced by levels of transaminases) and enhances passive release of AFP from injured cells, such opposite effects on AFP levels and cell proliferation clearly do not support the view that any dividing hepatocyte can resume AFP synthesis.

One interpretation would be that AFP synthesis can occur only during a definite stage of liver parenchymal cell ontogeny—in other words that AFP is the exclusive product of a 'transitional' cell, mitotically active and lying ontogenically between some stem cell (the 'oval' cell[6]) and the fully mature hepatocyte. This view is in very close agreement with the
Fig. 3 C3H male adult mice injected intraperitoneally at 0 h with 0.1 ml CCl$_4$ per 100 g and from day 0 with daily subcutaneous injections of prednisolone (0.5 mg per animal) or saline (*a*). Each point is the mean of 4–6 animals. ▲, Cellular proliferation time (CPT); ○ AFP; radioactivity.

findings and hypotheses of Onoe *et al.* (see also Abelev[7]), and is supported by the work of Guegen *et al.* These authors have found that in newborn rat liver cell cultures, glucocorticoids promote the proliferation of mature hepatocytes but block (reversibly) the proliferation of 'intermediary cells'. If one assumes that such an intermediate cell is the AFP producer, this *in vitro* situation would account for the kinetics of AFP observed in newborn rats treated with prednisolone.

This could explain the lag phase between the hepatocyte division wave and peak of AFP production during liver regeneration. Being dependent on concomitant recruitment of progenitor cells, AFP production would take place during a later phase of liver repair, that is, during a fugaceaous intermediate mitotic stage of the stem cell on its way towards the mature hepatocyte. Thus, the effect of prednisolone on AFP levels during CCl$_4$ intoxication would be the result of a balance between strong indirect stimulation of stem cell recruitment due to enhanced liver damage and to reduced regenerative capacity of the hepatocytes and, as in the newborn, direct repression of the AFP-producing cell. At over 1 mg per animal

per d, the AFP-enhancing effect of prednisolone progressively decreases in CCl_4-treated mice, which would fit this scheme.

We also found that prednisolone stimulates AFP production in tumour (3'-Me-DABu-induced)-bearing rats. AFP production of rat hepatoma is related to tumour growth rate[9] and this enhancing effect of prednisolone is probably part of the representative response of tumours to glucocorticoids which seems to reflect the growth of the tissue[10].

We conclude that physiological regulation of AFP is influenced by all factors, such as hormones, which control and influence the growth or the maturation of the liver and, more specifically, the proliferation and the differentiation of the intermediate pre-hepatocyte cell. Therefore, all conditions which modulate or interfere with general physiological maturation processes could also affect AFP metabolism. One such hindering situation is neonatal iron deficiency, the effect of which on serum AFP levels is depicted in Fig. 4.

Fig. 4 Effect of iron deficiency on AFP levels of newborn rats. Deficiency was induced by serially bleeding gestating rats and by submitting them to an appropriate diet; weaned rats were maintained on the same diet. ●, Controls; O, iron-deficient. Each point is the mean of 4–7 animals taken from 2–6 litters. Where indicated, bars represent limit values.

There are obvious analogies between albumin and AFP. The two proteins share similar physicochemical properties, such as molecular weight, isoelectric point and electrophoretic mobility, and both have dye-binding properties[11] and hormone carrier functions[12]. The biological significance of AFP could be that of a foetal 'emergency' albumin, produced by a transitional parenchymatous cell committed to liver function but restrained in mitotic activity.

Functional evidence for postsynaptic supersensitivity of central noradrenergic receptors after denervation

THE development of postsynaptic or postjunctional supersensitivity in peripheral, noradrenergically innervated tissue after deafferentation has been clearly demonstrated[1-3]. In addition there exists considerable functional and biochemical evidence that central dopaminergic receptors in the neostriatum become supersensitive after lesions of the nigro-neostriatal projection[4-8]. Neurochemical evidence has been provided which is consistent with the development of postjunctional supersensitivity of central noradrenoceptors after deafferentation. Thus after intraventricular injections of 6-hydroxydopamine (6-OHDA), a neurotoxin for catecholaminergic neurones, noradrenaline (NA) stimulated synthesis of cyclic AMP is potentiated[9-11]. Functional evidence for the development of this type of supersensitivity in central NA receptors is, however, lacking. An enhanced response to intracisternally administered α-methylnoradrenaline in 6-OHDA pretreated rats has been reported[12] but such an effect could be mediated by changes in either pre- or postsynaptic mechanisms. Our experiments were designed to provide functional confirmation for the presence of postjunctional supersensitivity in central noradrenoceptors after lesions of central noradrenergic neurones. Clonidine [2-(2,6-dichlorophenylamino)-2-imidazoline] is a directly acting α-NA -receptor agonist[13-15] and has been shown to lower body temperature by a central α-noradrenergic mechanism. Thus intraperitoneal, intracisternal or intrahypothalamic injections of clonidine decrease body temperature[16,17]. It was hypothesised that if central noradrenoceptive neurones become supersensitive after destruction of noradrenergic afferents by 6-OHDA, then clonidine-induced hypothermia should be potentiated in lesioned animals.

Rats which received stereotaxic 6-OHDA injections which lesioned both dorsal and ventral noradrenergic projections (Fig. 1) did not differ significantly from controls on baseline (predrug) colonic temperature (control group 37.05 ± 0.17 °C; experimental group 37.3 ± 0.21 °C), although there was a tendency for the lesioned group to have slightly raised colonic temperature. The mean temperature of the lesioned group was lower than controls after each dose of clonidine, but this failed to reach statistical significance. Highly significant differences were, however, obtained when the temperature decreases (baseline minus postdrug temperature) were compared in the two groups. The hypothermic responses to several doses of clonidine in control and lesioned animals are given in Fig. 1. At each dose, clonidine produced a significantly greater drop in colonic temperature in the lesioned animals than in controls ($P < 0.01$). At the lowest dose administered (0.05 mg kg^{-1}), clonidine did not significantly reduce colonic temperature in the control group but did produce significant hypothermia in the lesioned animals ($P < 0.01$). Ten days after the last clonidine injection the animals were killed by cervical fracture and the brains were dissected into hypothalamus, hippocampus and cerebral cortex. Cortex and hippocampus were combined and NA was measured in each sample[19]. Control NA values were: hypothalamus 2.07 ± 0.03 μg g^{-1} and hippocampus–cortex 0.24 ± 0.01 μg g^{-1}. The 6-OHDA lesions reduced hypothalamic NA to 26% and combined hippocampal–cortical NA levels to 16% of control levels. These data indicate that the 6-OHDA produced extensive damage to both the dorsal and the ventral noradrenergic bundles[20]. Although not measured in our present experiments, identical lesions do not significantly affect striatal dopamine levels[21,22].

Because these resulted in significant damage to two of the

major ascending noradrenergic bundles, an additional experiment was done in an attempt to determine whether the increased hypothermic response to clonidine was a consequence of damage to the ventral or the dorsal NA projection. The surgical procedure was the same as above except that one group of animals ($n = 8$) received 6-OHDA lesions (4 μg per 2 μl) of ventral noradrenergic bundle ($A, -1.4$; $L, \pm 0.9$; and $DV, +1.0$ mm; coordinates taken from stereotaxic zero), whereas others ($n = 8$) received lesions to the dorsal noradrenergic bundle ($A, +2.6$; $L, \pm 1.1$; and $DV, +3.7$ mm; coordinates taken from stereotaxic zero). The injection rate was 0.2 μl min⁻¹. Control animals ($n = 8$) were sham operated. One month after the surgery, the animals were injected with clonidine-HCl (0.1 mg kg⁻¹) and colonic temperature was measured 120 min later. The baseline (preclonidine) temperatures of the three groups did not differ significantly although there was a tendency for the ventral bundle lesioned animals to be slightly hyperthermic (controls 37.04 ± 0.17 °C; dorsal noradrenergic bundle 37.0 ± 0.11 °C; ventral noradrenergic bundle 37.48 ± 0.10 °C). Clonidine significantly decreased rectal temperature in each group ($P < 0.01$). Compared with controls, however, only the animals receiving ventral noradrenergic bundle lesions showed a significant enhancement of the hypothermic response to clonidine ($P < 0.01$). The temperature decrease was 0.67 ± 0.17 °C in controls, 0.75 ± 0.28 °C in the dorsal bundle lesioned group and 1.30 ± 0.11 °C in ventral bundle lesioned rats. The biochemical results of this experiment are given in Table 1. Ventral noradrenergic bundle lesions reduced hypothalamic NA by 89%, but did not have a statistically significant effect on hippocampal–cortical levels of NA. Lesions aimed at the dorsal noradrenergic bundle on the other hand reduced levels of hippocampal–cortical NA by 94% and hypothalamic NA by 69%.

Our results indicate that central noradrenoceptors, like central
Fig. 1 Effect of clonidine-HCl on body temperature in controls (○) and in rats receiving 6-OHDA lesions of ascending noradrenergic projections (●). The 6-OHDA injections were aimed at the ascending noradrenergic projections caudal to the substantia nigra in male Wistar rats (280–320 g). The coordinates were: $A, +1.0$ mm; $L, \pm 1.3$ mm; and $DV, -2.1$ mm according to König and Klippel[18]. 6-OHDA hydrobromide was injected bilaterally (4 μg in 2 μl, dosage expressed as the base, dissolved in 0.15 M saline containing 0.2 mg ml⁻¹ ascorbic acid) through a 34 gauge needle at a rate of 0.4 μl min⁻¹. Control animals underwent sham operations. Three months after the surgery, both groups received intraperitoneal injections of clonidine-HCl in the order 0.1, 0.05 and 0.25 mg kg⁻¹ (dosage expressed as the salt) with 4 d between each drug administration. Colonic temperature was measured before and 120 min after the injection and was determined by inserting a probe 4 cm into the rectum. Ambient temperature was 22–24 °C Data represent means ±s.e.m. of 8 animals in each group. The groups differed significantly at each dose ($P < 0.01$).

Table 1 Effect of 6-OHDA lesions of the dorsal or ventral noradrenergic bundles of hypothalamic and hippocampal–cortical levels of NA

	Hypothalamic NA (μg g⁻¹)	Hippocampal–cortical NA (μg g⁻¹)
Controls	2.17 ± 0.08	0.24 ± 0.01
Dorsal noradrenegic bundle lesion	0.66 ± 0.06* (31%)	0.014 ± 0.01* (6%)
Ventral noradrenergic bundle lesion	0.24 ± 0.04* (11%)	0.21 ± 0.01 (85%)

Data represent means ±s.e.m. of 8 animals in each group. Numbers in parentheses indicate percentage of control values.
*Significantly different from controls ($P < 0.01$).

dopamine receptors, undergo changes after deafferentation which are consistent with the postjunctional supersensitivity hypothesis. Thus, the dose–response curve of the hypothermic response to clonidine, a noradrenoceptor agonist, was shifted to the left in animals bearing lesions of at least two of the major ascending noradrenergic projections (Fig. 1). Such a shift in the dose–response curve has been taken as a primary indicator of postjunctional supersensitivity[1-3]. Reid[23] found that the hypothermic effect of clonidine (0.5 mg kg⁻¹) was not significantly increased 7–12 d after intracisternal injections of 6-OHDA, although there was a tendency for the experimental animals to show a greater drop in temperature. The reason for this discrepancy is not clear but may result from differences in procedure, or it may be that Reid did not obtain sufficient reductions in NA. Another criterion for postjunctional supersensitivity is that the enhanced response has a gradual onset and increases with time. Further studies will be required to determine if the enhanced hypothermic effect of clonidine satisfies this second criterion.

In the second experiment, an attempt was made to determine to what extent lesions of the dorsal or ventral noradrenergic bundles contributed to the observed effects. Although the lesions were not completely effective in destroying one system without damaging the other, reasonably discrete lesions were obtained (Table 1). It is obvious from the results of this experiment that the potentiation of clonidine-induced hypothermia was a consequence of damage to the ventral noradrenergic bundle. These data suggest, therefore, that clonidine produces hypothermia by an action on central noradrenoceptors which are normally innervated by the ventral noradrenergic bundle. They also suggest that this ascending system, which terminates mainly in the hypothalamus[20], may have an important role in thermoregulation. It would be of interest to determine to what extent animals with lesions of the ventral noradrenergic bundle may have thermoregulatory deficiencies.

# Spontaneous voltage fluctuations in retinal cones and bipolar cells

TRIFONOV[1] and others have suggested that vertebrate rods and cones release transmitter continuously in the dark and that the effect of light is to suppress this release by making the inside of the cell more negative. On this hypothesis the bipolar cells, which receive information from cones, should be electrically noisy in the dark, because of random fluctuations in the release of cone transmitter, and relatively quiet in the light when the release of transmitter is suppressed[2].

Such an effect is illustrated in Fig. 1a, which is an intracellular recording from a hyperpolarising bipolar cell in the isolated eyecup of the turtle, *Pseudemys scripta elegans*. In darkness, the cell voltage fluctuated at low frequency in an apparently random manner over a range of about 5 mV peak-to-peak. Steady illumination of the centre of the receptive field produced a maintained hyperpolarisation of about 6.5 mV and a considerable reduction in noise. When the light was turned off, there was a brief depolarising transient of almost 30 mV followed by slow recovery of both dark voltage level and noise. The voltage variance was 1.53 mV^2 in darkness and 0.045 mV^2 in light.

The possible order of magnitude of the events underlying the dark noise of a bipolar cell may be estimated as the change in voltage variance divided by the change in mean voltage[7] and is found to be 0.24 mV. This is similar to the amplitude of a miniature end-plate potential (e.p.p.), but the ionic movement underlying the event must be much smaller than that in a miniature e.p.p. since the input resistance of bipolar cells is likely to be two or three orders of magnitude higher than that of a muscle fibre. At present it is uncertain whether the hypothetical events underlying the bipolar cell noise are analogous to the effects produced by single acetylcholine molecules or to those of the packets of molecules which produce miniature e.p.ps.

There was often no significant and reproducible change in variance when the bipolar cell depolarised in response to an annulus of light, but in some cells a consistent reduction in noise did occur. This is illustrated in Fig. 1b, where the dark variance of 0.072 mV^2 was reduced to 0.029 mV^2. Since depolarisation of bipolar cells by an annulus is mediated by hyperpolarisation of luminosity horizontal cells[3,6], these findings suggest that the horizontal cells liberate hyperpolarising transmitter at a relatively high rate in darkness and at a lower rate when hyperpolarised.

Figure 2 illustrates the unexpected result that a steady light suppresses noise in cones as well as in bipolar cells. The record in Fig. 2a was obtained on a red-sensitive cone, which from its small receptive field was taken to be an isolated cone not coupled to its neighbours[8]. The cell was unusually noisy and the dark variance of 0.40 mV^2 was reduced to 0.025 mV^2 during illumination which hyperpolarised by about 14 mV at the initial peak. Effects of this kind were observed consistently, although the cells were usually less noisy than in the example given. A more typical result was obtained from a green-sensitive cone (Fig. 2b) in which light reduced the dark variance of 0.018 mV^2 to
Fig. 1 Intracellular recordings from centre-hyperpolarising, red-sensitive bipolar cells Abscissae measure time and ordinates give membrane potential relative to mean voltage in darkness (called zero). a, Response to a 210-μm diameter centred spot which delivered 4 13 × 10^4 photon μm^{-2} s^{-1} to the retina at 639 nm; b, Response of another cell to an annulus of 630 μm internal diameter and 1,300 μm external diameter; photon flux was the same as in (a). The relatively low variance and small light response are attributed to damage by the impaling microelectrode. A PDP-11 computer (DEC) was used to digitise the signals and calculate the variances; dark values given in the text are the mean of measurements taken before and after illumination. 1,024 points were sampled at 5 ms intervals after passing the signal through an RC high-pass filter with 1 s time constant and a 3-pole low-pass filter with 50 Hz cutoff frequency. Micropipettes were drawn from capillary tubing containing a fused partition ("θ tubing"), as they were found to fill consistently and to show sufficiently low intrinsic noise Bipolar cells and cones (Fig. 2) were identified by electrical criteria established from dye marking experiments[3-6].

0.004 mV^2 or less (less because much of the noise in the light may be instrumental in origin). Since the spatial properties of cells with low electrical noise indicate that they are coupled electrically to neighbouring cones, it seems likely that coupling
Fig. 2 Recordings from cones in darkness and during steady central illumination. *a*, Response of an isolated red-sensitive cone to a 6-μm spot delivering 8.05×10^5 photon μm^{-2} s^{-1} at 639 nm; *b*, Response of a green-sensitive cone to a 132-μm spot delivering 1.67×10^6 photon μm^{-2} s^{-1} at 559 nm. The relatively low noise in the dark is characteristic of coupled cones.

reduces noise (see refs 9, 10). Lights which hyperpolarised by more than a few mV consistently reduced noise, but very dim lights gave no significant change and it is uncertain whether the initial slope of the curve relating noise to light intensity is positive or negative.

It is surprising to see noise suppression in a cone, because the natural expectation is that random absorption of quanta should give 'photon noise' as it does in a photomultiplier tube or in an invertebrate photoreceptor[11]. The synaptic action of horizontal cells on cones[6] might contribute to the variance in the dark, but this cannot account for the main observation because small areas of illumination (Fig. 2) suppress the noise even though their effect on horizontal cells is very small. It therefore seems necessary to suppose that there is a source of electrical noise in the dark which is reduced as the cone is hyperpolarised by light and more than compensates for the fluctuations introduced by the random absorption of light quanta. A possible

source of "dark noise" would be random closure of the light-sensitive ionic channels either spontaneously or as a result of variations in the concentration of a blocking or opening substance. In the kinetic model of Baylor *et al.*[12], it is assumed that light releases a blocking molecule which hyperpolarises the cell by closing ionic channels. If the relationship between hyperpolarisation (*u*) and the concentration (*z*) of the blocking molecule is of the form

$$u/u_{max} = z/(z+K)$$

and if the variance of *z* is proportional to *z*, then the variance of *u* should be maximal when $z = K/3$ and $u = u_{max}/4$ (ref. 7). In terms of this hypothesis, our data require that the dark value of *z* be about $K/3$ and that the cell be hyperpolarised in darkness by about 5 mV from the potential it would have if all the light-sensitive ionic channels were open all of the time.

Evidence that sensory axons are mitogenic for Schwann cells

WE have obtained preparations of peripheral nerve tissue in culture which provide either Schwann cell populations, essentially free of connective tissue cells such as fibroblasts, or outgrowing neurites from sensory (or autonomic) ganglia entirely free of ensheathing Schwann cells or connective tissue elements. Thus, these two major elements of peripheral nerve can be studied and characterised separately or in recombination. We report here that the 'bare' sensory ganglion neurite provides a potent stimulus for thymidine incorporation and mitosis in Schwann cells.

Tissue culture techniques utilised in obtaining separation of these two components from the rat peripheral nervous system will be reported in detail elsewhere. Briefly, to obtain Schwann cells, rat dorsal root ganglia (DRG) obtained just before birth were stripped of their capsule and after explantation were exposed to cytosine arabinoside (ara-C)[1] and fluorodeoxyuridine (FdU)[2]. Cultures were fed with medium containing these compounds at 10^{-5} M concentrations during days 1 and 3 *in vitro*, and with regular medium during day 2 and subsequently. After 10 d *in vitro* ganglia were transplanted to new culture dishes where they provided a fresh outgrowth of neurites and Schwann cells within 5–7 d, and this outgrowth was essentially free of connective tissue cells. The neurites could then be easily eliminated from these cultures by removing the ganglionic mass containing the neurone somata (Fig 1*a*). After neurite breakdown the population of Schwann cells previously related to the neurites was retained. This population

is hereafter referred to as a Schwann cell bed. To obtain unensheathed neurites, the schedule of exposure of DRG to ara-C and FdU was continued through day 7 *in vitro* in alternation with the regular medium as described above. In addition, after day 7 the cultures were maintained on medium containing FdU, which suppresses subsequent Schwann cell proliferation. After about 1 month of continued exposure to FdU, Schwann cells could not be detected in the outgrowth arising from the ganglion. The ganglion could then be transplanted to a new dish where it provided a fresh growth of neurites completely free of Schwann cells in the absence of antimitotic agents. These cultures are hereafter referred to as bare neurite preparations.

Schwann cell beds prepared as described above may contain fibroblasts in some cases. In the experiments to be described below the incidence of fibroblasts was so infrequent that they did not interfere with the observations. In addition, fibroblasts in culture are easily distinguished from Schwann cells on the basis of their larger size, flatter shape and lack of specific relationship to neurites[3]. We have observed that with two additional 1-d exposures to ara-C and FdU it is possible to completely eliminate fibroblasts from the cultures, and to obtain populations of Schwann cells virtually free of fibroblasts. Our general culture technique uses a collagen substrate in a modified Petri dish, a medium containing 25% human placental serum and 10% 9-d chick embryo extract (50% in saline), nerve growth factor, and a 5% CO_2–95% air atmosphere[4].

Autoradiography after application of ^{3}H-thymidine (0.5 μCi ml^{-1} in regular medium) to Schwann cell beds on successive days after ganglion removal demonstrates a decreasing number of labelled Schwann cells over a period of about 10 d; after this time less than five cells per hundred are labelled. It is then possible to transfer ganglia providing bare neurites into these culture dishes, both in areas occupied by Schwann cells and in areas free of Schwann cells. In more than ten separate experiments of this type we have consistently observed that: the presence of a ganglion providing bare neurites located remote from the Schwann cell bed has no effect on the Schwann cell labelling index; Schwann cells in beds only partly invaded by neurites exhibit a stimulation of ^{3}H-thymidine incorporation

only in those bed regions directly invaded by bare neurites (Fig. 1, *a–c*); the degree of stimulation provided by bare neurites is dramatic, with about 90% of the Schwann cells in the invaded area incorporating ^{3}H-thymidine after exposure for 42 h. The number of Schwann cells greatly increases in areas invaded by neurites and frequent mitotic figures are seen. Ganglia providing bare neurites not placed near Schwann cell beds do not generate a Schwann cell population, indicating that the implanted ganglia did not obtain this capability during the course of the experiment.

One of these experiments in which a ganglion providing bare neurites was placed along the border of an extensive Schwann cell bed is shown in Fig. 1. The labelling index is greatly increased in the zone of interaction between neurites and Schwann cells, but not elsewhere. The neurite population on the opposite side of the implanted ganglion is, at this point, essentially cell-free, but in preparations kept for a week or more after this stage Schwann cell invasion of the entire neurite halo occurs. The identity of these cells as Schwann cells is based not only on their general size and morphology (Fig. 1*b* and *c*) but also on electron microscopic observations of their distinctive ensheathing relationship to the axon.

The literature on Schwann cell proliferation during development and nerve injury contains many instances where the proliferative capability of the Schwann cell population is documented (reviewed in ref. 5). It is clear that Schwann cell proliferation in damaged nerve has often been ascribed to the presence of degeneration products within the nerve; the growing axon has not generally been considered a factor in Schwann cell proliferation; and there has been little discussion of the possible mechanism by which Schwann cell numbers are controlled during embryonic development. Our observations indicate that the presence of a growing nerve fibre during either initial growth or regeneration must be considered a potent stimulus to Schwann cell proliferation; there may, of course, be other stimuli.

The demonstrated mitogenic capacities of the axon may explain several recent *in vivo* observations. Thomas[6] has observed that repeated crushes (which enable optimal axon
Fig. 1 *a*, Autoradiogram illustrating interaction between bare neurites and quiescent Schwann cells. Schwann cells derived from a dorsal root ganglion explant extend radially from the vacated site of the excised ganglionic mass (DRG$_{ex}$). A second ganglion (DRG$_b$) from which Schwann cells had been eliminated (by previous treatment with ara-C and FdU) was implanted in an area adjacent to the Schwann cell bed 8 d after excision of the first ganglion. Within 3 d bare neurites from the second ganglion (DRG$_b$) invaded the Schwann cell bed and the culture was exposed at that time to ^{3}H-thymidine for 42 h. The culture was then fixed with 4% formaldehyde in phosphate buffer, processed for whole mount autoradiography using Kodak NTB2 emulsion, and stained with erythrosin β-Toluidine blue stain. At this low magnification the Schwann cell nuclei appear as small specks with the Schwann cell processes aligned in a radial manner from the zone marked DRG$_{ex}$. Darkly stained processes originating at DRG$_b$ interact with and become unsheathed by Schwann cells derived from DRG$_{ex}$ but remain unensheathed, at this early stage, on the opposite side of the ganglion. Counts of labelled and unlabelled Schwann cell nuclei were made in the fields designated by the circles. Counts were: 1, 115 (labelled)/15 (unlabelled); 2, 31/71; 3, 0/120; 4, 0/129; 5, 1/59. ×18. *b*, Higher magnification of field 1 shown in *a*. This field clearly lies in the zone of interaction between Schwann cells and bare neurites. Most of the detectable Schwann cell nuclei in this area are covered with silver grains; only a few unlabelled nuclei (arrows) are present. ×204. *c*, Higher magnification of field 4 shown in *a*. In contrast to *b* this field has not been invaded by bare neurites from the implanted DRG and none of the nuclei is labelled. In general the labelling index in quiescent Schwann cell beds is less than 5%, compared with a labelling index of more than 80% in areas where proliferation is stimulated by actively growing neurites. ×204.

regrowth) of a peripheral nerve leads to a remarkable over-production of Schwann cells in the distal nerve stump reaching a point at which these cells are applied in multiple layers around each single axon. Also, in crush lesions of the abnormal peripheral nerve roots of dystrophic mice, where a paucity of Schwann cells and myelin segments provides much less degenerating material than in normal nerve, an increase in the number of myelin segments and, presumably, Schwann cells is induced by crush injury[7]. The importance of the axon in provoking Schwann cell proliferation is also indicated by observations, on the proximal stump of severed or crushed sciatic nerve, that proliferation occurs independently of widespread nerve fibre or myelin degeneration and in conditions in which nerve regeneration is most actively occurring[8].

Our observation of the axon–Schwann cell interaction resulting in mitogenesis illustrates one use of cultures containing either 'pure' Schwann cell populations or bare neurite preparations. These preparations may be useful in further analysis of the interaction between neurite and Schwann cell, as well as in studies of the basic properties of the Schwann cell itself.

Biological reactivity of PVC dust

CONCERN has been expressed about the biological potential of polyvinyl chloride (PVC) and its associated monomer vinyl chloride monomer (VCM)[1]. During the industrial processing of PVC, workers can be exposed to varying quantities of this material in the form of a dust. At the present time, however, there is little detailed biological or biochemical information on the effects of inhaled or ingested PVC, or on the reactivity of this dust material. The biological reactivity of other dusts (silica, asbestos) have been studied by a haemolysis technique[2] which is useful for assessing the degree of membrane-induced damage by a variety of toxic materials. Other *in vitro* screening systems using lung[3] and other cells[4] have also provided useful information on structural and biochemical changes induced by particulate matter. Here we report on the haemolytic potential of PVC dust, comparison of which is made with the highly haemolytic and biologically reactive chrysotile asbestos A (UICC standard reference sample) and the effect of PVC on lung fibroblast cultures.

The haemolysis technique used has been described in detail previously[2]. The degree of haemolysis was expressed as a percentage of the totally lysed sample and the results presented as the means and ranges (if any) of, at least, quadruplicate assays. Two samples of PVC were tested (KM 1 and KM2) both of which were obtained as finely-divided dried powders which had been formed by standard processing procedures for use in fabrication work.

The first sample (KM 1) was highly haemolytic at relatively low concentrations, 100% haemolysis (over 50 min) being achieved by between 7.5 and 10 mg of dust (Fig. 1*a*). With increasing concentrations of PVC, haemolysis seems to be reduced, but this effect is most likely the result of some of the released haemoglobin binding to the dust, which is then spun down into the pellet. Sample KM 2 PVC was found to be practically non-
Fig. 1 Haemolysis by PVC dusts and chrysotile asbestos. *a*, Haemolytic potency of KM 1 (○) and KM 2 (●) PVC samples after 50 min; *b*, change in haemolysis with time by 7.5 mg samples of UICC chrysotile asbestos A (△) and KM 1 (●) PVC. Briefly, a 1 % (v/v) suspension of packed rabbit erythrocytes in veronal buffered saline, pH 7.4, was used in all the experiments. The incubation mixture normally consisted of dust sample with 1 ml 1 % erythrocyte suspension + 3 ml veronal buffered saline. After incubation and agitation for 50 min (or varying time intervals) at 37 °C the samples were centrifuged at 2,000 r.p.m. for 20 min and the extinction of the supernatant read at 541 nm. Controls consisting of a totally lysed sample (1 ml 1 % erythrocyte suspension + 3 ml water) and a fragility control (1 ml 1 % erythrocyte suspension + 3 ml veronal buffered saline) were treated identically in each experiment.

haemolytic. A sample of 100 mg of KM 2 PVC gave an equivalent haemolytic effect to 1 mg of sample KM 1. The haemolytic activity with time of a sample of KM 1 PVC (7.5 mg) was compared with an equivalent mass of chrysotile asbestos A (Fig. 1*b*). It is evident that the asbestos is a faster haemolytic agent, although total lysis is achieved by PVC after 1 h.

During the processing of different forms of PVC, a variety

Fig. 2 Haemolysis by washed samples of KM 1 PVC dust (7.5 mg) and the resulting supernatant fluids from these washings compared with the haemolytic activity of the untreated dust sample. KM 1 PVC *a*, Untreated; *b*, washed once; *c*, washed twice; *d*, washed three times; *e*, wash 1; *f*, wash 2; *g*, wash 3.
of agents are used which could contribute to the haemolytic effect of the dust. Therefore, samples (7.5 mg) of KM 1 PVC were washed once, twice and three times (5 s each wash, in 3 ml veronal buffer on a whirlimix; followed by centrifugation, 2,000 r.p.m. for 20 min) and the haemolytic potency of the washed dust samples and the supernatant PVC fluid were compared with the lytic potential of an untreated PVC sample (Fig. 2). After a single wash, the haemolytic potency of KM 1 PVC is reduced by over 60% and subsequent washes reduce the activity of the dust even further. Thus the removal of some surface-associated material, which must exist in a reasonably soluble form, considerably reduces the biological potency of this PVC dust. It is also evident that this material, once removed from the dust surface and diluted out in solution, has very limited haemolytic activity (Fig. 2).

The effect of KM 1 PVC was studied on the levels of cell mat DNA, RNA, protein and hydroxyproline (assessment of collagen) in lung fibroblast cultures maintained *in vitro* for 24 d. The methods of isolation and cell culture and the analyses for DNA, RNA protein and hydroxyproline have been detailed previously[3,5]. Before addition of different concentrations of KM 1 PVC (50–200 µg ml^{-1} culture medium or 0.5–2.0 mg per culture) the dust sample was first washed in a balanced salt solution containing antibiotics (see legend to Fig. 3). Other methods of dust sterilisation (heat, autoclaving, radiation)

Fig. 3 The effect of different concentrations of KM 1 PVC on lung fibroblast cultures. The PVC sample was first washed with an antibiotic solution (penicillin (100 units) streptomycin (100 µg) in 1 ml) and then added as a single dose to 3-d-old cultures (in logarithmic growth). Cultures were maintained in 10 ml of 20% foetal bovine serum plus Waymouth's medium containing additional ascorbic acid[5], changed twice weekly and removed for analysis on day 24.

were not considered to be feasible and while the washing procedure undoubtedly reduces the ability of this PVC sample to damage cell membranes (Fig. 2) fibroblast cultures treated with the dust all had lower levels of cell mat hydroxyproline after 24 d (Fig. 3). Some fluctuation in DNA levels was apparent with different dust concentrations but the significance of these is doubtful without further experimentation. There is little change in the level of total protein or RNA in the PVC-treated cultures.

From these preliminary findings we conclude that certain

forms of PVC dusts exhibit a high haemolytic potential because of the presence of a readily soluble, surface-associated agent. Exposure to this type of PVC dust may thus constitute an additional health hazard because of the increased biological activity of the dust. Work is in progress to determine the nature of the haemolytically-active agent by assessing a wide range of PVC dusts of which complete knowledge has been obtained of the chemical processing. The possibility that VCM is the active agent has been explored, but both samples tested were found to contain immeasurable amounts of VCM (<1 p.p.m.). Nevertheless, the present study indicates that the introduction of a washing procedure after the processing of KM 1 PVC dust would certainly reduce or abolish the haemolytic activity of this material.

Mechanism of induction of haemolytic anaemia by phenylhydrazine

A COMPOUND with the optical spectrum of a ferrihaemochrome was produced when ferricyanide-oxidised phenylhydrazine was added to a solution of ferrihaemoglobin[1]. The three isomers of methylphenylhydrazine similarly resulted in ferrihaemochromes, but 4-hydrazinobenzoic acid did not[2]. The induction of haemolytic anaemia by a substituted phenylhydrazine was related to the reactivity of its oxidised form with ferrihaemoglobin to produce a ferrihaemochrome[2,3]. Further studies of the reaction of oxidised arylhydrazine with ferrihaemoglobin have established that the formation of a ferrihaemochrome-like product and the character of the optical spectrum of this product depend on the nature and position of substituents on the benzene ring of phenylhydrazine.

Substituted phenylhydrazine hydrochlorides were obtained from commercial sources or were synthesised by standard procedures. Each compound was purified by recrystallisation from 2 N HCl or ethanol, and the structure and purity of the recrystallised product were confirmed by its NMR spectrum, infrared spectrum, melting point, and analyses for C, H, N, and Cl. Oxyhaemoglobin solutions were deoxygenated by the passage of oxygen-free[4] nitrogen or helium, and the resulting ferrohaemoglobin was oxidised to ferrihaemoglobin by the addition of excess ferricyanide. To a solution of ferrihaemoglobin in excess ferricyanide, a solution of arylhydrazine hydrochloride in water or ethanol was added, and the optical spectrum that resulted was recorded with the Cary Model 17 instrument. The spectra obtained with 3- and 4-chlorophenylhydrazine were similar to that previously reported with unsubstituted phenylhydrazine[1]. The spectra obtained with 3,4- and 3,5-dichlorophenylhydrazine were distinguished by a more prominent absorption band in the red than the others. 2-Chloro- and 2,3-, 2,4-, and 2,5-dichlorophenylhydrazine resulted in spectra with a single broad maximum at around 540–550 nm and without a band in the red. 2-6-Dichlorophenylhydrazine, 2,6-dimethylphenylhydrazine, 2-hydrazinobenzoic

acid, and 4-hydrazinobenzoic acid each resulted in slow and incomplete formation of ferrihaemochrome. On the other hand, the ethyl ester of 4-hydrazinobenzoic acid resulted in the quantitative formation of a ferrihaemochrome. Results with the isomers of dichlorophenylhydrazine are shown in Fig. 1.

Arylhydrazine hydrochloride and potassium ferricyanide were mixed in oxygen-free solution, and the reduction of ferricyanide was followed at 420 nm (Fig. 2). In agreement with the stoichiometry of the oxidation of arylhydrazine to aryldiazene[5,6], 2 mol of ferricyanide were rapidly consumed per mol of phenylhydrazine or 4-hydrazinobenzoic acid; further reduction of ferricyanide was very slow. 2,6-Dimethylphenylhydrazine, not shown here, also reduced two equivalents of ferricyanide very rapidly. 2,6-Dichlorophenylhydrazine, on the other hand, reduced ferricyanide more slowly, but after 10 min had consumed more oxidant than either phenylhydrazine or 4-hydrazinobenzoic acid.

The finding that each substitution on the benzene ring of phenylhydrazine resulted in a ferrihaemochrome with a different optical spectrum indicates that the ferrihaemochromes are compounds of ferrihaemoglobin with ligands that include the substituted benzene ring of the oxidised arylhydrazines and supports the suggestion that the optical spectrum obtained when oxidised phenylhydrazine was added to ferrihaemoglobin resulted from the binding of phenyldiazene $(C_2H_5N = NH)^1$. The bond was postulated to form between the iron atom of ferrihaem and the nitrogen atom bound to the benzene ring in the phenyldiazene molecule[5]. The low reactivity of 2,6-dichlorophenyldiazene and of 2,6-dimethylphenyldiazene can be explained by the steric hindrance of their respective di-*ortho* substituents to the formation of such a bond. The reactivity of oxidised ethyl 4-hydrazinobenzoate suggests that the low reactivity of oxidised 4-hydrazinobenzoic acid is due not to the ring position or size of the carboxyl group, but to its negative charge.

The effect of adding arylhydrazine to oxyhaemoglobin was examined with the compounds of Fig. 2. Phenylhydrazine

Fig. 2 Oxidation of arylhydrazines by potassium ferricyanide. The disappearance of the absorption peak of potassium ferricyanide at 420 nm was followed at 23 °C. Absorbance of 6.0× 10^{-4} M potassium ferricyanide (......). Interval between addition of arylhydrazine hydrochloride and beginning of absorbance record (--------). Absorbance after arylhydrazine hydrochloride was added to make 1.5×10^{-4} M solutions of: phenylhydrazine (————); 2,6-dichlorophenylhydrazine (—————); 4-hydrazinobenzoic acid (– – –).

caused a rapid change in colour to greenish brown followed by progressive precipitation of protein. 4-Hydrazinobenzoic acid resulted in complete replacement of oxyhaemoglobin by a mixture of ferrihaemoglobin (75%) and ferrihaemochrome (25%) without precipitation. 2,6-Dichlorophenylhydrazine resulted in slow transformation of oxyhaemoglobin to 15% ferrihaemoglobin after 2.5 h. Beaven and White[7] reported that 2- and 4-nitrophenylhydrazine reacted with oxyhaemoglobin to produce precipitates of "green haemoglobin" but that 2,4-dinitrophenylhydrazine produced only ferrihaemoglobin. We found that 2- and 4-nitrophenylhydrazine reacted with ferrihaemoglobin in the presence of excess ferricyanide to form ferrihaemochrome-like compounds but that 2,4-dinitrophenylhydrazine did not. Substituted phenylhydrazines, including ethyl 4-hydrazinobenzoate, that resulted in the quantitative formation of ferrihaemochromes also induced haemolytic anaemia in experimental animals while 2- and 4-hydrazinobenzoic acid, 2,6-dichlorophenylhydrazine, and 2,6-dimethylphenylhydrazine did not[2,8]. Thus, the ability of an arylhydrazine to cause both oxidative denaturation of oxyhaemoglobin and haemolytic anaemia in animals paralleled the ability of a product of its oxidation to react rapidly and quantitatively with ferrihaemoglobin to produce a ferrihaemochrome.

Phenylhydrazine results in the formation of ferrihaemoglobin from oxyhaemoglobin[9], and phenylhydrazine is oxidised to phenyldiazene by oxygen[5]. The two products, ferrihaemoglobin and phenyldiazene, react rapidly and quantitatively with each other or form a ferrihaemochrome. All three reactions are essential because 4-hydrazinobenzoic acid, which was shown to take part in the first two but not the third of these reactions, did not result in oxidative denaturation or anaemia. An amino acid replacement in the haem pocket destabilises haemoglobin by breaking non-polar contacts between haem and globin[10] and results in unstable haemoglobin haemolytic anaemia[11]. The binding of phenyldiazene was postulated to destabilise haemoglobin in phenylhydrazine-induced haemolytic anaemia[5]; however, the acuteness of the latter anaemia contrasts with the chronic nature of the former. The production of free radicals and hydrogen peroxide in the reduction of molecular oxygen and the bound oxygen of oxyhaemoglobin by phenyl-

Fig. 1 Spectra of ferrihaemoglobin (————) and of ferrihaemochromes produced by oxidised dichlorophenylhydrazines: 2,3-dichloro (- - - - - - - - -); 3,4-dichloro (- — - — - —); 3,5-dichloro (- ———— ——); 2,6-dichloro (— — — —). To 4.00 ml of 5.0×10^{-5} M ferrohaemoglobin in 0.05 M sodium phosphate (1:1) buffer (*p*H 6.84), 25 or 26 μl of 0.1 M potassium ferricyanide and 12 μl of 0.05 M arylhydrazine hydrochloride were added in succession. Spectra were recorded 1, 5, and 10 min after the addition of arylhydrazine. All three recordings are shown for 2,6-dichlorophenylhydrazine. Reactions with the other isomers were nearly complete after 1 min, and only the 5-min spectra are shown. The 10-min spectra showed little change. The spectra resulting from the 2,4-dichloro and 2,5-dichloro isomers were very similar but not identical to that resulting from the 2,3-dichloro isomer

hydrazine[12-14] can account for the marked difference in rate of haemolysis. Abnormally high concentrations of these reactive oxidants would lead to an accelerated rate of oxidation of the porphyrin rings[15,16] and the thiol groups[17] of phenylhydrazine-induced ferrihaemochrome. The resulting disruption of normal non-polar interactions between haem and globin and between the polypeptide chains of globin would then cause rapid formation of Heinz bodies, the presence of which is associated with haemolysis[18]. The induction of haemolytic anaemia only by those arylhydrazines that resulted in the quantitative formation of ferrihaemochromes favours a molecular mechanism for the induction of oxidative denaturation by an arylhydrazine in which the oxidation of susceptible groups within the haemoglobin molecule is facilitated by the destabilising effect of a large ligand that includes the aryl portion of the arylhydrazine.

Role of hybrid tetramer formation in gelation of haemoglobin S

THE transformation of erythrocytes containing haemoglobin (Hb) S from pliable biconcave disks into rigid pointed "sickled" forms, which underlies the pathology of sickle cell disease, results from the tendency of this mutant haemoglobin to polymerise and produce an intracellular gel on deoxygenation. In the genetic variants of sickle cell disease, the different types and proportions of non-S haemoglobins present in the red cells together with Hb S are important in determining the extent of the sickling tendency and the severity of the disease. Red cells containing Hb S along with a substantial proportion of foetal haemoglobin (Hb F, $\alpha_2\gamma_2$) sickle less readily than cells having a similar proportion of the normal adult type, Hb A ($\alpha_2\beta_2$). Such differences can be demonstrated with solutions of haemoglobin mixtures *in vitro* by measuring the minimum gelling concentrations (MGC), that is, the minimum concentration of total haemoglobin at which the mixture will form a gel on complete deoxygenation. The higher MGC of Hb S–F mixtures compared with S–A mixtures correlates with the lesser sickling tendency of the former combination within red cells.

There is growing evidence that tetramers of deoxy Hb S ($\alpha_2\beta_2^S$) aggregate as helical polymers in sickled cells and gels, but it is not known whether non-S haemoglobins can be included in these polymers, or if they play some other part in gel formation. Ultracentrifugation of deoxygenated haemoglobin mixtures indicated that Hb F was excluded from the solid phase of the gel, whereas some Hb A was included[1]. In solutions of oxyhaemoglobin, the tetramers are in a fairly

rapid dissociation equilibrium with $\alpha\beta$ dimers, and in mixtures of two haemoglobins (such as S–F or S–A) it has been shown that a large proportion of the haemoglobin exists as hybrid tetramers ($\alpha_2\beta^S\gamma$ or $\alpha_2\beta^A\beta^S$)[2]. There have been little experimental data concerning the possible role of such hybrid tetramers in sickling and gelation. We have approached this problem by comparing the gelling behaviour of mixtures of haemoglobins in which hybrid formation was allowed to occur, or was prevented by two different methods.

The first method used to prevent hybrid formation was based on the extremely slow rate of dissociation of deoxyhaemoglobin tetramers. The non-S haemoglobin (Hb A or F) was deoxygenated with N_2 gas in one flask, while in another flask, oxygen was eliminated from a solution of Hb S or Hb C_{Harlem} ($\alpha_2\beta_2^{6Val, 73Asn}$) which had been converted into the cyanmet form to prevent gelation. Although a solution once gelled could be liquified by chilling for the purpose of mixing, the non-gelling cyanmet form was chosen to avoid the possibility of partial aggregation which might prevent complete mixing. An appropriate volume of deoxyhaemoglobin A or F was then transferred anaerobically to the flask containing the oxygen-free cyanmet haemoglobin so that Hb S or C_{Harlem} comprised 40% of the final mixture. In spite of mixing, the deoxyhaemoglobin should remain almost entirely in the tetrametric state and thus be unable to hybridise. After chilling and thorough mixing, the cyanmet haemoglobin was converted to the deoxy form by anaerobic addition of sodium dithionite (one mol per mol total haem) and the MGC was determined at room temperature[3]. Controls for these experiments consisted of the same haemoglobins mixed in the oxy state to permit hybrid formation before deoxygenation and gelling.

The second method used to avoid hybridisation consisted of reacting the non-S haemoglobin component (Hb A or F) with a bifunctional cross-linking reagent, difluorodinitrophenylsulphone. Macleod and Hill have shown that the predominant reaction product contains an internal cross link between the amino termini of the two α chains[4]. After reaction, the cross-linked haemoglobin was separated from unreacted haemoglobin by gel filtration on Sephadex G-100 in 1 M $MgCl_2$; in this medium the non-cross-linked haemoglobin is fully dissociated into $\alpha\beta$ dimers whereas the cross-linked haemoglobin, fixed as tetramers, is eluted first by virtue of its higher molecular weight[4]. At the end of gelling experiments with mixtures of Hb S (or C_{Harlem}) and cross-linked haemoglobins A or F, electrofocusing in the deoxy state on polyacrylamide gels[2] confirmed the absence of hybrid tetramers. Control gelling experiments used the unreacted portion of the non-S haemoglobin eluted as the slower-moving fraction from the Sephadex column. After gelation, electrofocusing of these mixtures in the deoxy state revealed a large proportion of haemoglobin at the position of hybrid tetramers.

We studied three mixtures, Hb S+Hb A, Hb S+Hb F and Hb C_{Harlem}+Hb A. The effect of hybrid formation on gelation of mixtures of Hb A with C_{Harlem} was of special interest because of our earlier findings with this unusual mutant, in which each β chain carries both the "sickle substitution" β^{6Val}, and a second substitution, β^{73Asn}. Pure HbC_{Harlem} has a much higher MGC than Hb S, indicating that the β^{73Asn} substitution somehow inhibits gelling. Addition of Hb A, however, lowers the MGC of Hb C_{Harlem}, so that in mixtures containing 50% or more of Hb A, the MGC is equal to those of Hb S–A mixtures of equivalent proportions. Therefore, we postulated that the presence of hybrid tetramers having one normal β chain ($\alpha_2\beta^A\beta^{C\ Harlem}$) might eliminate the inhibitory effect of β^{73Asn} (refs 5 and 6).

The results of the gelling experiments are shown in Table 1. As expected, with the usual gelling procedure (in which hybrids occur) the MGC is much higher with mixtures of Hb S and F than with S–A mixtures. By contrast, when hybrid formation was prevented by either technique, the gelling points of the S–F mixtures were much lower, and equal to those of S–A mixtures. Thus the inhibitory effect of Hb F on gelation (and

Table 1 Effect of hybrid tetramer formation on the MGC of haemoglobin mixtures

Hb composition of mixture (40:60)	Hybrids present		Hybrids absent (or minimal)	
	Hb mixed in oxy state	Hb A or F non-cross-linked control	Hb mixed in deoxy state	Hb A or F cross-linked
Hb S + Hb A	30.2	31.6	29.4	30.2
Hb S + Hb F	39.4	37.2	30 3	32.6
Hb C_H + Hb A	30 0	31.6	35.9	37.7

Haemoglobin dialysed against 0.15 M potassium phosphate, pH 7.35, deoxygenated with N_2 gas at 25 °C, sodium dithionite added, final pH of haemoglobin 7.1; mean MGC values expressed in g Hb dl^{-1}.

sickling) seems to require the formation of $\alpha_2\beta^S\gamma$ hybrids. These findings suggest that the presence of one γ chain in the tetramer is unfavourable for polymerisation. In Hb S–F mixtures, the formation of such hybrids lowers the number of Hb S tetramers which do polymerise well. Accordingly, if hybridisation is prevented, the gelling point is lower; in fact, the presence of non-hybridising Hb F tetramers seems to have an effect on gelation equal to that of Hb A.

With mixtures of Hb C_{Harlem} and Hb A, on the other hand, the effect of hybridisation was the opposite of that seen with the Hb S–F mixtures When $\alpha_2\beta^A\beta^{C\ Harlem}$ hybrids were allowed to form, the MGC was equal to that of Hb S–A mixtures, whereas preventing formation of these hybrids led to a much higher gelling point. On the basis of earlier experiments, we suggested only one of the two β^{6Val} regions of the Hb S tetramer provided an intermolecular contact in the polymer, while the other β chain probably provided other important contacts[7,8]. The present findings support this idea, and suggest that the $\alpha_2\beta^A\beta^{C\ Harlem}$ hybrids enter the polymer. The normal β chains apparently favour polymerisation more than chains having a β^{73Asn} residue.

It was surprising to find that the presence or absence of hybridisation made little or no difference in the gelling of Hb S–A mixtures. Our findings differ from those of Moffat[9], who reported slightly lower MGC values for Hb S and Hb A mixed in the oxy state than in the deoxy state. It is not clear whether this discrepancy stems from differences in experimental conditions (type of buffer, pH) or technique. One possible interpretation of our results is that, with Hb S–A mixtures, two effects of hybrid formation on gelation are counterbalanced; if we suppose that Hb S tetramers favour gelation more than SA hybrids, then when hybrid formation occurs, the effect of reducing the number of S tetramers may be balanced by the effect of increasing the total proportion of tetramers capable of polymerising (the remaining S tetramers and the SA hybrids).

The present data shed some additional light on the so-called "sparing" effect of Hb A on gelation of Hb S. Singer and Singer first pointed out that the addition of Hb A to Hb S reduced the partial concentration of Hb S required for gelation[10]. This is also found under the conditions of our experiments. The MGC of Hb S alone is about 22 g dl^{-1} while that for a 40:60 mixture of Hb S with Hb A is about 30 g dl^{-1}, so that the partial concentration of Hb S is about 12 g dl^{-1}. Our experiments demonstrate that this sparing effect of Hb A does not require the formation of $\alpha_2\beta^A\beta^S$ hybrid tetramers. Furthermore if (and only if) hybrid formation is prevented, the same sparing effect is provided by Hb F. It seems unlikely that $\alpha_2\gamma_2$ tetramers would enter the polymer more readily than $\alpha_2\beta^S\gamma$ hybrids, the formation of which inhibits gelation. Thus, non-S Hb tetramers (A or F) seem to facilitate gelling in an equal, nonspecific manner which may not involve entry into the polymers.

These results may also help interpret our earlier findings that deoxygenated mixtures of Hb S with cyanmet Hb F showed the same gelling behaviour as Hb S–A mixtures[3]. Using

techniques of electrofocusing in the deoxy state, Bunn and McDonough have recently shown that cyanmethaemoglobin fails to form stable hybrids with deoxyhaemoglobin[11]. Deoxygenation may promote dissociation of hybrids in a mixture of Hb S with cyanmet–Hb F, so that such a mixture may be comparable with the S–F mixtures in the present experiments in which hybrid formation was prevented. In that case, cyanmet Hb F or Hb A tetramers seem to facilitate gelling in mixtures with deoxy Hb S to the same extent as do deoxy–Hb A or F tetramers. As noted above, these effects need not involve entry into the helical polymers.

Primary electron acceptor complex of photosystem I in spinach chloroplasts

PHOTOSYSTEM I (PSI) is the photochemical reaction complex involved in the generation of a low potential reductant in oxygen-evolving photosynthetic organisms. The primary photochemical reaction in PSI has been identified as the photo-oxidation of a reaction centre chlorophyll complex P700 (ref. 1). This photo-oxidation occurs both at room temperature and in the frozen state at temperatures as low as 4.2 K. At cryogenic temperatures this photo-oxidation has generally been found to be irreversible[2]. Malkin and Bearden[3] showed that the electron acceptor for this photo-oxidation reaction is a bound ferredoxin. This ferredoxin has two iron–sulphur centres with very low redox potentials ($Em_{10} = -550$ and -590 mV)[4-6] It has been proposed that these centres are the primary electron acceptor of PSI[3,4]. More recent evidence suggests it may not be[7-11], and we have shown[11] that when the bound ferredoxin is chemically reduced, illumination at low temperature results in the photo-oxidation of P700 without any change in the bound ferredoxin, this oxidation is reversible. In photosynthetic bacteria a component with an EPR signal at $g = 1.82$ has been identified as the primary electron acceptor of the photochemical system[12,13] and it is possible that a similar component might be involved in chloroplast photochemical reactions. McIntosh et al.[14] obtained kinetic evidence for the presence in PSI particles of a component with an EPR signal at $g = 2.06$ and $g = 1.76$ which showed a reversible redox change on illumination of the particles at low temperature parallel to that of P700. The changes observed were small and it was not possible to obtain a spectrum of the component. Using a more highly purified PSI preparation we have now obtained strong evidence that this component is the primary electron acceptor of PSI.

Figure 1 shows the EPR spectrum of a sample of PSI

particles frozen under illumination in the presence of sodium dithionite and methyl viologen. Spectrum A shows the spectrum at 18 K and 20 mW power. In these conditions the iron–sulphur centres can be clearly seen and are completely reduced. Spectrum B shows the spectrum of the same sample at 9 K and 100 mW. In these conditions the signals due to the iron–sulphur centres of the bound ferredoxin and the methyl viologen free radical show power saturation effects. A new signal can be seen at $g = 1.76$ and $g = 1.86$. This signal is frozen in only in samples prepared in the extreme reducing conditions used for this sample. For example, little or none of this signal can be seen in samples frozen with dithionite but without methyl viologen and is not observed in samples frozen with dithionite in the dark. It is observed in photosystem I particles, and seems to be most concentrated in those samples with the highest P700 to chlorophyll ratio. We have therefore concluded that it is an electron transport carrier with an extremely low redox potential associated with PSI.
Fig. 1   EPR spectra of PSI particles showing the signal at $g = 1.76$ due to the primary electron acceptor of PSI. Highly purified particles were prepared from broken spinach chloroplasts[15] by Triton treatment[16] followed by DEAE chromatography. The sample was reduced by illumination at room temperature in the presence of 0.2% $Na_2S_2O_4$ and 15 μM methyl viologen. Chlorophyll concentration 1.5 mg ml^{-1}. EPR spectra were recorded as described previously[4,11]. The conditions for each spectrum were as follows. a, Frequency 9.24 GHz, power 20 mW, modulation amplitude 10 G, scan rate 500 gauss min^{-1}, gain 500–temperature, 18 K. b, as for a, except that the temperature was 9 K and power 100 mW. The spectra were recorded in the dark.

The g value of this component is very similar to that of the kinetic change reported by McIntosh, $et\ al.$[13]. We have examined the effect of illumination on this signal. We have shown that in PSI particles frozen with both P700 and the bound ferredoxin in the reduced state the photo-oxidation of P700 is reversible[11]. Figure 2 shows this reversible photo-oxidation in triton PSI particles. Figure 3 shows the effect of illumination of the same sample at lower temperature (9 K) and high power. The signal at $g = 2.00$ due to P700 is, much smaller in these conditions, however it can be seen that the signal at $g = 1.76$ is induced by illumination in these conditions and disappears again when the light is turned off. The kinetics of the time course shown in Figs 2 and 3 are machine limited. They do, however, indicate that P700 photo-oxidation and the appearance of the $g = 1.76$ signal occur on illumination and are fully reversible in the dark. The kinetic measurements of McIntosh $et\ al.$ indicate that the decay kinetics of the two signals are the same. In samples in which the bound ferredoxin is oxidised before illumination, illumination in the conditions described here results in irreversible oxidation of P700 and reduction of the bound ferredoxin, little or no $g = 1.76$ signal is then observed. If the $g = 1.76$ component is frozen largely in the reduced state as in the
Fig. 2   The effect of illumination at low temperature on the EPR signal of P700 in Triton PSI particles. Triton PSI particles (1.5 mg chlorophyll ml^{-1}) were reduced by exposure to 0.2% $Na_2S_2O_4$ pH 9.0 for 45 min (ref. 11), before freezing to reduce the bound ferredoxins. Left, EPR spectrum in the $g = 2.00$ region. Conditions as in Fig. 1. Power 20 mW, temperature 18 K. The sample was illuminated in the spectrometer with a 1000 W projector. Right, time course of the effect of illumination on the P700 signal. Instrument settings as above except that the change in amplitude of the $g = 2.00$ signal was followed with time.

sample shown in Fig. 1 the extent of P700 photo-oxidation on illumination at cryogenic temperatures is greatly decreased. In digitonin-triton particles the $g = 1.76$ component is more enriched than in Triton particles and a signal at $g = 1.86$ is seen as well as at $g = 1.76$ on illumination. This observation together with that of McIntosh $et\ al.$[14] who observed kinetic changes around $g = 2.06$ suggest that the component has an EPR spectrum around $g = 2.00$ with g_z about 2.06, g_y about 1.86 and g_x about 1.76. This spectrum might be due to an iron–sulphur centre in a novel environment or to an unknown type of iron centre as has been proposed for the bacterial primary electron acceptor.
Fig. 3   The effect of illumination at low temperature on the $g = 1.76$ signal in PSI particles. The same sample was used as in Fig. 2. Left, EPR spectra in the $g = 2.00$ region. Instrument settings as in Fig. 1 with Power 100 mW, temperature 10 K. Gain as indicated. Right, time course of the effect of illumination on the $g = 1.76$ signal. Instrument settings as above except that the change in amplitude of the $g = 1.76$ signal was followed with time.

These experiments show that chloroplasts contain a redox carrier which is reduced, probably at very low potentials, in parallel with the photo-oxidation of P700. This reduction is reversible at temperatures down to 8 K. When this component is reduced P700 photo-oxidation is inhibited. When secondary electron acceptors are available P700 photo-oxidation is irreversible and this component cannot be detected. These

results suggest that the component with an EPR signal at $g = 1.76$ is the primary electron acceptor of PSI.

Genetic relationship of a primate RNA tumour virus genome to genes in normal mice

HUEBNER and Todaro[1] and Temin[2] proposed that the genomes of RNA tumour viruses originate from genes in DNA of normal cells. Subsequently, a class of RNA tumour viruses (endogenous or class 1 viruses) was discovered and shown by molecular hybridisation to contain RNA genetically related or identical to genes in normal cells[3-8]. Both the biological and hybridisation data leave little doubt that normal cells carry genes capable of giving rise to class 1 RNA tumour viruses (see refs 7 and 8 for reviews). A second class of RNA tumour viruses is more distantly related to cell genes (exogenous or class 2 viruses, see refs 7 and 8). Mouse and chicken class 2 viruses, however, are genetically related to class 1 viruses from the same species[7-12] and the genome of one class 2 mouse RNA tumour virus (Rauscher leukaemia virus) consists primarily of RNA sequences that are related distantly to genes in normal mice but not to genes found in several other animals[13]. Indirect evidence has indicated that primate RNA tumour viruses and certain mouse RNA tumour viruses are unusually closely related[10,11,14,15], suggesting that the viruses have a common origin, for example, in genes of mice. We report here that a primate RNA tumour virus isolated originally from a woolly monkey sarcoma and passaged in marmosets does contain a genome that by molecular hybridisation criteria is related to genes found in mice. The data further indicate that a small portion of the primate RNA tumour virus genome is related to genes of normal primates.

The virus analysed here, simian sarcoma virus (SiSV) or woolly monkey virus, was isolated from a natural sarcoma
Fig. 1 Hybridisation of ^{125}I-RNA from SiSV to cell DNA. Hybridisation mixtures contained viral RNA and cell DNA (weight ratio $= 1{:}8 \times 10^6$, DNA concentration $= 8.3$ mg ml^{-1}, RNA $= 500$ c.p.m., 10^8 c.p.m. µg^{-1}) in 0.4 M PO$_4$, pH 6.8. Mixtures were boiled for 5 min, then incubated at 60 °C. *a*, Hybridisation mixtures (5 µl) were incubated for 100 h (C_0t (DNA) $= 10^4$), then exposed to 20 µg ml^{-1} RNase at 37 °C for 120 min in the indicated concentration of NaCl. Acid-precipitable radioactivity was used to measure the percentage RNA hybridised[4,13]. *b*, Hybridisation mixtures were incubated for different lengths of time, then exposed for 60 min at 37 °C to 20 µg ml^{-1} RNase in 0.6 M NaCl. *c*, Hybridisation mixtures containing different DNA-RNA ratios (DNA $= 10$ mg ml^{-1}) were incubated for 160 h (C_0t (DNA) $= 2 \times 10^4$) then exposed for 60 min at 37 °C to 20 µg ml^{-1} RNase in 0.6 M NaCl. Dashed line indicates hybrid yield as a function of the ratio DNA-RNA, subtracting the contribution by rapidly-annealing DNA sequences. This function was subjected to a double reciprocal analysis (1/hybrid yield against RNA-DNA ratio) and yielded an x-intercept value of 0.022 (45% RNA hybridised). This is taken to reflect the percentage RNA that could be hybridised to infrequent DNA sequences at infinite DNA input. Percentage RNA that could complex repeated plus infrequent DNA sequences at infinite DNA input is therefore 56. Sources of cell DNA: *a*: ○, 7IAPI (SiSV); NRK (SiSV); +, mouse; □, gibbon; ■ woolly monkey; ▲, chimp; △, human; *b* and *c*: ■, HF (SiSV); ×, mouse; △, woolley monkey; ▲, human. Less than 25% of the acid-precipitable radioactivity was lost from the RNA after 160 h of incubation at 60°. RNase-resistant radioactivity obtained without DNA are subtracted from each hybrid yield value (3–5% of the input radioactivity).

of a woolly monkey[16]. The monkey tumour was homogenised, and a cell-free extract was placed on normal marmoset lung cells (line 1283), which then began to produce virus. The virus-producing cells were inoculated into a marmoset (71AP1) causing the development of a tumour which was explanted and grown in culture. The tumour cells produced a virus, referred to here as SiSV (71AP1). To the best of available knowledge, none of the biological materials, save possibly the original woolly monkey itself, had direct contact with rodents or rodent cells. SiSV (71AP1) has subsequently been introduced into several other cell lines, including marmoset HF cells and normal rat kidney NRK cells.

The experiments reported here involve hybridisation of 70S RNA isolated from SiSV (71AP1) and labelled with ^{125}I *in vitro*[17] to DNA purified from a variety of animal tissues or cultured cell lines. As the objective was to examine genes of normal cells for sequences related but not necessarily identical to the viral RNA, conditions of hybrid formation and detection capable of monitoring imperfect RNA–DNA complexes was required. Hybridisation of viral RNA to cell DNA at 60 °C in 0.4 M PO_4 has been found to be a suitable condition of hybrid formation for this purpose[13]. The condition of hybrid detection most suitable for detecting imperfect complexes formed between SiSV (71AP1) RNA and cell DNA (8×10^6-fold weight excess) was treatment of the hybridisation mixture with 20 μg ml^{-1} RNase A in 0.6 M NaCl (Fig. 1a). The experiments used a 120 min exposure of the hybrid mixture to RNase. In these conditions, RNA from SiSV (71AP1) formed RNase-resistant complexes with DNA from rat NRK or marmoset 71AP1 cells infected with SiSV (50% of the RNA) and with DNA from normal mice (20% of the RNA). The RNA–DNA hybrids were maximally protected from degradation by RNase in 0.6 M NaCl; some complexes were destroyed in solutions containing less NaCl. Hybrid yield using DNA from uninfected primates was only 5–10% of the RNA when RNase treatment was carried out for 120 min (Fig. 1a), but was as high as 20–25% when RNase treatment was limited to 60 min (Table 1).

Table 1 presents hybridisation results for ^{125}I RNA from SiSV (71AP1) to DNA from many animals, using a single condition of hybrid formation (60 °C, 0 4 M PO_4, $C_0t = 10^4$) and hybrid detection (RNase treatment in 0.6 M NaCl at 37 °C for 60 min). DNA from mice or rats hybridised more SiSV RNA than did DNA from other animals, but appreciable hybridisation was obtained with DNA from some Old World primates and, to a lesser extent, from New World monkeys. DNA from chimpanzees hybridised 25% of the SiSV RNA, whereas DNA from humans hybridised only 5–10%. DNA from the lower animals examined, excluding mice and rats, hybridised only 1–10% of the RNA.

The kinetics of hybridisation of SiSV (71AP1) RNA to DNA from NIH Swiss mice or from SiSV-infected marmoset HF cells was that expected from DNA sequences present only a small number of times per genome (Fig. 1b). By a C_0t of 2×10^4, 35% of the RNA had hybridised to DNA from mice and there was no indication that the hybridisation reaction was slowing. A small portion of the RNA (10%) annealed rapidly to DNA from mice or infected marmoset HF cells. DNA from humans or woolly monkeys reacted poorly with SiSV RNA, even at high C_0t. The t_m in 0.15 M NaCl of the hybrid structures formed with DNA from mice or chimpanzees was only about 65 °C, compared with 80 °C for hybrids involving DNA from SiSV-infected marmoset 71AP1 cells. Therefore, the virus-related sequences in the DNA of mice and chimpanzees are less closely related to the viral genome than are the proviral DNA sequences in the DNA of SiSV-infected cells.

The DNA–RNA ratio in the experiments described above was 8×10^6. If each viral subunit has a molecular weight of

Table 1 Hybridisation of RNA from SiSV to DNA from various animals

DNA source	Hybrid yield (% RNA hybridised)
Mice, rats and infected cells

RNA–DNA hybridisation mixtures were constructed as described in the legend to Fig. 1a, then exposed to 20 μg ml^{-1} RNase at 37 °C for 60 min in 0.6 M NaCl. Letters in parentheses indicate the tissue or cell type used to obtain DNA. C, Cultured cells; S, spleen; L, liver; Tu, tumour; M, muscle; B, brain; T, thymus; E, embryo; A, whole animal; WBC, White blood cells.

3×10^6 (ref. 18) and if the viral-related sequences exist only once per genome, complementary DNA should be 27-fold in excess. If the viral-related sequences in the mouse DNA, however, are only distantly related to RNA from SiSV (71AP1), after hybridisation the RNA–DNA hybrids can exist in reversible equilibrium with free RNA. Raising the amount of DNA would then drive more RNA into RNA–DNA hybrids. Figure 1c shows that at a C_0t of 2×10^4, increasing the DNA–RNA ratio to 30×10^6, resulted in hybridisation of 45% of the SiSV (71AP1) RNA with normal mouse DNA—a hybrid yield equivalent to that obtained with DNA from SiSV-infected marmoset HF cells. Again there was indication that 10–11% of the RNA hybridised to repeated DNA sequences. These data when analysed by a double reciprocal representation showed that 56% of the SISV RNA would have hybridised to mouse DNA at infinite DNA input (see legend to Fig. 1).

Several reports[14] have suggested an unusual genetic proximity between viral sequences in primates, including man, and those in viruses from mice[10,11,15]. It has also been demonstrated that both 'endogenous' and 'exogenous' mouse RNA tumour viruses carry genomes related to DNA sequences in normal mice[7,13,19]. Taken together, these observations indicate that the primate viruses also contain genomes related to genes in normal mice, a conclusion verified by our studies. The concept of mouse–primate relationship of RNA tumour virus nucleotide sequences is supported by the isolation from cultured asian mouse cells of a virus containing proteins antigenically related to analogous proteins from primate RNA tumour viruses[20].

The homology between SiSV RNA and normal mouse

DNA can be used as an indication that SiSV originated in mice and subsequently entered primates. The weaker homology between SiSV RNA and primate DNA may reflect genetic change promoted by recombination with the new host[2]. The hybridisation results show a closer homology of the virus to Old World monkeys than to New World monkeys, indicating genetic interaction of the virus with Old World monkeys. SiSV (71AP1) was isolated from and has subsequently had contact solely with New World monkeys or cells derived from New World monkeys. We have been told by the owner of the woolly monkey from which SiSV was obtained that this household pet cohabited for 1–2 years with a gibbon before the woolly monkey developed a sarcoma. Possibly, the gibbon carried the virus and transmitted it to the woolly monkey. The possibility of an Old World primate transmitter of a mouse virus as a means for generating primate RNA tumour viruses is being studied.

We thank S. Gillespie and F. Wells for assistance, Drs W. C. Saxinger, F. Deinhardt, R. G. Smith, R. E. Gallagher, and R. C. Ting for discussions, and especially E. Johannsen for obtaining tissues from several of the animals studied.

Specific binding of CAP factor to *lac* promoter DNA

CATABOLITE repression in *Escherichia coli* is mediated by the cyclic AMP dependent catabolite activator protein (CAP). Growth conditions where the induced catabolism of certain sugars is energetically favourable, primarily in the absence of glucose, promote the intracellular induction of a high cyclic AMP concentration; CAP binds cyclic AMP, is activated, and stimulates mRNA synthesis from promoters of catabolite repressible operons[1–4]. The mechanism by which CAP influences the interaction between RNA polymerase and promoter DNA in unknown. Purified CAP preparations exhibit a cyclic AMP-dependent DNA binding activity, but efforts to detect specific binding to promoters of catabolite repressible genes have been unsuccessful; all DNAs tested have shown similar binding affinities[5,6]. The only evidence for a specific interaction between CAP and promoter DNA is a fluorescent probe study which showed that a *lac* transducing phage DNA molecule induces a conformational change in CAP that is not seen with the wild-type phage molecule[7]; but no

effort was made to correlate this difference with *in vivo* CAP behaviour. Here I report experiments which demonstrate that the CAP factor binds specifically to a site within the *lac* promoter. This binding is sensitive to mutations which affect the ability of CAP to stimulate *in vivo* and *in vitro lac* gene expression.

These experiments were made possible by the recent isolation of a 200 base pair DNA fragment containing an intact *lac* control region[8]. The fragment, designated *Hae*200, was generated by digesting 1,000 base pair sonicated *lac* fragments with the *Hae*III restriction endonuclease of *Haemophilus aegyptius*[9] and was shown to contain the entire control region by the following criteria: first, an *in vitro* transcription system using *Hae*200 as a template synthesises mRNA which extends into the region coding for the NH_2 terminus of β-galactosidase, the product of the *z* gene (J. M., unpublished). Second, polyacrylamide gel electrophoresis of a digest of DNA from a strain containing the L1 deletion, known to cover both the COOH-terminus of the *i* gene and part of the *lac* promoter[10,11], shows that only the mobility of the *Hae*200 fragment is altered by the deletion[8]. Therefore the entire region from the end of the *i* gene to the beginning of the *z* gene must be on the fragment. Figure 1 shows a map of the *lac* region and the fragments generated by *Hae*III digestion.

I have investigated the ability of CAP to bind these fragments to nitrocellulose filters; details of the binding conditions are given in the legend to Fig. 2. The CAP preparation used in these assays, when used in an *in vitro* transcription system, will stimulate mRNA synthesis off the *Hae*200 fragment up to twentyfold. This stimulation is dependent on cyclic AMP and saturates at CAP concentrations similar to the maximum concentrations used in the binding assays (J. M., unpublished). All binding was carried out in the presence of a large excess of unlabelled, sonicated λ*plac*$_5$ DNA fragments; in the absence of these fragments no specific binding could be detected. Figure 2 displays the DNA binding activity of CAP towards the *Hae*200, *Hae*175, and *Hae*120 fragments. In these conditions CAP shows significantly greater affinity for the promoter containing *Hae*200 fragment than for either of the other fragments. The binding is dependent on cyclic AMP and can be inhibited by cyclic GMP, a competitive inhibitor of cyclic AMP[1]. At higher concentrations of CAP the specificity becomes considerably less dramatic as the effect reported here is dependent on both the absolute CAP concentration and the CAP–DNA ratio.

If the affinity for *Hae*200 is functional it should be affected by promoter mutations which alter the ability of CAP to stimulate *lac* transcription. A suitable test for this is the CAP independent double mutant L8-UV5. L8, probably a point mutation, maps under the L1 deletion and gives a fifteenfold reduction in CAP stimulation[10–12]. UV5 is a second mutation which reverts L8 to a CAP independent, *lac*+ phenotype[13]. Figure 3 shows that the affinity of CAP for *Hae*200 from L8-UV5 is significantly less than that for the wild-type frag-

Fig. 1 Map of the *lac* control region with the location of *Hae*III cuts as determined by Gilbert *et al.*[8]. Regions of interest on *Hae*200 are given in more detail, as determined by Gilbert *et al.*[16], Dickson *et al.*[14] and Beckwith *et al.*[13].

*Hae*III fragments
ment, especially at low CAP concentrations; although the *Hae*175 fragments from the same preparations of the two strains bind with equal affinity (see also Fig. 2). The L1 deletion itself completely eliminates the ability of CAP to influence *lac* transcription[10,11]. Figure 3 shows that the fragment corresponding to *Hae*200 isolated from the L1 strain (about 80 base pairs shorter than that from wild type) also shows little affinity for CAP. Similar effects have been seen with CAP preparations
Fig. 2 Filter binding affinity of CAP for the *Hae*200, *Hae*175, and *Hae*120 fragments. Each binding reaction contains in 200 µl: 20 mM Tris-HCl pH 8.0, 10 mM KCl, 3 mM $MgCl_2$, 0.1 mM EDTA, 0.25 mM cyclic AMP or cyclic GMP, 100 µg ml^{-1} bovine serum albumin, 10 µg ml^{-1} sonicated λ*plac₅* fragments, and ^{32}P-labelled restriction fragments, from 1,000 to 5,000 c.p.m. per assay. Labelled fragments were purified as described by Gilbert and Maxam[17], the specific activity of the fragments was about 10 Ci per mM phosphate The fragments, dialysed into 10 mM Tris-HCl pH 7.5, 0.1 mM EDTA, were made up to 10 mM KCl, 10 mM $MgCl_2$, 0 1 mM dithiothreitol and 200 µg ml^{-1} BSA. 10 µg of carrier, sonicated 1,000 base pair fragments were added along with enough *Hae*III enzyme to yield a complete digest after an incubation of one hour at 37 °C. The digested fragments were made up to 2 M NH_4OAc and precipitated with two volumes of ice-cold 95% ethanol They were resuspended in 0.5 M NH_4OAc, again ethanol precipitated, then electrophoresed through a 5% polyacrylamide TBM (0.1 M Tris-borate pH 8.3, 2 mM $MgCl_2$) gel[17]. The radioactive bands, identified by autoradiography, were cut out and eluted into 0 5 ml of 0.5 M NH_4OAc, 10 mM $Mg(OAc)_2$, 0.1 mM EDTA, 0.1% SDS, containing 20 µg of tRNA. The DNA was then ethanol precipitated, resuspended in 0.5 M NH_4OAc, reprecipitated, and stored in 100 µl of 10 mM Tris-HCl pH 7.5. CAP was purified by the method of Pastan *et al.*[18], modified by the omission of dithiothreitol throughout. The purified protein was dialysed into 20 mM Tris-HCl pH 8.0, 50 mM KCl and stored at 4 °C For the binding assay, salts, cyclic AMP, CAP, DNA fragments and BSA were incubated for 10 min at room temperature in silicated glass tubes, then filtered through S & S B-6 nitrocellulose filters that had been presoaked in 0.1 N NaOH, washed thoroughly in double distilled water and equilibrated with binding buffer. The filters were then washed twice with 0.15 ml binding buffer without BSA, dried thoroughly, and counted in toluene Omnifluor. Backgrounds in which no CAP was added have been subtracted in all cases. Typically these were between 5 and 10% of the input counts. Those cases in which bound counts were below background have been recorded as 0% counts bound. purified in different ways and with several DNA preparations. I conclude that the observed DNA binding activity is functional and must be involved in the CAP regulatory function.

As for the mechanism of this regulation, the *lac* promoter sequence of Dickson *et al.*[14] reveals that the L1 deletion covers a symmetry region of about 16 bases which may be the CAP binding site. This site is about 10 base pairs removed from a region to the right of the L1 deletion in which several mutations have been mapped and sequenced which reduce the affinity of the polymerase for the promoter in a *crp*⁻ background[14,15]. The polymerase probably recognises the DNA sequence in this mutatable region and this recognition event is a likely candidate for CAP regulation. This regulation may be effected either by a change in the conformation of the DNA, in which case there would be no direct CAP–polymerase interaction, or by a direct stabilisation through a CAP–polymerase–DNA complex. Although CAP has not been shown to interact directly with the RNA polymerase, conformational changes induced by promoter DNA sequence information may make possible such an interaction. Alternatively, the direct protein–protein interaction needed (about 2–3 kcalorie since CAP enhances the promotion by a factor of fiftyfold *in vivo*) may be too weak to have been detected by the methods used so far.

I thank Walter Gilbert for discussions and for help with the manuscript. This work was supported by a Public Health Service grant from the National Institute of General Medical Sciences.

Translation of plant messengers in egg cells of *Xenopus laevis*

MAMMALIAN and plant virus messengers can be translated in living egg cells and oocytes of the tadpole of *Xenopus laevis*[1-6], and this method could be useful in the study of messenger

Time (h)
Fig. 1 The effect of injection of crude plant RNA extract on the synthesis acid precipitable material by egg cells of *Xenopus laevis*. The RNA was extracted from self-pollinated styles of *Petunia hybrida* using the cold phenol method[7]; 20–30 ng RNA was injected per egg together with 0.25 µCi ³H-leucine (specific activity 32 Ci mmol⁻¹) in a total volume of 100 nl injection medium[1]. In the control experiments the same amount of radioactivity was injected also in 100 nl. Injection was carried out with a microinjection device with which nanolitre quantities could be injected without precalibration[11]. After incubation during the indicated times in saline solution[1] containing 1 mg actinomycin D l⁻¹, eggs were homogenised in 0.5 ml of a buffer containing 0.05 M Tris-HCl(pH, 7.6), 5 mM Mg acetate, 25 mM NH₄Cl, 6 mM β-mercaptoethanol and 0.2% SDS in a Braun homogeniser, and finally taken up in 2 ml of this buffer. After centrifugation at 2,500g at 4 °C an equal volume of 20% TCA was added to the supernatants and after 30 min at 0 °C the precipitate was centrifuged down at 30,000g. The pellet was re-suspended in 10% TCA, heated at 90 °C for 15 min, cooled and again centrifuged at 30,000g. The pellet was resuspended in 0.1 ml of a proper buffer per egg cell; 10 µl was counted in a toluene-based scintillation liquid in a Philips Liquid Scintillation Counter. ●, No RNA injected; O, 20–30 ng total RNA extract injected per egg cell.

activity in general. Here I describe the results of experiments aimed at the use of this method for studying plant messenger RNA.

During the incompatibility reaction in *Petunia hybrida*, the style reacts to self and cross pollination by differential gene activity as measured by the synthesis of RNA[7]. Since these differences were most likely to be observed in messenger RNA, protein synthesis was also studied. Polysomes extracted from pollinated styles were incubated *in vitro* with a 105,000*g* rat liver supernatant[8]. The quantitative patterns of protein and RNA synthesis were very similar in the time after pollination[8]. Qualitative analysis of the newly synthesised polypeptides by means of electrophoresis, however, with or without SDS and urea, and isoelectric focusing, always showed one broad dominant peak and very little incorporation in other parts of the gel. These results did not agree with those obtained for RNA synthesis[9]. Nevertheless, this *in vitro* system demonstrated that it was possible to use animal enzymes to study the translation of plant messengers. It was therefore decided to investigate the possibility of using *Xenopus* egg cells for this purpose. Unfertilised egg cells could be collected the morning after injection of a female with hormone[10]. The egg cells were treated according to the procedures described by Gurdon *et al.*[1] except for the addition of 1 mg actinomycin D per l incubation medium. The effect of injection of total RNA extract from self-pollinated styles is given in Fig 1. At first the plant RNA tends to inhibit the translation of endogenous RNA but subsequently its translation occurs at an almost constant rate for several hours.

To prove that the level of incorporation is proportional to the amount of mRNA injected into the cell and depends exclusively on mRNA, a total cold phenol extract from five self-pollinated styles was electrophoretically separated in a tandem polyacrylamide gel[6]. The gel was then cut into five parts, comprising the RNA with sedimentation values of 28S and more, between 18S and 28S, 18S, between 5S and 18S, and 5S or less. Equal amounts of the re-extracted RNA were injected into *Xenopus* eggs and the radioactivity in the acid-precipitable material was measured (Fig. 2).

Fig. 2 The stimulation of incorporation of ³H-leucine by different RNA fractions. A crude RNA extract from 10 styles was separated electrophoretically in polyacrylamide tandem gels[7]. After electrophoresis the gels were cut into five parts. The corresponding parts were homogenised in such a volume of double concentrated injection medium that the concentration of RNA in all fractions was about 20 ng per 50 nl. The gel slurry was centrifuged at 10,000*g* for 10 min at 4 °C and the supernatants collected. Aliquots were diluted 1:1 with ³H-leucine and 100 nl of this mixture was injected into each egg cell. Incubation, extraction and measurement of radioactivity were as described in Fig. 1. Solid line; absorbance trace of one gel. Hatched blocks; Incorporation of ³H-leucine per µg RNA.
Fig. 3 Distribution of radioactivity after electrophoresis of protein extracts from treated *Xenopus* egg cells. Electrophoresis was carried out in the lower gel of 13.5% polyacrylamide with a stacking gel of 2.7% polyacrylamide at 3 mA per gel and 70 V in the presence of 4 M urea at pH 8.3 (0.05 M Tris-glycine buffer containing 0.2% SDS). Electrophoresis was stopped when cytochrome c had migrated 25 mm in the lower gel. The stacking gel was removed and counted as fraction number 1. The lower gel was cut into 1-mm slices (Mickle Gel Slicer). Gel slices were combusted (Packard Sample Oxidyser) and counted. *a*, Only endogenous RNA is translated; *b*, 25 ng of total RNA extract injected per egg cell.

Although most of the RNA was recovered as ribosomal and transfer RNA, the highest incorporation levels per mg RNA were obtained after injection of RNA from the parts of the gel in between those peaks. The conclusion, therefore, has to be that incorporation of ^{3}H-leucine only depends on the amount of messenger injected. The most difficult part of this study, however, is to prove that the proteins synthesised in *Xenopus* after injection of plant RNA contain plant proteins. After electrophoretical separation in SDS–urea–polyacrylamide gel the patterns of distribution of label were different for proteins synthesised in either the presence or absence of total plant RNA extract (Fig. 3). Immunological proof of identity will be conclusive when only one messenger is used and the protein synthesised this way has antigen activity. When a complete RNA extract is used, however, the method becomes questionable, especially since many plant proteins have no antigenic activity. In this special case, however, RNA was extracted from self-pollinated self-incompatible styles. Thus it could be assumed that part of the proteins translated from it were involved in the incompatibility reaction, that is the inhibition of the pollen tube growth in the style. Therefore, if the right plant proteins were synthesised in *Xenopus*, application of these proteins to cross-pollinated styles would have the same effect on pollen tube length as a protein extract from self-pollinated styles, whereas

Table 1 The effect of proteins synthesised in *Xenopus* eggs on pollen tube length

Pollination	Addition	% Reduction of compatible tube length
	—	0
	Water/buffer	2
	Endogenous *Xenopus* proteins	2–5
Compatible ($S_3 \times S_2$)	Protein extract of *Xenopus* after injection of RNA from $S_3 \times S_3$	30–40
	Protein extract of self-pollinated styles	20–40
Incompatible ($S_3 \times S_3$)	—	20–40

Protein samples were obtained as described in Fig. 1, except for heating at 90 °C, but dialysed against running tap water, double distilled water or electrophoresis buffer (see Fig. 3) for at least 24 h. They were subsequently applied to the style by dipping the stigma in this solution, containing 400–600 µg protein per ml as determined according to Lowry *et al.* After 30 min at room temperature the styles were pollinated as indicated and incubated at 25 °C for 24 h. Pollen tube lengths were measured by ultraviolet fluorescence microscopy[12].

proteins synthesised with endogenous *Xenopus* RNA would have no effect. The results are as listed in Table 1.

Proteins synthesised in *Xenopus* after injection of RNA extracted from cross-pollinated styles also showed an effect on pollen tube growth. But stimulation was found only when the proteins were tested in a combination of pollen and style that did not contain any of the *S* alleles present in the combination of pollen and style from which the RNA was extracted. Reduction of pollen tube length was found when these *S* alleles were identical. These results indicate that the primary gene product of the *S* allele is synthesised in the style after pollination. They also tend to show that the polypeptides are involved in the recognition reaction which is very specific. Since these polypeptides can be synthesised in *Xenopus* egg cells with plant messengers, we may conclude that the machinery for the synthesis of proteins in eukaryotic plants and animals is very similar and that this method provides a useful tool in the study of gene activity in both plants and animals.

I thank professor H. F. Linskens for his continuous interest and J. R. de Haas for providing the *Xenopus* eggs. Part of this research was made possible by financial support from the Association Euratom-ITAL.

Aminoacylation of transfer RNA microinjected into *Xenopus laevis* oocytes

THE microinjection technique perfected by Gurdon and his collaborators[1,2] represents an excellent method for the study of the *in vivo* effects of drastically changing the molecular contents of the injected cells. We have demonstrated[3] that radioactive yeast transfer RNA injected into oocytes of *Xenopus laevis* is not appreciably degraded after 20 h of

incubation inside these cells. It seems therefore, possible to modify the quantity and characteristics of the tRNAs present in frog oocytes and to test the effects that such changes may have on protein synthesis and other cellular processes. An important control in such a study is to determine whether the tRNAs microinjected into frog oocytes are functional in the sense that they can be aminoacylated by the recipient cell. This report presents evidence demonstrating that the amphibian oocyte is capable of aminoacylating yeast tRNAs injected into these cells at concentrations which are greatly in excess of their endogenous tRNA content.

The method used for microinjection of oocytes[3] and for the preparation of protein synthesis elongation factor 1 from wheat embryos[4] have been published previously. Specific
Fig. 1 The aminoacylation of yeast ³H-tRNA injected into *Xenopus* oocytes assayed by the formation of ternary complex with EF1 and GTP. Bulk yeast ³H-tRNA was prepared by the method of Brungraber[12] from a uracil-requiring strain of yeast (13088) grown in ³H-uracil. This method includes a step to deacylate endogenous aminoacyl-tRNAs. Carrier yeast tRNA was added to facilitate isolation. The specific activity of this material was of 500 c.p.m. pmol⁻¹. Electrophoretic analysis showed that this material contained negligible 5S RNA. *a*, 80,000 c.p.m. of the uninjected ³H-tRNA was incubated with 2 mg of wheat EF1 and GTP as described by Tarragó et al.[13] and passed through a Sephadex G-200 column (55 × 1.5 cm) which was equilibrated and eluted with a buffer containing 20 mM Tris-HCl pH 7.5, 10 mM MgCl₂, 50 mM NH₄Cl, 1 mM GSH, and 75 μmol GTP. Fractions of 1 ml were collected and aliquots were precipitated with cold 5% TCA, filtered through Millipore membranes and counted. *b*, 54,000 c.p.m. of ³H-tRNA (specific activity 140 c.p.m. pmol⁻¹) was incubated and passed through the same column in identical conditions. This ³H-tRNA has been aminoacylated *in vitro* using a crude wheat embryo aminoacyl-tRNA synthetase solution prepared according to Muench and Berg[14] and a mixture of the 20 natural non-radioactive amino acids. A control experiment showed that the reaction mixture could aminoacylate 1.5% of yeast tRNA with phenylalanine. *c*, Yeast ³H-tRNA recovered after its injection into *Xenopus laevis* oocytes was fractionated in the presence of EF1 and GTP as in *a*. This material containing a total of 120,000 c.p.m. with a specific activity 500 c.p.m. pmol⁻¹, had been injected into 50 *Xenopus laevis* oocytes (50 nl per oocyte) and these cells were incubated at 21 °C for 5 h in amphibian saline. The ³H-tRNA was recovered by phenol extraction as described in Table 1 and the water phase was precipitated with 3 volumes of ethanol at −20 °C. The precipitate was collected by centrifugation at 20,000 g for 30 min and the ³H-tRNA was redissolved in 200 μl of water and added to the ternary complex incubation mixture. *d*, Fractions 40 to 56 of *c* were pooled and precipitated with ethanol as in *c* and the ³H-tRNA was dissolved in 0.5 ml of H₂O and brought to pH 10 with NH₄OH and incubated at 37 °C for 30 min. This treatment deacylates the tRNA and inactivates the wheat EF1 that might be present in these fractions. The mixture was then neutralised with HCl and reprecipitated with ethanol. The precipitate was dissolved in 200 μl of H₂O and incubated with EF1 and GTP as in *a*. 27,000 c.p.m. of ³H-tRNA were run on this column.

details of the experimental procedures are given in the legends to the figures and table.

Controls on the state of the ³H-tRNA recovered after microinjection and on the efficiency of recovery were performed. Electrophoresis on 7.5% polyacrylamide gels according to Peacock and Dingman[5] showed that the material recovered by phenol extraction of oocytes 5 h after microinjection had mobility identical to the original ³H-yeast tRNA. Microinjection of ¹⁴C-Phe-tRNA followed immediately by phenol extraction of the injected cells gave a recovery of approximately 80% of the acid precipitable radioactivity in the water phase.

The small amounts of tRNA that could be injected and recovered from these cells and the necessity to differentiate the injected material from the endogenous tRNA required a new method for the assay of the aminoacylation of total yeast ³H-tRNA. The method of choice determines the capacity of the ³H-tRNA recovered from the injected cells to form a ternary complex with GTP and with protein synthesis elongation factor 1 (EF1) from wheat embryos. It has been demonstrated previously that wheat embryo EF1, like bacterial EF Tu, interacts with aminoacyl-tRNA but not with unacylated tRNA in the presence of GTP[6,7]. Figure 1a shows the elution of uninjected yeast ³H-tRNA on a Sephadex G-200 column after incubation with EF1 and GTP. This preparation which has been chemically deacylated fails to interact with the protein factor and elutes as free tRNA (molecular weight 25,000). In Fig. 1b the same experiment is performed with yeast ³H-tRNA that has been aminoacylated *in vitro* with a crude preparation of wheat aminoacyl-tRNA synthetases and the 20 different non-radioactive amino acids. It is clear that approximately 40% of the tRNA now elutes as a heavier peak (molecular weight 80,000) indicating that by aminoacylation it has acquired the capacity to interact with EF1 and GTP. In a separate experiment in which GTP was absent from the incubation mixture and the column buffer (not shown), the tRNA aminoacylated *in vitro* did not elute with a heavy peak but as in Fig. 1a. Figure 1c shows the results obtained with the original unacylated yeast ³H-tRNA recovered 5 h after its injection into *Xenopus* oocytes and incubated with EF1 and GTP. Its elution pattern has changed drastically from what was observed in Fig. 1a since now 80% of the ³H-tRNA elutes in the ternary complex fraction. To ascertain that this behaviour was due to *in vivo* aminoacylation, fractions 40 to 56 represented in Fig. 1c were pooled and chemically deacylated and, after concentration, run again with EF1 and GTP. Figure 1d shows that deacylation of the tRNA recovered after microinjection destroys its capacity to interact with EF1 and GTP.

It may be concluded therefore that the great majority of the yeast tRNA species microinjected as unfractionated tRNA can be aminoacylated very efficiently by the living oocyte. The amount of yeast tRNA introduced into each cell was approximately 100 ng which is 2.5 times the amount of endogenous tRNA[8].

Direct quantification of *in vivo* aminoacylation in injected oocytes was attained by the use of a pure species of tRNA. The assay consisted in measuring the appearance of radioactivity precipitable with cold TCA in the aqueous phase after phenol extraction of oocytes that had been incubated in a medium containing ¹⁴C-phenylalanine. Table 1 shows that no detectable radioactivity is obtained when uninjected oocytes or oocytes injected with unfractionated tRNA are treated. The amount of tRNA specific for phenylalanine in these cells is too low to be detected in the conditions used. Oocytes microinjected with purified tRNA^Phe, however, show considerable incorporation of radioactivity in the tRNA fraction. The identity of this radioactivity as aminoacyl-tRNA is established by its sensitivity to pancreatic RNase, mild alkaline hydrolysis and to hot TCA treatment. Incubation of the oocytes injected with tRNA^Phe with ¹⁴C-threonine does not yield radioactivity bound to the tRNA. In the table it is also shown that microinjection of tRNA^Phe whose amino acid acceptor capacity

Table 1 The aminoacylation of pure yeast tRNA^{Phe} microinjected into oocytes

| Experiment	Oocytes	Treatment	c.p.m. precipitated with cold TCA per oocyte
1	Uninjected		55
	Injected with 8 pmol of unfractionated yeast tRNA		88
	Injected with 8 pmol of pure yeast tRNA^{Phe}		1,150
	Same as above	^{14}C-Thr instead of ^{14}C-Phe	42
2	Uninjected		38
	Injected with 8 pmol of tRNA^{Phe}		840
	Same as above	RNase hydrolysis	72
	Same as above	pH 10 for 15 min at 37 °C	129
	Same as above	90 °C for 15 min in 5% TCA	49
3	Uninjected		57
	Injected with 8 pmol of pure yeast tRNA^{Phe}		1,285
	Injected with 16 pmol of yeast tRNA^{Phe} oxidised		43

The aminoacylation of tRNA^{Phe} was assayed by incubating duplicate groups of five oocytes each with ^{14}C-phenylalanine of a specific activity 270 μCi μmol^{-1} at a concentration of 3×10^{-5} M for 2 h at 21 °C in 50 μl of a modified Holtfreter's medium containing 20 mM Tris-HCl pH 7.4 and 10 ng ml^{-1} each of penicillin and streptomycin sulphate, 63 mM NaCl, 0.7 mM KCl, 0.9 mM CaCl$_2$, 1.0 mM MgCl$_2$ and 0.22 mM NaHCO$_3$. The oocytes were extracted by homogenising in 4 ml of cold mixture containing 2 ml of buffer (0.2 M sodium acetate 10 mM MgCl$_2$, 5 mM EDTA and 0.1% Triton X-100) and 2 ml phenol. The water phase was separated by centrifugation and duplicate aliquots of 0.5 ml were precipitated with cold 5% TCA. The precipitate was retained on Millipore membranes and the radioactivity was measured in a scintillation counter with 60% efficiency. Unfractionated yeast tRNA was purchased from Calbiochem; pure yeast tRNA^{Phe} from Boehringer. The yeast tRNA^{Phe} was oxidised[11] but the amine treatment not included. When ^{14}C-threonine replaced the radioactive phenylalanine (experiment 1) the specific activity was 181 μCi μmol^{-1} and the concentration of 5×10^{-5} M. In experiment 2, where indicated, 0.5 ml aliquots of the water phase after phenol extraction were treated with 10 μg of pancreatic RNase or with mild alkali or heated in 5% trichloroacetic acid as given in Table 1.

has been destroyed by periodate oxidation fails to incorporate radioactivity.

Figure 2*a* shows the time course of the aminoacylation in oocytes injected with 20 pmol of tRNA^{Phe} per cell. The reaction is not yet complete after 2 h incubation when at least 25% of the injected tRNA has been aminoacylated with ^{14}C-phenylalanine. Exact estimates of the amounts of Phe-tRNA synthesised would have to consider whether the radioactive amino acid is diluted by the internal pool of free amino acid in the oocyte before it is incorporated in the tRNA. The amount of free phenylalanine in *Xenopus* oocytes has been estimated to be approximately 60 pmol per oocyte (Bravo and Allende, unpublished) a quantity that would yield a fourfold dilution of the ^{14}C-phenylalanine taken up by the cell in 2 h. Recent evidence obtained in other cells indicates that this dilution may not take place[9,10].

The effect of injecting different amounts of tRNA^{Phe} on Phe-tRNA formation in the oocytes can be seen in Fig. 2*b*. In this experiment the incubation was carried out for 2 h so that the values obtained with the lower tRNA^{Phe} concentrations represent extent rather than rate of aminoacylation. With limiting amounts of tRNA^{Phe} aminoacylation of 85–90% of the injected tRNA was obtained without considering dilution by the internal pool of free phenylalanine. This result is corroborative evidence that such dilution may not take place in this sytsem.

Using the values shown in these figures it is possible to calculate that each oocyte has enough phenylalanine-tRNA synthetase to catalyse the aminoacylation of approximately
Fig. 2 The effects of time and tRNA concentrations on the *in vivo* aminoacylation of tRNA injected into *Xenopus laevis* oocytes. *a*, 20 pmol of pure yeast tRNA^{Phe} were injected into each oocyte and duplicate groups of five oocytes were incubated at 21 °C for the times indicated in amphibian saline medium containing 3×10^{-5} M ^{14}C-phenylalanine, specific activity of 270 μCi μmol^{-1}. The amount of aminoacylation was determined as described in Table 1 and the pmol of aminoacylated tRNA^{Phe} per oocyte were calculated disregarding cellular dilution of the specific activity of the ^{14}C-phenylalanine. *b*, The amounts of tRNA^{Phe} indicated were injected into each oocyte of duplicate groups of five and incubated for 2 h in the same medium. The amounts of aminoacylation were determined as above.

10^{10} molecules of tRNA^{Phe} min^{-1}. This rate is approximately an order of magnitude higher than the rate of incorporation of phenylalanine into protein in these cells (Bravo and Allende, unpublished).

In conclusion, the results presented above indicate that tRNA microinjected into amphibian oocytes is functional in the sense that it can be aminoacylated *in vivo*. Cells microinjected with tRNA^{Phe} contain more than 500 times the normal concentration of this specific tRNA and 150 times the amount of Phe-tRNA. It should, therefore, be possible in the future to study the effects that such an unbalance provokes on protein synthesis and other cellular processes.

Translation of natural mRNAs *in vitro* by extracts of a mutant in protein synthesis

NATURAL mRNAs contain specific signals for initiation and termination of protein synthesis[1,2]. To further understand these processes and their regulation in the cell, we have been screening mutants defective in translation of natural mRNAs but not of artificial templates.

The temperature-sensitive *Escherichia coli* mutant, N4316, is one of this class. At 36 °C, *in vivo*, N4316 suppresses the termination codons UAA and UGA, but not UAG (ref. 3). At
Fig. 1 Analysis of MS2 and MS2 (623) products on SDS polyacrylamide gels was according to Maizel[16] using 15 % acrylamide and 0.8 % bisacrylamide in the separating gel and 5 % acrylamide in the stacking gel. Products were labelled with ^{35}S-methionine (see Table 2). Incubations were terminated with 13 mM EDTA, and 2 μg RNase I. After 8 min at 35 °C, proteins were concentrated by precipitation with 5 volumes of acetone at −20 °C. Electrophoresis was at 90 V for 1 h and 180 V until the tracking dye reached the end of the gels. X-ray films (RP X-Omat, Kodak Corp) were exposed for 4 d. Bacteriophage λ proteins labelled with ^{35}S-methionine were a gift from C. Epp and P. Ray (University of Toronto). Samples from left to right were as follows: λ proteins, 200×10^3 c.p.m.; MS2, 20.4×10^3 c.p.m.; MS2, 40.8×10^3 c.p.m.; MS2 (623), 28.0×10^3 c.p.m.; MS2 (623), 56.0×10^3 c.p.m.; no RNA, 9.4×10^3 c.p.m.; no RNA, 18.8×10^3 c.p.m. Counting efficiency for ^{35}S was 50 %. The leftmost channel contains phage λ late polypeptides labelled *in vivo* with ^{35}S-methionine. These are indexed according to their gene of origin; 'h' is a host peptide(s). The numbers refer to the molecular weights of these peptides in kdaltons. By extrapolation 'h' has a minimum molecular weight of 10,500. The major product of *in vitro* synthesis (coat protein) migrates like a peptide of molecular weight 10,800±300. ^{125}I-labelled (or unlabelled) authentic coat protein[11] was found repeatedly to have the identical migration in these gels as the *in vitro* synthesised product.

Table 1 Protein synthesis by N4316 extracts programmed with amber mutants of the maturation and replicase cistrons of MS2 RNA

RNA	d.p.m. ^{3}H-histidine incorporated ($\times 10^{-3}$)		
	36 °C	46 °C	46 °C+RF
MS2	194	38.4	146
*am*5	41.0	23.5	66.0
*am*9	152	35.0	113

All experimental details were as described previously[7] except that incubations contained 5 μCi ^{3}H-histidine (58 Ci mmol[−1], Radiochemical Centre). Where indicated, 1.3 μg of rescue factor (RF) prepared without the DEAE cellulose step[7] and 12.5 μg of each mRNA were used to programme the S30 extracts of N4316. Radioactivity incorporated into hot TCA-insoluble products was measured. *Am*5 and *am*9 lysates, gifts of Dr M. Kozak and D. Nathans (Johns Hopkins University) were grown as described[9], and contained less than 0.1 % revertants. Controls with extracts from the parental strain D₁₀, showed no temperature sensitivity and no stimulation by the rescue factor. Incorporation without mRNA, about 10 % of the total, was subtracted from each value. Counting efficiency for ^{3}H was 20 %. Products were analysed as described by Ganoza *et al.*[5]. The bulk of the released MS2 and *am*9 products correspond in molecular weight to maturation protein (40,000).

30 °C the mutant does not suppress[3]. This observation implied a temperature-dependent lesion in termination, and a moderate defect in this function was demonstrated *in vitro*[4–6]. The mutation, however, seems pleiotropic. At 43–45 °C, translation *in vivo* is impaired and cells die[3]. In extracts of N4316 synthesis of the coat protein coded by R17 and f2 phage RNAs is greatly reduced at restrictive temperatures[4–6]. The defect *in vitro* seems to be in an early function of translation[7]. This function does not involve the initiation reaction in the usual sense, since the rate and extent of formation of the Fmet-tRNA–ribosome–f2 RNA complex is unimpaired[6,7]. The synthetic defect can be reversed by adding a soluble protein from wild type cells[7]. This "rescue" protein has been purified and is free of known enzymes and factors involved in protein synthesis[7].

In this communication we further examine the temperature-sensitive defect in *in vitro* synthesis and its reversal by measuring systematically the reading of a number of cistrons from a spectrum of phage mRNAs. The measure of translation of specific cistrons was made possible through the use of mRNAs bearing known amber mutations. Our data indicate that the early translation lesion is general, and is the more drastic and important defect. Furthermore, the early defect in cistron reading is not the result of an interference with initiation by termination intermediates in the intragenic regions of the mRNAs.

To score for specific cistrons, histidine was used as label because it is not present in the coat protein and synthesis was programmed by early amber mutants of the maturation cistron (*am*5) or the replicase cistron (*am*9), so that only one protein was measured at a time. Protein synthesis in extracts of N4316 directed by *am*9 is temperature sensitive and can be restored by rescue factor (Table 1). The *am*9 mRNA directs synthesis and release of a product that corresponds in molecular weight to the maturation protein (unpublished).

Protein synthesis catalysed by N4316 extracts using the *am*5 template is also temperature sensitive and the defect is reversed by rescue factor (Table 1). Analysis of the products on SDS polyacrylamide gels done after separation of nascent and free proteins showed that the smaller level of translation with *am*5 at 36 °C is due to a low level of replicase synthesis (unpublished). To overcome this problem, an amber mutant of the coat protein which overproduces replicase was used. As shown in Fig. 1, MS2 (623) RNA, programmes a product corresponding in molecular weight to the phage replicase. The synthesis of this product is temperature sensitive in N4316 and is reversed by the rescue factor (Table 2, experiment 1). Protein synthesis directed by Qβ RNA is also temperature sensitive and is restored by the rescue protein (Table 2, experiment 5).

These data show that the rescue protein works on all phage

cistrons and with all mRNAs tested (R17, MS2, f2 and Qβ). The maturation protein is coded by the 5'-terminal segment of the phage RNA. Since synthesis of this protein is defective in extracts of N4316 (Table 1), it is unlikely that the impaired synthesis at restrictive temperatures is the result of a defect in the release mechanism.

Further evidence that the defect cannot be accounted for by a problem in termination only is given in Table 2. Synthesis programmed with a non-polar mutant (*am*11b) of R17 phage is thermolabile and is reversed by the rescue protein. In *am*11b, the UAG codon is 59 codons away from the normal signal for termination of coat protein synthesis. Synthesis programmed by *am*11 of f2 is also temperature sensitive (Table 2). This phage has two amber mutations, one in the maturation cistron, and the other at the 50th codon of the coat protein cistron. These experiments indicate that steric hindrance by ribosomes is not responsible for the impaired translation.

No coat protein is produced when the MS2 (623) RNA is used as messenger (Fig. 1). This rules out misreading of the amber codons by the N4316 strain. These experiments show that the mutant N4316 has a marked effect on translation

Table 2 Protein synthesis in extracts directed by different mRNAs

Experiment no.	RNA	d.p.m. incorporated ($\times 10^{-3}$)			
		40–41 °C		43–46 °C	
		−RF	+RF	−RF	+RF
1	MS2 (623)	229	259	62.0	110
2	R17	327	—	12.5	195
	*am*11b	254	—	19.0	206
3	R17	181	—	18.5	152
	*am*11b	217	—	16.5	176
4	f2	368	415	65.6	201
	*am*11	329	328	50.4	197
5	Qβ	761	—	35.5	345

Experimental details were as described (ref. 7 and Table 1) except that 5 μCi of ^{3}H-lysine (3.7 Ci mmol^{-1}, New England Nuclear) as used in experiments 1, 2 and 5; 5 μCi ^{35}S-methionine (147 Ci mmol^{-1}, New England Nuclear) in experiment 4; and 5 μCi ^{3}H-histidine in experiment 3. Where indicated 2.3 μg of RF were used. Phages MS2 (623) (a gift from Gordon Carmichael, Harvard Biolabs) and Qβ (a gift from David Hoar, University of Toronto) were grown and purified and the RNA extracted as described previously[9]. Revertants were less than 0.1%. Where shown, synthesis was programmed by 11 μg of each RNA. Radioactivity incorporated into acid-insoluble products was measured. Optimum temperatures for synthesis were used as permissive temperatures as follows: experiments 1 and 4, 40 °C; and experiments 2, 3 and 5, 41 °C. Non-permissive temperatures were as follows: experiment 1, 43 °C; experiments 2, 3 and 4, 45 °C, and experiment 5, 46 °C. S30 extracts from N4316 were used in these experiments. Controls with the parental strain, D$_{10}$, showed no temperature sensitivity, and no stimulation by rescue factor with any of the RNAs. The predominant ^{35}S-labelled products directed by R17, f2 or Qβ RNAs at 45 or 40 °C, with or without rescue factor, migrated on 10% acrylamide gels (ref. 10 and Fig. 1), with identical mobility to authentic coat protein extracted from f2 phage. Products smaller than coat protein were observed with MS2(623) or *am*11 RNA. Other bands observed after prolonged exposure with Qβ or f2 RNA with and without factor were about 65,000 and 35,000–40,000 in molecular weight.

apart from its effect on chain termination. This defect affects translation of all mRNAs tested and all cistrons examined to approximately the same extent.

Other mutants of the same class exhibit similar phenotypes (unpublished). We therefore suggest that there exist functions vital to translation or its regulation in the cell which are not scored by any of the known partial assays of translation.

We thank Miss A. Tırpak for help in growing phages and Dr J. P. van der Meer for a gift of rescue factor used at the beginning of this work. This work was supported by an MRC of Canada grant to M.C.G.

Symmetry recognition hypothesis model for tRNA binding to aminoacyl-tRNA synthetase

THE fidelity of the transfer of the genetic information at the translational level depends largely on the accuracy with which each transfer RNA (tRNA) is aminoacylated by its cognate synthetase. The search for the common sites on tRNA which the enzyme recognises has resulted so far in a rather confusing picture. Practically all parts of the tRNA molecule have been implicated as the possible recognition site(s)[1,2].

Based on the general three-dimensional structure of tRNA (ref. 3) and the observation of the repeating sequences in various aminoacyl tRNA synthetases[4-7], a model for the binding of tRNA and aminoacyl tRNA synthetase (aa-RS) is proposed where the internal symmetry of tRNA coincides with that between "unit domains" of the enzyme.

The three-dimensional structure of two crystal forms of yeast phenylalanine tRNA has been determined by the X-ray crystallographic method[8-10]. The structure is shown in Fig. 1. An examination of the structure reveals that the molecule contains two types of symmetry elements relating two regions: a pseudo twofold axis and a pseudo twofold screw axis within a molecule as shown in Fig. 2. The regions related by the twofold axis overlap with, but are larger than, those related by the screw axis.

Some aa-RSs are composed of multiple subunits of the "smaller protomer" (molecular weight 35,000–50,000) and others contain one or more subunits of the "large protomer" (molecular weight 70,000–100,000)[1,2]. It has been suggested that the "large protomer" is composed of two homologous sequences[4-7]. This sequence homology implies that the three-dimensional structure of the protomer is likely to contain two structural domains as was the case in the crystal structure of Fab' fragment of a human immunoglobulin[11], where the two structural domains in one chain are related to each other by a pseudo screw axis. A preliminary X-ray crystallographic study of *Escherichia coli* methionine tRNA synthetase, part of which was enzymatically cleaved off, shows a structural domain of a prolate ellipsoidal shape (Reisler, J.-L., unpublished) with approximate axial lengths $22 \times 22 \times 30$ Å. The estimated molecular weight corresponding to the volume of this structural domain (based on the assumption that the partial specific volume of the average protein is 0.74 ml g^{-1} (ref. 12)), 49,000, which is in the range of the expected value of 43,000 for one half of the protomer. The most likely symmetry elements relating two structural domains in such a protomer are a pseudo twofold axis and a pseudo screw axis. Thus, one such structural domain can be considered a "unit domain" and two or more such "unit domains", which are related by pseudo twofold and/or screw axes, could form the assumed three-dimensional structure of a functional enzyme.

The model proposed here is based on the following assumptions: First, the aa-RSs recognise the common tertiary structural features of tRNAs. This is supported by the observations that the misacylation occurs in heterologous systems. (for example, *E. coli* tRNAs charged by yeast enzymes[13,14]) as well as in homologous systems[14]. Second, the specific recognition then selects the cognate mates. The hypothesis put forward is that the pseudo-symmetric regions of a tRNA are recognised

by the pseudo-symmetric regions of an aa-RS consisting of more than one "unit domain". For the enzymes with two identical small protomers, the true symmetry is assumed to convert to the pseudo symmetry by an asymmetric conformational change either on dimerisation or on ligand binding. This "symmetry recognition" can be achieved by coinciding the symmetry axes of the same type from tRNA and the enzyme, for example, the pseudo twofold axis of the tRNA with the pseudo twofold axis of the enzyme, while maximising the contact area as shown schematically in Fig. 3. In making the schematic complex, the regions of nucleotide sequence which vary the most among different tRNAs (dotted portion in Fig. 1) are kept further away from the enzyme and the overall contact area on tRNA is localised more on the "inside or diagonal side" of the L-shaped tRNA as has also been suggested by Rich and Schimmel (unpublished).

The symmetry-matching process will align tRNA and the enzyme in register and provide contact areas including some
Fig. 1 Schematic drawing of the 3-D structure of yeast phenylalanine tRNA in the orthorhombic crystal[9]. The amino acid acceptor (AA) arm and the TψC (T) arm form a continuous double helix and the anticodon (AC) arm and the DHU (D) arm form the other partially continuous double helix. These two helical columns form an "L", where the D and T loops are at the corner of the "L". The phosphate–ribose backbone is shown as a continuous wire except for the three dotted segments, variable (V) loop and two segments in the D loop. The number of nucleotides in these three segments varies among different tRNAs. The secondary and tertiary base pairs are shown as long or bent slabs and the additional tertiary hydrogen bonds between the bases are shown as dark straight lines. Tertiary hydrogen bonds involving riboses and phosphates are not shown. The molecule is rather flat with the approximate thickness of 20 Å. The backbone conformation at the 3'-end in the crystal is more extended than shown here.

non-symmetric regions. The contact areas on the enzyme are not expected to be one continuous elongated crevice, but two partially isolated regions, one on each "unit domain". Similarly, the contact areas on tRNA are expected to be centred around parts of two symmetric regions and their neighbourhoods. There are two alternative general contact areas on tRNA as shown in Fig. 3c and d, both of which include two symmetry-related regions (AA and AC stems) as well as parts of the AC loop and the D stem (for abbreviations, see the legend of Fig. 1). Most of the implicated enzyme recognition sites (AA stem[1,2,15], AC stem[16], D stem[13], anticodon[1,2,17]) belong in the symmetric regions or their neighbourhoods. More of these implicated recognition sites are in contact with the enzyme in the model shown in Fig. 3c than the one in 3d.
Fig. 2 Two views of yeast phenylalanine tRNA in the orthorhombic crystal[9]. The large, medium and small circles represent the centres of the phosphates, the riboses, and the bases, respectively. The pseudo twofold axes are indicated by arrows when on the plane and by a solid ellipse when perpendicular to the page. The pseudo twofold screw axes are indicated by one-headed arrows. The twofold symmetry related backbones are shown in black. The backbones related by twofold screw axes are shorter than those related by twofold axes. A few nucleotides at the 3'-terminal end are not shown. The aa-RS recognition sites implicated by various experiments[1,2,13,15-17] are circled by dotted lines.

The specific recognition sites of tRNA for the cognate enzymes are likely to be different for different tRNAs within the contact areas, but the common scheme by which tRNA and the enzyme align is proposed to be by the recognition of the pseudo-symmetric regions on both molecules.

The model proposed here enables one to make a few predictions. First, any increase or decrease in the symmetry in the pseudo symmetric regions (AA and AC stems primarily) will lower tRNA-enzyme binding properties. Such change of the symmetry can occur when a base pair is replaced by an unusual base pair such as a GU pair, or vice versa. The charging specificity may or may not change because the specific recognition site(s) may be in or in the neighbourhood of the symmetric regions. Second, any alterations in the T arm or D loop (and V loop in case of the model shown in Fig. 3c) which do not change the relative positions of the AA and AC stems and the pseudo-symmetry between them will not affect the binding or charging.

Fig. 3 Schematic drawings showing the matching of the pseudo twofold symmetry axes of tRNA and aa-RS: two orthogonal views of a, tRNA; b, two symmetry related "unit domains" in an aa-RS; and c and d, two alternative ways of forming tRNA-enzyme complex models by coinciding the twofold axes of both molecules. The matching of the pseudo screw axes can be achieved in a similar fashion with slightly different arrangement between the two molecules.
specificity. Third, for each model complex (Fig. 3c or d) there are two ways tRNA can interact with the enzyme: one is as in Fig. 3c or d, the other is by keeping two "unit domains" the same but rotating tRNA by 180° around the pseudo twofold axis, allowing the AC stem to interact with "unit domain" A and the AA stem to interact with B (see Fig. 3b). Since the symmetry is not true, these two modes of binding are likely to show two different tRNA binding properties.

This research was supported by grants from the National Institutes of Health and the National Science Foundation. I thank Alex Rich and Paul Schimmel for a preprint describing their model, Jean-Loup Risler for the unpublished results of the X-ray studies on modified *E. coli* methionyl-tRNA synthetase, and Joel Sussman and Marilyn Warrant for assistance. *Note added in proof:* The same hypothesis can be applied to the recognition between tRNA and other proteins with more than one domain or subunit, such as reverse transcriptase and its primer tRNA.

Influence of conformation on effect of macroions on kinetics of ionic reactions

POLYELECTROLYTES are known to alter drastically the rate of many ionic reactions in solution[1,2]. In general, it may be said that the polyelectrolyte effect has an important role in the observed changes of the rates of reaction. The high electrostatic field in the neighbourhood of the macroion generates an inhomogeneous distribution of the ionic reactants—counterions being concentrated in a rather small volume surrounding the polymeric chains. It has been clearly shown[3,4] that even when the ionic substrate is decomposed by specifically reactive groups incorporated into the polyelectrolyte molecule, the electrostatic interaction is the causative factor of the observed accelerated rate of decomposition. This polyelectrolyte effect may be a relevant factor on the activity of catalytic bio-polyelectrolytes, for example enzymes.

So far, almost all the polymers studied have had a random coil conformation. Since conformation is a very important parameter in determining the catalytic activity of natural biopolyelectrolytes, we compare here the accelerating power of the α-helix conformer of a poly(amino acid) in solution to that observed in the presence of the corresponding random coil conformer.

Previously, the effect of the conformation of poly(L-glutamic acid) in solutions on the rate of polymerisation of vinylpyridine has been reported[5]. Rates were found higher for the α-helix conformer, but the mechanism and interpretation of the effect is not straightforward. Overberger and Podsiadly[6] have demonstrated the importance of polymeric chain aggregation on the rate of a solvolytic reaction. This conformation involves only intermolecular hydrogen bonding, consequently it has no bearing on intramolecular hydrogen bonding occurring in biopolymers.

The rate of decomposition of 2,4-dinitrophenylphosphate
Fig. 1 Acceleration factor k_t/k_0 ($k_0 = 0.19 \times 10^{-4}$ s^{-1}) for the decomposition of DNPP against pH in the presence of poly (L-lysine). a, $R = $ [poly(L-lysine)]/[DNPP] $= 290$; b, $R = 100$. Dashed line, fraction of α-helix, f_H, of poly(L-lysine) against pH (refs 7 and 10). ●, present work. The substrate decomposition was followed spectrophotometrically at 358 nm. At this wavelength the two reaction products, dinitrophenol and dinitro-(substituted aniline), absorb in alkaline solutions. Alternatively, the formation of the aniline alone may be followed in acidic medium ($pH < 3$) at the same wavelength[3,8,9]. All the rate measurements were performed at 30 ± 0.1 °C, and the course of the reaction followed up to 50% conversion; in this range the kinetic law is strictly first order for DNPP.

(DNPP) in solutions of poly(L-lysine) (PLL), a poly(amino acid) capable of undergoing a pH-sensitive α helix $\rightleftharpoons$ random coil conformational transition[7], was determined. DNPP reacts specifically with the free-NH$_2$ groups in simple amine solutions[8,9] as well as in poly(ethyleneimine) solutions (E.B., R.F.-P., and D.T., unpublished), in an analogous fashion to p-nitro-phenyl phosphate[3]. The same reaction takes place with the free-NH$_2$ groups in PLL. The DNPP decomposition occurs by way of the dianion ($pK_2 = 4.5$) throughout all the pH range studied. In this pH region the hydrolysis of DNPP in water is independent of pH (refs 8 and 9 and E.B., R.F.-P., and D.T., unpublished).

The conformational transition of PLL in the presence and absence of the substrate was followed with circular dichroism measurements (JASCO J-20 Recording Spectropolarimeter). As shown in Fig. 1, the transition is not affected by the presence of the substrate and the values agree with those reported in the literature[7,10].

Figure 1 shows the results of the kinetic experiments at various pH. The acceleration of the decomposition is expressed as k_t/k_0, k_t being the first-order rate constant in poly(amino acid) solutions at each pH value. The rate constant k_0 is the corresponding value in water since at the concentrations used in this work simple amines do not contribute significantly to the rate of decomposition of DNPP[3,8,9]. Figure 2 shows the pH profile of k_t/k_0 for DNPP decomposition in solutions of poly(DL-lysine) (PDLL), which does not undergo the α helix $\rightleftharpoons$ coil transition; at all pH values it exists as a random coil[11]. The maximum at pH 8.9 in PLL solutions (Fig. 1) and that observed in PDLL solutions (Fig. 2) correspond to the effect of the random coil polyions on the rate of DNPP decomposition. A single maximum has also been observed for the decomposition of this substrate and p-nitrophenyl phosphate in solutions of random coil macroions possessing -NH$_2$ groups in their molecules (ref. 3 and E.B., R.F.-P., and D.T., unpublished). At the pH of the first maximum in Fig. 1, PLL is 98% random coil. These maxima are accounted for by the decreasing charge density of the weak polyelectrolyte, and by the increasing number of free -NH$_2$ groups when the pH of the solution increases (which may be considered similar to bifunctional catalysis). Further support for this interpretation

is given by the data illustrated in Fig. 3. It may be seen that k_t/k_0 for PLL random coil increases up to a constant maximum value as the concentration ratio R = [PLL]/[substrate] increases. The constant k_t/k_0 value is attained when all the dianion is concentrated close to the chain where the reaction with $-NH_2$ groups takes place. The minimum value of R at which k_t/k_0 becomes constant is dependent on the charge of the substrate and on the charge density on the macroion, as demonstrated in previous work[3,4].

The model postulates two stages for the DNPP reaction: first, attraction of the substrate dianion to the vicinity of the polymeric chain, and second, attack of DNPP ions by the free–NH_2 groups on the macroion. Any change of charge density or number of free amino groups must give rise to changes in k_t/k_0. One way of producing these changes is to alter the pH, as shown in Fig. 2 and the first maximum in Fig. 1. Another way is to alter the conformation of PLL, the transition taking place at pH 10.0. Figure 1 shows that a second maximum appears at pH 10.4 in the α-helix region (82% of PLL is in the α-helix conformation at pH 10.4). In spite of the smaller degree of ionisation of PLL in the alkaline solutions, where the second maximum is observed, the fact that the average distance between adjacent lateral groups, measured along the polymeric chain, is reduced from 3.6 Å, for the random coil, to 1.5 Å for the α helix[11], produces a marked increase in k_t/k_0. Thus, a new maximum appears in the accelerating factor due to the sudden increase in charge density of PLL and possibly also, in the availability (or increase in local concentration) of $-NH_2$ groups in the α-helix conformer. The magnitude of the factor by which the α helix is more effective than the random coil in accelerating the rate of DNPP decomposition was estimated using the equation,

$$(k_{helix}-k_0)/(k_{coil}-k_0)$$

The rate constants k_{helix} and k_{coil} for the pure conformers were calculated from the observed k_t and the fraction of α helix (f_H). The comparison was made with data corresponding to pH 10.4, the α helix being 5.5 times more effective than the random coil. If the data refer to a degree of ionisation of 0.11 for the amino groups of both conformers, the α helix becomes 12 times more effective.

The proposed model is so far only qualitative and it is

Fig. 3 k_t/k_0 against R, measured at degree of neutralisation, $i = 0.9$. ●, [DNPP] = 6.7×10^{-6} M, plus the corresponding amounts of PLL; ×, [DNPP] = 8.3×10^{-6} M, [PLL] = 2.4×10^{-3} N; ○, [DNPP] = 2.4×10^{-5} M, [PLL] = 2.4×10^{-3} N; □, [DNPP] = 8.3×10^{-6} M, [PLDL] = 3.3×10^{-3} N.

probable that other interactions (hydrogen bonding, local environment and so on) also contribute to some extent.

Errata

reviews

THE current generation of physicists and engineers is probably more familiar than any of its predecessors with the name of Fourier because of the many modern applications of Fourier analysis and Fourier transforms, which range from diffraction theory and spectroscopy to circuit analysis and quantum mechanics. In the 19th century Fourier profoundly influenced Kelvin and Heaviside; and as early as 1833 William Rowan Hamilton was writing of "Fourier, whom I place at the head of the French School of Mathematical Philosophy, even above Lagrange and Laplace".

So the prospective reader of a biography of Fourier* might expect to find an account of a typically great theorist, probably withdrawn from the buffetings of normal life, in accordance with the popular picture of a man of science. But that picture is open to question, especially as regards those generations of French scientists of which Fourier was a member. Maupertuis fought in the army of Frederick the Great. Lazare Carnot was the "organiser of victory" and the planner of Napoleon's most successful campaign. Charles, of Charles' Law, was one of the crew of two in the first manned flight of a hydrogen balloon. And Gay Lussac for many years held the world's balloon altitude record of 23,000 feet, which he established in 1804. But as is well brought out in Dr Herivel's new biography, none of these experiences was more intense than those of Fourier, whose life combined science and action in a remarkable way. When he started his classical work on the theory of thermal conduction he was about 35 years old—a distinctly late beginning

Joseph Fourier: The Man and the Physicist. By John Herivel. Pp. xi+350 +5 plates. (Oxford University Press: London; Clarendon: Oxford, April 1975.) £9.75.

Physicist extraordinaire

R. V. Jones

for a theorist—and he had already had a most adventurous career.

Born at Auxerre in 1768, he went to the Ecole Militaire in that town, and thence to the Abbey at St. Benoit with the intention of entering the Benedictine Order. Returning to Auxerre without taking his vows, he was made an Abbé in 1790; but he became so caught up in the maelstrom of the French Revolution as to be named at one time for execution; and a little later he became President of the Revolutionary Committee in Auxerre and, as such, a chief agent of the Terror. As so often happened, this republican prominence rebounded, and he himself was imprisoned in 1794. Released, he was nominated to the Ecole Normale, only to be imprisoned once more in Paris in 1795. Again released he went to the École Polytechnique, where in 1797 he succeeded Lagrange in one of the Chairs. In 1798 he was summoned to join Napoleon's Expedition to Egypt, along with many other eminent men of learning. After the military defeat of

this Expedition, Fourier was held as hostage for all the other savants by Admiral Sir Sidney Smith, an experience which resulted in friendship rather than resentment, for the Admiral saved Fourier's papers from destruction and later returned them to him in France.

Fourier became Prefect of the Department of Isère and was stationed at Grenoble, where he succeeded in organising the draining of the swamps of Bourgoin, a project which had been afoot since the time of Louis XIV. At the same time he was editing the general introduction to the *Description of Egypt*, the great compilation of the results of the Egyptian Expedition. Created a Baron in 1802, he was still Prefect of Isère in 1815— and still at Grenoble, right in the path of Napoleon's famous march on Paris. Vacillating about the surrender of Grenoble to his old Emperor, who had to batter the gates open after Fourier had conveniently withdrawn himself to the country, he incurred Napoleon's displeasure and was dismised from his post as Prefect, only to be appointed Prefect of the Rhône by a mollified Napoleon a few days later. But after Waterloo, Fourier's Napoleonic favours did not endear him to Louis XVIII, and so within three months he was removed from his second prefecture. Louis indeed refused for a time to confirm Fourier's election to the Academie des Sciences but relented in 1817, and from 1822 until his death in 1830 Fourier was permanent Secretary of the Academie. All these events are described with great historical care by Dr Herivel, who has provided an illuminating selection of Fourier's letters, along with many helpful biographical notes about the multitude of characters with whom Fourier became involved.

It was during his period in Grenoble that Fourier worked on the conduction of heat; and, as Dr Herivel emphasises, his first basic contribution was to

postulate that the flow of heat could be treated as that of an indestructable substance. In view of its antecedence in the caloric theory, and of its subsequent universal acceptance, it is hard to appreciate that Fourier had great difficulty in persuading Laplace, Biot and Poisson of its validity. Their doubts about his physics were reinforced by parallel doubts about his non-rigorous treatment of trigonometrical series, but in both instances his instincts proved correct. Refusing to be discouraged by the objections, Fourier developed his treatment of the heat conduction problem into one of the classical triumphs of physics, and incidentally developed his use of trigonometrical series in the solution of his differential equations of conduction. All 'that is well brought out by Dr Herivel, who has deliberately concentrated on Fourier as a physicist and a man, on the grounds that Fourier the mathematician has been well covered. But I would have been grateful had some of Fourier's mathematics been included in the same volume because although, even if we agree with Dr Herivel that "It would be unrealistic to strike a balance between Fourier the man and Fourier the savant", the interplay of mathematics

and physics in Fourier's achievements must be a phenomenon of great interest. But, even regarding Fourier as a physicist alone, it is hard to understand why there is no reference in the book to Fourier's invention of the method of dimensions, which almost every subsequent physicist has used (Maxwell, for example) and which is a sure criterion of Fourier's insight.

Dr Herivel almost conveys a sense of disappointment that conspicuous though Fourier's civic role was it "can merit no more than a footnote in the history of the period whereas both as a physicist and as a mathematician he was undoubtedly one of the major figures of the nineteenth century and beyond". But what is really remarkable, as in the case of Handel, is that interspersed among the passages of a tempestuous and worldly career, Fourier should have achieved such heights of contemplativ. creation. Men of science who still have to battle with administrators who are reluctant to regard them as equals may point with gratitude to the example of Fourier. And their gratitude may be extended to Dr Herivell for this, within its limits, excellently annotated and documented account of Fourier and his times.

Tissue connection

Connective Tissue: Macromolecular Structure and Evolution. (Molecular Biology—Biochemistry and Biophysics, vol. 19.) By Martin B. Mathews. Pp. xii+318. (Springer: Berlin and New York; Chapman and Hall: London; May 1975.) £15.30.

THIS monograph, the 19th in the series *Molecular Biology—Biochemistry and Biophysics,* is an excellent review of the macromolecular structure and evolution of connective tissue. During recent years the advances in this field have been substantial indeed and this is the first time that an attempt has been made to consider this vast, widely scattered literature in the context of evolution and taxonomy.

The general construction and arrangement of the book are admirable. The first six chapters, amounting to about half the text, consist of a concise survey of the biochemistry of the macromolecular constituents of connective tissue: collagen, elastin, structural glycoproteins and polyanionic proteoglycans. The emphasis lies very much on the description of primary levels of organisaton, although relevant conformational data are mentioned and occasionally described. Each chapter also presents a most comprehensive account of the comparative biochemistry of these macromolecules, leading to considerations of molecular phylogeny. These considerations are,

however, hampered by the rather limited amount of structural information, particularly concerning amino acid sequences, which is now available. The coverage of collagen and glycosaminoglycans is extensive and this makes even more noticeable the somewhat limited space given to the discussion of elastin. This is unfortunate as the structure of that protein must still be regarded as controversial and the reader would have been helped by a more critical appraisal of the literature.

Professor Mathews' own particular interests—changes in cartilage biochemistry with embryonic development, maturation and ageing, and the taxonomic distribution of glycosaminoglycans—are presented in the next three chapters These contain separate sections for individual tissues, among which particular emphasis is given to cartilage, bone and notochord. Apart from their evolutionary significance, they are a mine of information and contain some original, unpublished work from the author's laboratory.

The last chapter is concerned mainly with the molecular properties and interactions of collagen and proteoglycans and because it encompasses so many facets of the subject, it should appeal to readers from many other disciplines.

The style is direct and unpretentious and the author admirably combines erudition and lucidity of exposition. This book will be most welcome to those working in this field.

A. Serafini-Fracassini

Environmental mechanics and thermodynamics

Fluid Mechanics and Thermodynamics of our Environment. By S. Eskinazi. Pp. xv+422. (Academic: New York and London, February 1975.) $26 00; £12.50.

IN comparison with other books on the motion of fluids by the same author, this one is a little disappointing in its production and layout. According to the preface the word 'environment' takes a variety of meanings and it is a word which is certainly made use of far too often in the text; usually, the more precise term 'atmosphere' or 'ocean' would suffice in its stead. The book is aimed at engineering students interested in air-borne and water-borne pollution but, though there is an obvious need for a concise introductory text which covers this field, this presentation leaves one with the impression that it is partly an attempt to jump on the current bandwagon of concern over man's use of the Earth as a waste disposal unit. The diagrams are the worst feature of the book and are sometimes amateurish in style. Their reproduction is usually on so small a scale that details tend to be obscured.

On the good side, the book is a useful introduction to both physical meteorology and oceanography, necessary parts of the curriculum of anyone studying pollution. Usually, these two subjects are treated separately but here the author has brought together their simpler aspects in one unified text and has attempted to present the material in a manner not requiring formal courses in fluid mechanics and thermodynamics as prerequisites On the whole he has succeeded although a good background in physics and mathematics is essential for a full understanding of the content of the book. Nevertheless, in one or two places, the reader is plunged into discussions of turbulent flows without the benefit of earlier treatment of simpler laminar models. Although it can be argued that flows in the atmosphere are rarely laminar, the difficulties of the treatment of the motions of a real atmosphere are often daunting to an undergraduate with no training in hydrodynamics

The book should prove most useful to the experienced scientist or engineer who requires a knowledge of the rudiments of meteorology and oceanography. It may also find some application in courses in geophysics which are not solely confined to a study of the solid Earth.

C. W. Titman

Non-earth science

Planetary Geology. By Nicholas M. Short. Pp. xv+361. (Prentice-Hall: Englewood Cliffs, New Jersey, April 1975.) $17.95.

THE content of this book is both narrower and wider than the title *Planetary Geology* would imply. The only extraterrestrial body to have been visited by man, extensively sampled and studied with a variety of on-site instruments is, of course, the Moon; and so it is hardly surprising that over 50% of the book should be devoted to lunar studies. Making allowances for the general introduction, the summing up and a chapter each on meteorites, the origin of planets and general aspects of the Solar System, only 15% of the book remains for "Mars, Venus, and the planets beyond"—a fair reflection of the present state of knowledge.

On the other hand, the term 'geology' is plainly inadequate, even for the seven chapters which summarise our physico-geological knowledge of the Moon. Dr Short is an employee of NASA and has used the perspective this gives him to write a book which sets the science firmly against the operational and methodological background of lunar exploration. This "inquiry- and problem-oriented" approach gives the book a distinctive flavour which I found a welcome change from the artificial world of the average text. The inclusion of wider contextual details may lead to some cavilling among academic purists, but the effect is surely to enhance rather than detract from the purely scientific story.

In a fast-moving field such as this, rapid dating of material is an obvious and serious problem. This book takes account of work caried out by to July 1974 (a remarkable achievement under present circumstances), which makes it the most up-to-date and comprehensive text on the subject now available. It would be a pity if it were allowed to age, for it forms an excellent foundation upon which to build later results; and I hope that Dr Short will be granted both the facilities and inspiration for frequent updating. Not that he is a stranger to revision. The first draft of this text was used and evaluated by students and then extensively rewritten in the light of the criticism and suggestions received. This is a procedure which many other authors could well adopt with benefit to themselves and advantage to their suffering readers.

Chromosomin re-emerges from limbo

Acidic Proteins of the Nucleus. (Cell Biology: A Series of Monographs.) Edited by Ivan L. Cameron and James R. Jeter. (Academic: New York and London, December 1974.) $28.50; £13.70.

CHROMOSOMIN was described by Edgar and Ellen Stedman about 35 years ago as one of the three major components of chromosomes, the other two being nucleic acids and histones. They postulated that it could have a structural role in the chromosome whereas the histones were gene regulators. Partly because of this speculation and partly because chromosomin proved very refractory to handle, it disappeared into the limbo of half-forgotten things for a quarter of a century (during which time the histones were studied intensively) but re-emerged about 10 years ago, renamed the non-histone or acidic chromosomal proteins, as a result of experiments which suggested that they, and not histones, might contain regulatory elements.

These proteins are complex. Upwards of 50 individual peptides (not all of which are strictly acidic) can be demonstrated and many, perhaps most, are probably not involved in regulation. Like a gold strike, this area is, therefore, full of promise, challenge and excitement; but for every worthwhile discovery, there are many disappointments. Monographs on the subject, for this reason, have been slow to appear and this is one of the first to be devoted entirely to the acidic proteins of the nucleus. It is, therefore, of special timeliness and interest.

It has 10 contributions. Vincent Allfrey first discusses control in prokaryotic and eukaryotic systems, drawing analogies between them; he also outlines preliminary experiments on the isolation of specific DNA-binding proteins. Gordhan Patel then presents a detailed review of methods for the isolation and fractionation of acidic proteins, which is followed by an account by LeSturgeon and Wray of their work with phenol-soluble acidic proteins. The fourth chapter, by Lewis Kleinsmith, discusses modification by phosphorylation and the possible role of this in modulating nuclear function. Chapters 5 by Bruce McGunn and 6 by LeSturgeon, Totten and Forer are concerned mainly with the nucleoproteins of Physarum polycephalum. Chapter 7, by Berendes and Helmsing deals with the non-histone proteins of Dipteran polytene nuclei and is of particular interest since it brings together some biochemical findings and the morphological evidence about gene activity. The chapter, by the editors themselves reviews changes which have been reported in acidic proteins during cell growth. Tom Spelsberg devotes a chapter to a consideration of the role of nuclear acidic proteins in binding steroid hormones and, finally, Stewart Gilmour reviews the evidence that acidic proteins are involved in gene regulation in eukaryotes and discusses some of the models which have been proposed.

It is inevitable that any contemporary account of this field should be diffuse but gene regulation in eukaryotes is one of the greatest remaining challenges to the biologist and the acidic proteins of the cell nucleus are clearly implicated in it. The editors (Ivan Cameron and James Jeter) have managed to obtain contributions from several of the most experienced people in the field and the volume provides a reasonably comprehensive, up-to-date summary. It can, therefore, be recommended to laboratories in which work of this kind is being undertaken or contemplated.   **John Paul**

announcements

Awards

The 1975 **Hewlett-Packard-Europhysics Prize** for solid state physics has been awarded to **V. S. Bagaev, L. V. Keldysh, J. E. Pokrovsky** and **M. Voos.**

H. S. Schwartz has been awarded the **Johananoff International Fellowship** for advanced biomedical studies.

The Pontifical Academy of Sciences has awarded the **Pius XI Gold Medal** to **S. W. Hawkins** for his work on membranes.

Miscellaneous

Lunar Research. NASA is continuing to encourage and support research on all aspects of lunar science. Scientists with new ideas, techniques and special capabilities are encouraged to participate. NASA's lunar programmes include: experimental and theoretical research on lunar materials, lunar data analysis and synthesis, and supporting research and technology.

Further information from Dr E. A. Flinn, Director, Lunar Programs Office, Code SM, NASA, Washington, DC 20546.

International meetings

September 2–6, **Function of living plant collections in conservation,** Kew (Christine Brighton, Royal Botanic Gardens, Kew, Richmond, Surrey, UK).

September 9–11, **Applications and economics of remote sensing systems,** Silsoe, Bedfordshire (Mr T. S. Bell, ADAS, MAFF, Block B, Government Building, Brooklands Avenue, Cambridge, CB2 2DR, UK).

October 22, **Applications of analytical techniques to industrial effluents,** Colchester (Analytical Division, Chemical Society, 9 Savile Row, London W1X 1AF, UK).

October 26–November 1, **Alcoholism and drug dependence,** Sao Paulo, Brazil (International Council on Alcohol and Addictions, Box 140, 1001, Lausanne, Switzerland).

See how they run

THE chart in the centre of this week's issue of *Nature* is not, you will be disappointed to hear, the result of furtive investigations by the staff under trying conditions. None of our sub-editors was dispatched with binoculars to phone-boxes in Whitehall to catch glimpses of faceless men doing a quick sprint out of their ministry to black government cars waiting to take them to assignments in other ministries. No laser beams were trained on the curtained windows behind which whispered conferences were being held. All the information is in the public domain. The research was no more exciting than several days of delving through annual reports, some telephone calls and a few fivepenny bus rides to pick up official documents. And in a way the product of the research isn't exciting either. Old hands on the London scene will look at the chart and say that there is nothing on it they didn't know about already—and that there is enough inter- and intra-departmental committee structure in Whitehall to convert our simple little picture into a veritable cat's cradle of inter-connections.

Indeed the old hands are right. The proliferation of working parties, study groups, panels and sub-committees is unending and we could have easily devoted six months of our time to trying to put together a coherent picture of this fine detail. But how many are there who can even be called old hands? The majority of British scientists will probably find that even our elementary chart reveals quite a lot they hadn't realised before. Who runs Kew? Harwell? What ministry pays for space research? How much is spent on defence? How are we represented in Europe? At UNESCO?

It is, of course, almost in the very nature of a central bureaucracy almost exclusively concentrated in one city,

that those on the outside will take a Kafka-esque view of it. Contact with the outside world tends to be through the trusted advisers or council members; criticism from the press is greeted with stony silence, communications from outside tend to leave the individual feeling impotent. And yet the castle is fairly easily penetrable to those who take along a map, and most of its influential inhabitants have been scientists themselves. Moreover, because of the perennial problem that central bureaucracy has in accurately judging the feelings of those at the grass roots, anyone with the ability to communicate with the right bureaucrat at the right time can have a disproportionate influence—for good or bad.

Hardly anyone on this chart could be said to have got there by anything resembling a democratic process, and by the same token hardly anyone could be removed by anything resembling a democratic process. We are not about to advocate annual elections to councils and committees; what we do urge, however, is a much wider understanding of the rudiments of science policy-making, and maybe this chart will help.

Only one committee which we wished to list has had to remain ex-directory. The Defence Scientific Advisory Committee, we have been told (not by its chairman), prefers to remain anonymous, partly for fear of student action against its members. In view of the immense expenditure on defence research and the almost complete ignorance in the academic and student world of defence matters, anonymity can only serve to create further alienation.

● Extra copies of the chart are available. See page iii for details.

Earthquakes cause cancer: official probe shock

THE annual British Association meeting is upon us again, and so is the silly season for newspapers. Here are a few simplistic headlines science could well do without in the coming week.

Coffee-drinking causes cancer, scientist says

British astronomy leads the world

Concorde's effects harmless—government scientist

Cancer drug hopes

Sex at 80 keeps you fit—scientist

Earthquakes threaten North Sea oil

Tea-drinking causes cancer

Concorde 'will end world as we know it'—environmentalist

British astronomy in doldrums

New X-ray star no hazard to health

Scientists create life in laboratory

Can readers of *Nature* think of any others?

Weather watchers

As fewer and fewer agricultural regions have supplied increasing amounts of the food consumed by the countries where population growth is greatest, there has been growing concern about how the climate of the next few decades may affect world agricultural productivity. Henry Lansford, of the National Center for Atmospheric Research, Boulder, Colorado, reports.

ROBERTS

SOME atmospheric scientists, projecting trends of the past 30 years or so, foresee steadily decreasing temperatures accompanied by greater climatic variability—more droughts, floods, unseasonable cold spells, and other extreme events that certainly would reduce agricultural productivity, at least in the regions where they occurred. Professor Hubert Lamb, of the University of East Anglia, and Professor Hermann Flohn, of the University of Bonn have warned that this sort of climatic change seems to be in progress, together with Dr Reid Bryson, of the University of Wisconsin, and Dr Valter Orr Roberts, who formerly headed the National Center for Atmospheric Research (NCAR) and is now with the Aspen Institute for Humanistic Studies.

Other climatologists maintain that the climatic trend of recent years does not necessarily represent a long term change, but should be viewed as a fluctuation that may halt or reverse itself at any time. These climatological conservatives maintain that our understanding of the mechanisms of climatic change is so rudimentary that no sound basis exists for assuming that a downward trend in temperature will continue in the future. Among these conservatives are Dr B. J. Mason, who heads the British Meteorological Office, and people like Dr J. Murray Mitchell of the National Oceanic and Atmospheric Administration (NOAA), and Professor Helmut Landsberg, of the University of Maryland.

But even these conservatives are worried about the impact of climatic variability on world food supplies. The potential consequences of droughts and other climatic anomalies are greater than ever before because of present low levels of grain reserves, increasing use of semi-arid and other marginal lands for farming, and expectations of continuing high yields

from the new "Green Revolution" crops that are highly responsive to generous supplies of water and fertiliser.

During the past year and a half, atmospheric and agricultural scientists, as well as specialists in fields such as economics, international development, law and political science, have gathered for a succession of international conferences designed to identify some of the major problems of climate–food–social interactions and to try to develop new research strategies for attacking those problems effectively. The meetings have included:
● A conference on "Weather and Climate Change, Food Production and Interstate Conflict" held in New York City by the Rockefeller Foundation in January 1974
● A workshop on "The Impact on Man of Climate Change" held at the University of Bonn by the International Federation of Institutes for Advanced Study (IFIAS) in May 1974
● A conference on "World Food Supply in Changing Climate" held at Sterling Forest, New York, in December 1974 under the joint sponsorship of the American Society of Agronomy and the Aspen Institute for Humanistic Studies
● A pair of workshops, one on the policy implications of food and climate interactions and the other on the design of a study of the social, political, economic and ethical impacts of drought, held in West Berlin by IFIAS and the Aspen Institute in February 1975
● A conference on "Climate Change, Food Production and Interstate Conflict" held by the Rockefeller Foundation at Bellagio, Italy, in June 1975.

Although the participants at these meetings disagreed about a great many things, there seems to be fairly general agreement that the vagaries of climate do indeed represent a serious threat to world food supplies in

these precarious times of rapidly growing demand for food, low world grain reserves and increasing dependence of many heavily populated nations on a few regions of high agricultural productivity, usually halfway around the world from the regions of high consumption, for their food supplies.

The conclusions, recommendations, and resolutions that have come out of these conferences have ranged from the strident to the cautious. The IFIAS statement that emerged from the Bonn meeting, for example, said that:

"The nature of climatic change is such that even the most optimistic experts assign a substantial probability of major crop failures within a decade. If national and international policies do not take such failures into account, they may result in mass deaths by starvation and perhaps in anarchy and violence that could exact a still more terrible toll."

With more reserve and less rhetoric, the participants in the recent Bellagio Conference came to much the same conclusion. They agreed that:

". . . there is some cause to believe —although it is far from certain— that climatic variability in the remaining years of this century may be even greater than during the 1940–70 period", and concluded that "greater climatic variability than that of the last two decades could cause major crop failures quite beyond the current capability of agricultural science and technology to control or mitigate."

Although these climate–food meetings have not resulted in any solid consensus among atmospheric and agricultural scientists about just what the climate is going to do and how it will affect food supplies, much less about what international policies and mechanisms will be needed to cope effectively with conflicts that may develop among nations as a result, a few common conclusions seem to be
KAMRANY

Walter Roberts, Nake Kamrany and Viktor Korda in Berlin.

emerging from all the discussion and debate.

As far as the climate itself is concerned, there is fairly general agreement on two points:

● The climate of the first half of the twentieth century was considerably warmer than the average of the past 1,000 years, which suggests the possibility that cooler weather can be expected to follow.

● The average global temperature, which gradually increased during the first half of the century, has been decreasing during the past quarter of a century, at least at latitudes above 55 °N. This cooling was between 2 and 3 °C for some northern locations such as Iceland. Lamb points out, however, that the length of the growing season in England increased by two to three weeks during the first half of the century and has dropped back by about two weeks since 1945.

There is considerable disagreement about whether or not the cooling trend is likely to continue. One school of opinion, which includes Bryson, Flohn, Lamb and Roberts, sees a strong probability that the downturn in temperature that has occurred since 1950 will continue for at least another two or three decades. Other climatologists such as Mitchell and Landsberg maintain that the causes and mechanisms of climatic change are not understood well enough for anyone to make such a prediction with any assurance of success.

Although a number of the scientists who anticipate a global downturn in temperature participated in the Bellagio Conference, the group as a whole took a cautious view of the question of global cooling. The conference participants concluded that:

"It is not certain that the decline in Northern Hemisphere temperature will continue; it may halt or reverse itself. Even if the global average temperature were to decrease steadily over the next 20 years, it is unlikely that it would drop as much as one degree Celsius."

But they went on to point out that: "temperature change *per se* is not the most serious climatic threat to food production. The possibility of increased climatic variability, particularly in distribution of precipitation, is of greater concern."

The question of variability is another subject of controversy. Bryson and others believe that the cooling trend in the high latitudes of the Northern Hemisphere has changed large scale atmospheric circulation patterns by increasing the temperature contrast between tropical and polar regions. They believe that this has produced increased climatic variability—a higher incidence of droughts, floods, unseasonable cold weather and other extreme events that have characterised recent bad crop years such as 1972 and 1974.

Whether or not the climate is growing more variable, even the climatological conservatives such as Landsberg agree that climatic variability represents a continuing threat to uniform crop yields in many agricultural regions. Although the Bellagio Conference paticipants did not conclude that the climate is becoming increasingly variable, they agreed that "climatic variability—region by region and from year to year in particular regions—is and will continue to be large."

In discussing problems of climate and food, atmospheric scientists have frequently referred to the climate of the first half of this century as "benign," implying, perhaps unintentionally, that it provided the best possible growing conditions for crops everywhere. But at Bellagio the agricultural scientists pointed out that this is not so. The frequency of droughts in the Soviet Union increased sharply during that period. In parts of the midwestern United States, summer temperatures have often been too hot for

optimum yields from some crops that are grown there. A general cooling trend, while shortening the growing season in some northern regions, might result in a compensating increase in crop yields in regions further south. Professor Lamb has suggested that, in discussions of climate change, it would be wise to avoid using the words "benign" and "normal," as they both imply value judgments that are subject to considerable argument.

After listing some of the impacts that a cooling trend might have on agriculture—changes in distribution of precipitation, shorter growing seasons in high latitudes, and cooler growing temperatures in some regions—the Bellagio participants admitted that:

"Some effects of such climatic changes would be beneficial to agriculture and others would be detrimental, but the net effect, for the whole world or for any particular region, is not known."

To remedy this lack of knowledge of the agricultural impact of future climatic developments, it was recommended that a set of 'scenarios' specifying plausible future climatic sequences be developed and that the impact of each possible climatic future on agricultural production, the world food situation and international relations be assessed as precisely and quantitatively as possible.

Regardless of the changing casts of characters, different approaches, and specific conclusions that have characterised the recent climate–food meetings, one grim theme emerges from all of them. Whether or not any long term change to cooler temperatures or increasing climatic variability is in progress, there is a high probability that major regional and world food emergencies will occur during the next decade or two as a result of serious reductions in crop yields or major crop failures caused by climatic anomalies.

A number of possible research and policy strategies have emerged that could contribute to effective national and international responses to such emergencies.

It seems that the atmospheric scientists should accelerate their efforts to determine whether or not it is possible to predict climatic conditions a season or more in advance, as well as examining ways in which existing climatic information can be made more useful in coping with agricultural problems. An improved understanding of the workings and interactions of the five physical elements of the total climatic system—atmosphere, hydrosphere, cryosphere, lithosphere and biosphere—is badly needed. Both theoretical and empirical approaches to problems of climate change should be pursued. Agricultural scientists should

assess the potential impact of various climatic anomalies on various crops, particularly the new high yield varieties, and should consider plant breeding strategies, as well as techniques of crop, soil and water management, that can reduce the impact of climatic stresses on agricultural productivity. Special attention should be given to the role of soils in mitigating the impacts of drought, and to the improvement of dryland-farming practices, as more and more semi-arid lands are brought under cultivation.

Application of new and existing agricultural technology to improvement of crop yields in regions that supply food for their own consumption seems to be at least as valuable in the long run as striving to continue to increase yields in exporting regions such as the United States and Canada.

Policy makers must assess national and international policies on agriculture and food in the light of the probability that major food shortages, affecting large regions if not the entire world, can be expected to result from climatic stresses over the next few decades. Although years of bad climate such as 1972 may not necessarily reduce total world food production, they clearly have the potential for disrupting world food trade patterns and raising prices to the extent that people in some regions will go hungry not because there is no food, but because it costs so much that they cannot afford to eat properly. The potential is great for conflict among nations as well as for human suffering in the regions that are affected directly by climatic anomalies.

There does not seem to be any miraculous 'technological fix' waiting in the wings to save the day. Agricultural technology probably can be applied to achieve additional increases of 100% or more in crop yields in some regions, primarily those where food consumption is highest, but such increases are not likely in most of the present major food-producing regions.

Climate forecasting will be useful only if workable alternatives are available so that the farmer can respond to the foreknowledge that a drought or a short growing season is imminent. Weather-modification technology may have the potential for improving crop yields in some regions under some conditions, but it has not been demonstrated that cloud seeding can do much, if anything, to remedy major climatic anomalies such as large scale droughts.

Science and technology certainly have appreciable contributions to make to solutions to our growing climate–food–society problems. But the evidence that has emerged from the recent conferences indicates clearly that the responsibility for establishing a framework within which scientific and technological knowledge can be applied effectively to solving the problems rests as much with the policy makers as it does with the plant breeders, the climatologists and the cloud seeders. □

Failing to take the point

P. A. MOHR

A small experiment now taking place in Britain seems to be having results that warrant a little more attention from our drought-stricken sociological experts. I refer to the resistance of the Anglo-Saxon mind to metrication, a resistance which, whether inwardly sullen or sudden, is outwardly passive so long as our feet are not pushed to the wall. For the inevitably vociferous, the issue is seen in the emotive terms of an unimpeachable heritage threatened from without, and the City Editor of the *Sunday Telegraph* euphorically praises "the glorious indifference of the British people [to metrication]", himself excepted, presumably.

Because, here in the USA, metric measures are now unofficially and surreptitiously appearing in all sorts of odd corners, from the food and building industries to sports events, not to mention our completely ravished science, we are not indifferent to watching the unenthusiastic attitude of the British to losing their 2,000-year-old Roman measures. Admittedly, the decimal Roman measures became a little unmetrified after the UDI of Hengist and Horsa in a petrified British culture, but Anglo-Saxon we have staunchly remained for the 1,500 years since.

Are we now to throw over that measured tradition? Galileo learned, to his cost, the strength of tradition when, in the naive cause of truth, he tried fervently to upend it overnight. Pope Gregory's reform of the calendar was regarded by the English as even more of an occasion for cheating than the recent decimalisation of £.s.d. Tradition! Should we resist and drop metrication, except for odd corners of science that can easily be swept clean again; should we denigrate, admire or diplomatically ignore the resolution of South Africa in enforcing it by law in one fell swoop; or do we characteristically muddle on with a facade of creeping metrication that is merely a measure of creeping paralysis of will?

Certainly, the British Metrication Board, in urging the people of Britain to think metric for reasons of logic and utility alone, has completely misjudged the Anglo-Saxon mind. Those who oppose metrication see the ultimate argument quite clearly: metrication is alienation. Logic and possible future utility make no impact on the gloriously indifferent.

Can the Imperialists . . . (no, that won't do) . . . Can the opponents of metrication discover that the non–Anglo-Saxon world, by discarding multifarious old measuring systems, has impaired its heritage? It might make for an interesting discussion; but surely many would prefer to regard tradition as something not merely inherited, but to be fashioned for those who will inherit it, hopefully improved, from the living. Otherwise we would still be sticking to the measuring system of Boadicea, without the benefit of those delightfully duodecimal Roman "uncias" of length and weight. (British readers, now perhaps only able to afford their tobacco by the gram, may be interested to know that in the USA "one pound" of pipe tobacco has shrunk to 12 ounces, in precise conformity with the original definition, but not, alas, out of any respect for tradition.)

Need we go metric? Cannot measuring systems of the world co-exist as do languages? Is there a good case for Britain and the USA to drop, or stop, the whole costly and unwanted experiment and re-trench? As far as I am aware, the token metrication of Britain has barely entered everyday thought, estimation and judgment. One does not see Mr. Wilson, one of Britain's better known pragmatists, contemplating his bowl in centimetres and °C.

If metrication, an abomination of a word redolent of graduation in dietetics, really is desirable for us Anglo-Saxons, then it will not stem from the will of the people in their present mood. Either those in authority must coerce, or those favouring the change must be seen to step aside from the appointed bureaucrats of Whitehall and Washington, and start cutting ice, or, for those who disdain the methods of Sam Adams and the founders of the American Revolution, advertise the fact in the manner of the huge, state sign on the main Boston–Montreal highway: "Barre, 100 kilometers".

Maybe we can continue along the broad way, rather than take the narrow road of decision. But I fear that, in nautical parlance, we're tying ourselves in unfathomable knots.

international news

ALTHOUGH a crash research and development programme on solar energy has long been advocated by a small band of scientists and environmentalists, who see the Sun as a bountiful source of clean energy—and also by some Congressmen who see it as a useful source of votes—until recently the federal government has not seemed to share the enthusiasm. But there are now signs that the Energy Research and Development Administration (ERDA) has recast the priority of the solar energy programme it inherited from other government agencies earlier this year. Officials of ERDA are now publicly predicting that solar power could provide a very large contribution to energy needs in the United States in the twenty-first century.

The latest piece of evidence to that effect is contained in a report, published by ERDA earlier this month, in which the agency outlines an ambitious, 10-year research and development effort designed to reduce the costs of solar technologies and, it is hoped, to pave the way for their commercial introduction. ERDA states in the report that if the effort is successful, energy derived from the Sun could supply as much as 25% of the country's energy requirements by the year 2020.

Although it should be noted that the report is conspicuously devoid of cost figures—a factor which makes it difficult to compare ERDA's new proposals with previous government plans—solar enthusiasts are generally pleased that ERDA is slowly moving closer to their own predictions of what is possible (although it still has a long way to go). The new report, moreover, follows hard on the heels of the publication by

ERDA looks to the Sun

by Colin Norman, Washington

ERDA of an overall plan for energy research and development in which solar power is raised to the same level of priority as the breeder reactor and the thermonuclear power programme.

In spite of the generally optimistic tone of the report, however, ERDA is quick to caution that the potential contribution from the Sun will only be realised "if the costs of collecting and utilising solar energy can be reduced substantially"—in some cases by a factor of 100 or more.

The general approach outlined in the report is to press ahead as swiftly as practicable with demonstration projects, and to get early industrial participation in the effort to help pave the way to commercial introduction of the technology. A focal point for the programme will be a new solar energy research institute, a large laboratory which ERDA is planning to establish early next year which is expected to have a budget of about $50 million by 1980

The research programme is divided into three chief parts—direct thermal applications, such as solar heating and cooling; conversion of solar energy to electricity; and the development of fuels from plants.

Efforts in the first category are probably the most advanced. According to

a directive from Congress, ERDA plans to install up to 4,000 solar heating units in private homes and public buildings as part of a demonstration programme. (There are, however, unconfirmed rumours in ERDA and in Congress that the Office of Management and Budget—a powerful White House office similar in some respects to the British Treasury—will allow ERDA to install only 350 units.) The emphasis will shift to development of combined heating and cooling units in the late 1970s.

As for the conversion of solar energy to electricity, technologies to use wind power are closest to the demonstration phase. The National Aeronautics and Space Administration Agency is now building a small generating plant, and ERDA hopes to begin work next year on a larger unit. The commercial use of solar energy to generate electricity through photovoltaic cells will require some research breakthroughs to reduce the costs by a factor of at least 100, ERDA reckons, but demonstration plants with a capacity of between 1 and 5 MW are being planned for the mid-1980s. Similar sized plants for generating electricity from solar-produced steam are also planned for the mid-1980s, and in that case ERDA reckons that a cost reduction of between 50 and 70% will be required. The least advanced solar-electric concept at present is the idea of using ocean thermal gradients.

Finally, ERDA hopes to initiate a number of studies with industry in the late 1970s designed to explore the large scale use of plants and animal wastes to produce fuels such as alcohol and methane. □

NEW legislation on the conservation and use of mineral deposits was recently passed by the Supreme Soviet of the USSR and is to come into force on January 1, 1976.

The measures proposed do not, at first glance, seem particularly spectacular, and are concerned mainly with rational planning to reduce wastage, the introduction of new and more effective methods of ore dressing and petroleum processing, and improved methods of quality control, including the use of radioisotopes in both ferrous and non-ferrous metallurgy. The need for further prospecting for new beds and deposits and the improvement of prospecting methods is urged; this,

Legislation on use of Soviet minerals

from Vera Rich

incidentally, is regularly cited as a justification for the expenditure on the Soviet space programme, since, officially, Kosmos reconnaissance satellites are engaged, *inter alia*, in surveying mineral resources.

It is not, however, the measures themselves which attract attention so much as the urgency with which they are expressed. The Supreme Soviet "resolved: to consider as one of the

most important state problems the ensuring of rational, complex and economic use of mineral wealth and the intensification of its conservation within the aims of the further development of the socialist economy". In his address to the convocation, N. A. Tikhovov, Deputy Chairman of the Council of Ministers of the USSR, stated that in the past four years the Soviet national income has risen by 26%, the output of industry by more than 1.3 times, and real earnings by 19%. In order to continue thus to construct "the material and technical bases of a communist society", the rational use of mineral resources must be treated as a matter of great importance. Soviet

economic data are, traditionally, always presented in terms of percentages, and it is frequently difficult to refer them back to a base date, so as to calculate their meaning in real terms. Such figures for production as are readily available, however, give for the first half of 1975 240 million tons of oil, 141,000 million cubic metres of gas, 348 million tons of coal, 69:8 million tons of steel and 44 million tons o⁴ mineral fertilisers. Against this background of rapid expansion, the new laws seem to show a growing awareness that the mineral resources of the Soviet Union although vast, are still finite.

A *Pravda* editorial, dealing with the laws, stated: "Science is faced with great problems. Scientists are charged with creating new methods, techniques and technology which will allow mineral resources to be extracted without loss, with introducing them more fully into the national economy, and with ensuring the safety of mining operations". The Academy of Sciences of the USSR, the Academies of the Union Republics, the State Committee on Science and Technology and the various scientific research organisations as well as the Ministries concerned, will all be involved in implementing the new laws.

Meanwhile, surveying for new deposits continues. ☐

THE Baltic countries' scientific cooperation continues. Under the auspices of the Helsinki Convention for the prevention of pollution in the Baltic Sea, a meeting was recently held in the Swedish archipelago at which Swedish and Russian biologists studied each other's methods of intercalibration of measurements in marine biological experiments. The meeting was the second in a series (the first, last year, concentrated on chemical methods of measurement) which will continue next year with the additional participation of the other signatories of the Convention: Finland, Poland, the German Democratic Republic, the Federal Republic of Germany and Denmark.

● A new input into the Swedish nuclear energy debate promises to heat the simmering controversy yet again. This time the fuel is the publicity being given to a report prepared at Cornell University, New York; by Professor Robert O. Pohl, who challenges the traditional wisdom that nuclear energy causes fewer health problems than result from the same amount of electricity produced from coal. The report evidently asserts that the effects of radioactive waste from uranium mines should be included in calculations of nuclear health risks. On this basis, nuclear energy is said to be between 100 and 10,000 times as dangerous as has previously been thought.

Professor Pohl is reported to be critical of calculations done by the US Environmental Protection Agency (EPA) in a 1973 report *Environmental Analysis of the Uranium Fuel Cycle*. According to the EPA's estimates, the slag heap from a mine extracting uranium to produce about 1,400 million MWh of electricity would cause 60 cases of radiation damage—mainly lung cancer—after 100 years; 95% of these cases, it was estimated, would lead to death. So an annual rate of production of 10 million MWh would result in almost 0.4 deaths after 100 years. Professor Pohl points out that the slag at the mine contains thorium-230, which —by way of radium-226—decays to (radioactive) radon-222. During the decay of the thorium (and only 0.091% will have disappeared after 100 years) the slag will emit radon at a rate which Pohl estimates could result in a total of 396 deaths—presumably over more than 100,000 years. These calculations put nuclear energy in the same order of risk to health as coal-fired energy.

Scandinavian diary

from Wendy Barnaby, Stockholm

The report also questions the platitude that, although nuclear waste is dangerous, its volume is small enough to be controlled. On the contrary, if the slag is reckoned as part of the waste the disposal problem becomes enormous. For Sweden especially the difficulties would be immense: a ton of Swedish shale contains only 300 grams of uranium. The uranium required to produce 10 million MWh leaves 1 million tons of shale behind. Sweden's present annual electricity production is about 85 million MWh. The percentage of this provided by nuclear energy is negligible at the moment, but it is expected to rise to 12% by 1985.

Professor Pohl reportedly admits that thorium-230 and radon-222 would be formed wherever uranium occurs naturally, irrespective of whether it were mined or not. But he maintains that radon can escape more easily from the broken ground of a mine than from an undisturbed terrain. The effect of his views on the Swedish debate has yet to be seen; but it will probably provide another example of the fact that what may burst with a bang over the heads of the antinuclear lobby is, to the ears of the pronuclear government, merely a whimper.

● Experiments carried out by the Swedish Water and Air Pollution Laboratory show that the use of commercial preparations labelled 'non-toxic' and sold to disperse oil leaks in water has a far worse effect on marine life than the oil itself. The results indicate that if a dispersant is used to clean up oil spills, the effect on most marine life will be more severe and last for a longer time than if no dispersant is used.

The experiments, reported in the latest edition of the Royal Swedish Academy of Sciences magazine *Ambio*, were carried out on two dispersants commonly used throughout Europe: BP 1100X (British Petroleum) and Finasol OSR2 (Fina SA). According to the Swedish researchers, normal toxicity experiments are done with adult organisms under abnormal external conditions and for a short length of time On the grounds that such testing should be concentrated on the most vulnerable part of the organisms' life cycle, the Swedes used larvae instead. The type of larvae they worked with (Baltic herring, *Clupea harengus membras L.*) occurs naturally in the upper 10 metres of the water column, and is therefore especially susceptible to oil spills

The tests were done in jars containing brackish sea water to which was added Venezuelan crude oil with a density of 0.868 and a total sulphur percentage of 1.9. Some of the jars also had a dispersant mixed in. A control experiment with larvae in sea water only was carried out in parallel.

In the first set of experiments, in which larvae were exposed to different concentrations of water–oil and water–oil–dispersant mixtures, the larvae reacted 50 to 100 times more strongly to a mixture of dispersant and oil than to oil alone. The larvae deteriorated by swimming abnormally, then suffering injuries and finally dying.

In the second test, larvae were exposed to mixtures of different ages (0, 24 and 72 hours). The behaviour of the larvae showed that when oil and water were newly mixed, the resulting toxicity was higher than in older mixtures of oil and water. When a dispersant was added, however, the mixture's toxicity was even higher, and it remained almost unchanged after 24 and 72 hours.

Dynamics of chemical and biological reactions

from Henryk Eisenberg

IN a recent elegant study (Ben Basat and Bloomfield, *J. molec. Biol.,* **95,** 335; 1975) the kinetics of the spontaneous assembly of heads and tails of bacteriophage T4D, to form non-infective tail fibreless particles, were investigated. The authors used inelastic (or rather quasielastic) light scattering to follow an approximately 10% decrease in diffusion coefficients resulting from the attachment of the asymmetric tails to the icosahedral heads of the phage. The reaction was slow enough (the half time was about 500 s at the concentrations used) to be followed by measuring the average diffusion coefficients of the particles as a function of reaction time. The major finding was that the bimolecular rate of the reaction is about 1/500 that predicted by Smoluchovski in 1917 for a diffusion-controlled reaction between two spherical particles; the discrepancy can largely be explained by orientational factors. Careful analysis of the limits of and errors in quasielastic light scattering showed its usefulness as a tool in phage assembly studies, preferably in conjunction with other physical methods and with biological infectivity assays.

Fluctuations in time domain
Some readers may not be familiar with quasielastic light scattering. Note that one may associate with any process a 'noise' deriving from fluctuations around equilibrium states of particles in a system. Until recently it was not possible to determine the frequency spectrum of the fluctuations, nor to follow the evolution of this spectrum in time. From the time-averaged squares of the fluctuations classical elastic light scattering is derived. Fast electronic techniques and coherent monochromatic sources of radiation now make it possible to extract dynamic or kinetic parameters from the time-resolved analysis of the fluctuations.

The analysis is quite general and by no means restricted to the study of the fluctuations of scattered light. Fluctuations of fluorescence (Elson and Magde, *Biopolymers,* **13,** 1; 1974; Magde, Elson and Webb, *Biopolymers,* **13,** 29; 1974) or of electrical conductivity (Feher and Weissman, *Proc. natn. Acad. Sci. U.S.A.,* **70,** 870; 1973) in solutions, and also in nerve fibres, have been successfully examined. All that is required is that a change in the state of the system manifest itself by way of a measurable physical parameter. In technical terms the signal at a given time is compared (correlated) with itself at some previous time. In a subsequent averaging process the 'autocorrelation' function is formed. This is the Fourier transform of the spectrum and can be obtained by a simple mathematical operation. Those of us raised on the intuitive notion of the changing pitch of the whistle of an approaching or departing locomotive will easily recognise the Doppler spectrum—broadening due to the moving or reacting particle. It just so happens that modern technology often favours measurement in the time rather than the frequency domain (see *Photon Correlation and Light Beating Spectroscopy,* edit. by Cummins and Pike; Plenum, 1973; Chu, *Laser Light Scattering;* Academic, 1974; Berne and Pecora, *A. Rev. Phys. Chem.,* **25,** 233; 1974). A very broad range of phenomena has conveniently become accessible, in an experimental range having time constants corresponding to frequencies between 1 and 10^8 Hz.

In the study of the kinetics of macromolecular association and transconformation reaction two cases may be distinguished. The first case, which is also the topic of the Ben Basat and Bloomfield paper, focuses on the situation in which the reaction rate is slow compared to diffusion. If reactants and products have different translational diffusion coefficients, the scattered spectrum or autocorrelation function is that of a polydisperse system and can be resolved to provide concentrations of the various participants in the reaction. If the time of measurement is fast compared to the time of the reaction, the evolution of the latter is a function of time, and therefore the kinetic constants can be evaluated. This is what Ben Basat and Bloomfield have successfully done in the T4D phase head–tail assembly system.

The second case considers a reaction in dynamic equilibrium, in which the reaction rate is greater than, or comparable to, the diffusion rates for the reacting species. In this case theory predicts that the time autocorrelation function measured will be a sum of exponentials, whose decay constants are functions of both diffusion and reaction rates. However attractive this prediction may sound, conflicting and largely unsubstantiated claims have in the past resulted from studies of this kind. Decay curves of the autocorrelation function of reacting species are usually too complex to be resolved in a simple sum of exponentials in a unique, meaningful, way. But more recently Uzgiris and Golibersuch (*Phys. Rev. Lett.,* **32,** 37; 1974) reported a decay term independent of scattering angle in scattered-light intensity fluctuations from haemoglobin solutions. They attribute these fluctuations to the haemoglobin association–dissociation reaction; variations in experimental conditions affect the excess fluctuations in a predictable way.

Variations in method
Other examples exist, not necessarily related to the analysis of scattered light. In their very imaginative study, Feher and Weissman applied a constant voltage across an aqueous solution of an electrolyte, beryllium sulphate, in ionisation and hydration equilibrium. Fluctuations, on a fast time scale, occurred around the equilibria positions, and the reactants carried unequal charge. Therefore strong time-dependent fluctuations were observed in the ionic conductance and it was possible to measure the autocorrelation function of the conductance and derive meaningful kinetic constants for the ionisation process. These were in good agreement with results earlier obtained by the more perturbative temperature jump method. In another pioneering study Elson and his collaborators took advantage of the fact that the fluorescence of a dye, ethidium bromide, is strongly quenched upon binding to DNA. Once more fluctuations of binding (hence of fluorescence) occurred around the equilibrium state of the reaction. If a suitable exciting laser light was now focused on a tiny volume of the reac-

tion mixture, the concentration of fluorescing particles could be studied as a function of time and the autocorrelation function formed. The kinetic constants derived again were in good agreement with relaxation spectroscopy results.

In variety there is spice. New information can be derived from experiments in which external fields are imposed on a fluctuating system at thermal equilibrium. Ware and Flygare used electrophoretic scattering (*J. Coll. Interf. Sci.*, **39**, 670; 1972) in which charge-carrying scattering particles (in random Brownian motion) acquire and additional linear momentum by an applied d.c. electric field. In this situation the spectrum, or the autocorrelation function, can be clearly decomposed into contributions coming from the random, Brownian motion, and from the electrophoretic mobility of the particles. The resolution of the method is thus that, in priniciple, the motion of different particles, moving with different velocities, can be clearly distinguished. Hydrodynamic and sedimentation fields can, in principle, also be applied. In recent applications, Mustacich and Ware (*Phys. Rev. Lett.*, **33**, 617; 1974) reported on the study of protoplasmic streaming by laser light scattering and Josefowicz and Hallet (*Appl. Optics*, **14**, 740; 1975) described a sophisticated electrophoretic light scattering assembly suitable for analysis at low sample concentrations.

Clegg, Elson and Maxfield (*Biopolymers*, **14**, 883; 1975) introduced a new method in which a reaction is perturbed by repetitive application of a small pressure change. Reaction progress is followed by monitoring optical properties such as absorbance, fluorescence or light scattering. Phase-sensitive detection methods are used to enhance the low signal-to-noise ratio resulting from the slight perturbation. Yet the slight perturbation allows the analysis of closely spaced microstates, whereas the conventional perturbation methods, such as temperature-jump, often cause the system to transverse many intermediate conformations in the course of a single observation. This is of particular importance in reactions that involve the folding of biological macromolecules, in processes involving a multitude of partially ordered intermediate conformations.

In conclusion, a number of new tools for the study of reaction rates in chemical and biological reactions are being developed. In these new techniques advantage is taken of the spontaneous fluctuations around equilibrium states in the systems under study and, in other-instances, only minor perturbations are superimposed on these natural fluctuations.   □

Piezoelectric polyvinylidene fluoride

from Paul Calvert

THERE has recently been considerable interest in the development of piezoelectric (producing a voltage when stretched) polymer films. The current champion is polyvinylidene fluoride (PVDF (CH_2–CF_2)$_n$) which has a piezoelectric modulus d_{31} of 1–2×10^{-7} c.g.s.–e.s.u. compared to about 18×10^{-7} for barium titanate. The polymer, having the advantage of being available as a flexible film, is ready for use in microphones and possibly in loudspeakers. The origin of the piezoelectric effect in PVDF is still unknown and the matter is considerably confused by the complicated phase behaviour of this polymer. A pair of papers by Murayama and coworkers (*J. Polymer Sci.* Physics Edition, **13**, 929 and 946; 1975) of the Kureha Chemical Company in Japan, one of the two commercial producers of this polymer, go a long way towards clarifying the question if not to producing answers.

In 1969 Fukada (*Jap. J. appl. Phys.*, **8**, 960) and Kawai (*ibid.*, 975) showed that a piezoelectric effect could be produced in stretched and oriented films of several polymers when they were poled by applying an electric field of 500 kV cm^{-1} across the thickness of the film. When poled most polymers acquire a stable surface charge and are known as electrets. Except for PVDF there is no piezoelectric effect if the polymers are unoriented (Cohen and Edelman, *J. appl. Phys.*, **42**, 3072; 1971). This seems reasonable because the orientation process will tend to produce extended chain conformations of the polymer and in the vinyl polymers this would result in alignment of the permanent dipoles such as that of the –CF_2– group in PVDF. If the electric field caused these to point preferentially in one direction the material could be piezoelectric.

What makes PVDF special is its phase behaviour. There are three crystal forms: I, also known as β, II or α, and III, each of which can be produced by precipitation from a suitable solvent. Cooling from the melt gives form II which converts to form I on stretching. In form I the chains are extended so that the dipoles within one chain are parallel and the chains are packed into an orthorhombic lattice so that the dipoles on individual chains are parallel (Lando *et al.*, *J. Polymer Sci.*, A–1, **4**, 941; 1966) Obviously this form should be piezoelectric if it is properly oriented. Doll and Lando (*J. macromolec Sci. Phys.*, **2**, 205; 1968) showed that copolymerisation of tetra-

fluorethylene (CF_2=CF_2) with the vinylidene fluoride promoted formation of phase I and suggested that the 'head to head' groups (–$CH_2CF_2CF_2CH_2$) normally present at 5–10% in PVDF promote form I. Tadokoro *et al.* (*Macromolecules*, **8**, 158; 1975) go into this in more detail with infrared and Raman spectra and discuss the structures of form II, where the dipoles cancel, and form III which is similar to form I.

Hayakawa and Wada (*Adv. Polymer Sci.*, **11**, 1; 1973) have discussed the possible origins of piezoelectric effects in polymers and distinguish between intrinsic effects due to oriented dipoles and extrinsic effects due to trapped charges. On the face of it the former looks more likely for PVDF where the piezoelectric modulus increases with the content of form I whether produced by stretching or copolymerisation. Since the dipoles in form I are aligned it is simply necessary to assume that the crystals realign in the electric field or that more form I arises during the poling.

One observation that clashes with this is that of a negative piezoelectric modulus d_{33} in the film thickness direction by Burkard and Pfister (*J. appl. Phys.*, **45**, 3360; 1974). Any simple dipole model would predict a positive value; that is the film should get thicker when a field is applied parallel to the original poling field.

Murayama *et al.* report measurements on the decay of surface charge after poling. PVDF electrets have a charge of the same polarity as the field (homocharge) which is probably due to charges injected from the electrodes. This decays over a few hours to leave a charge of opposite sign (anomalous heterocharge) which is stable, even above the poling temperature. This anomalous heterocharge is correlated with, but not the origin of, the piezoelectric effect. They also observe that if a polyester film is placed between the positive electrode and the PVDF during poling the piezoelectric modulus and heterocharge are much reduced; between the negative electrode and the film it has little effect. No evidence is found for the production of more form I on poling and they argue that reorientation of existing crystals is very unlikely. Thus they conclude from their observations that the piezoelectric effect cannot be due to permanent dipoles but must be caused by the local migration and trapping of charges in the form I crystals. This process is somehow associated with charge injection from the positive electrode. The matter cannot really be considered settled until more is known about the nature of the induced dipoles and why form I in PVDF is particularly suitable By then there will probably be a new champion polymer.   □

Deuteron–gamma angular correlations

from P. E. Hodgson

WHEN deuterons are inelastically scattered by nuclei they leave the target nucleus in an excited state, which usually decays by gamma emission. The angular correlation between the inelastically scattered deuteron and the subsequent de-excitation gamma ray can provide important information about the mechanism of the reaction.

An illustration of this has recently been provided by the work of Scheib, Hofmann and Vogler (*Phys. Rev. Lett.*, 34, 1586; 1975) on the inelastic scattering of 10 MeV deuterons by ^{24}Mg. The angular correlation was measured for gamma rays emitted in the reaction plane, and in this case the correlation function is given by

$$W(\varphi_\gamma) = A + B \sin^2(\varphi_\gamma - \varphi_1) + \\ + C \sin^2 2(\varphi_\gamma - \varphi_2)$$

where φ_γ is the angle between the beam direction and the angle of emission of the gamma ray, and A, B, C, φ_1 and φ_2 are constants whose values are obtained by fitting the experimental data. The constants A, B, and C, are related to products of the reaction substate amplitudes, which may be calculated from a detailed theory of the reaction. This makes the correlation function much more sensitive to the details of the reaction than is the differential cross section, which is given by the sum of the absolute squares of all the reaction amplitudes. The sensitivity allows the correlation function to tell us more about the details of the reaction mechanism than we could learn from the differential cross section alone.

This is strikingly shown by the ^{24}Mg results. The figure shows the differential cross section compared with calculations using two different models of the reaction. The upper curves show the results of distorted wave calculations with three different sets of distorting potentials and assuming that the reaction takes place in a single step from the ground state to the 2+ excited state. The lower curves show similar calculations that also take into account the coupling to the 4+ state, so that some of the excited 2+ states are formed by first exciting the 4+ state directly, followed by de-excitation to the 2+ state. All the calculations used the symmetric rotator model including spin-orbit interactions.

When comparing such theories with the experimental data we look for a good fit to the main forward peak, which is given by both theories and all potentials, together with a qualitative agreement with the rest of the cross section. The angle and width of the second peak are given quite well but its magnitude is somewhat underestimated by all calculations, rather more so by the theory including the two-step

process than by the one-step theory. All these fits are acceptable, but do not distinguish between the two reaction mechanisms.

When we examine the deuteron–gamma correlation data the comparison is quite
Differential cross section for the inelastic scattering of 10 MeV deuterons by ^{24}Mg with excitation of the lowest 2+ state compared with distorted wave calculations with three sets of distorting potentials using the one-step theory (upper curves) and the two-step theory (lower curves). V is the depth of the real part of the distorting potential.

different. If the results for the parameter C in the above expression for $W(\varphi_\gamma)$ are compared with the results of the six calculations already mentioned, the greater sensitivity of the correlation function is obvious. The three calculated curves for the one-step theory differ markedly and none fits the data, even qualitatively; however two of the calculations for the two-step theory are in good qualitative agreement with the data, and in particular give the deep minimum found around 55°. These two potentials are quite similar, and correspond to the deuteron potentials known to be physically realistic by calculations based on the nucleon–nucleus potential and using the folding model. The third potential for the two-step theory is physically unrealistic and also fails to give a good fit to the angular correlation data.

It is of course well known from many other studies that two-step processes must be taken into account in a detailed treatment of inelastic scattering, and this is confirmed by the correlation analysis. What is new is the striking way that it definitely excludes the one-step process as a sufficient explanation; this shows that the correlation analysis could be a powerful way of determining the reaction mechanism in cases where it is not already known. □

Tunable alkali halide lasers

from John Walker

TUNABLE lasers, particularly dye lasers, now cover the whole of the visible spectrum, and are currently revolutionising optical spectroscopy. Unfortunately dye lasers do not operate in the near infrared, a region of great importance in molecular spectroscopy, pollution detection and fibre optic communications. Hence the significance of a recent paper by Mollenauer and Olson (*J. appl. Phys.*, 46, 3109; 1975) who have demonstrated tunable laser action in potassium chloride, and have suggested that the wavelength range 0.9 to 3 μm could be covered by suitable choice of alkali halide. These compounds, so important in our understanding of solid state physics and of point defects, have at last found a practical application.

Laser action over the range 2 5 to 2.9 μm was achieved using the $F_A(II)$ centre in lithium-doped potassium chloride pumped by a krypton ion laser at 647.1 nm. An input power of 40 mW was necessary when the KCl crystal was at 77 K, and lasing could be induced at temperatures up to 200 K.

The operation of the laser can be explained as follows. The $F_A(II)$ centre consists of a halide vacancy (an F centre) trapped by an impurity

metal ion—in this case lithium occupying a potassium lattice site. The centre is excited by the pump laser and then relaxes by rearrangement of the chloride ions around the vacancy. A population inversion is thereby achieved between the relaxed excited state and the unrelaxed ground state, which is emptied by further atomic rearrangement into the relaxed ground state. The system is therefore an ideal four-level laser.

Similar arguments apply to the F and the $F_A(I)$ centres, but in their case the excited state relaxation is very small, and there are competing de-excitation processes, making them unsuitable for laser action. However, two other potentially useful defects are the F_2^+ centre (a pair of adjacent halide vacancies), and the $F_B(II)$ centre (similar to the $F_A(II)$, but with two impurity atoms). These centres should enable a total tuning range of 0.9 to 3 μm to be achieved, and Mollenauer and Olson are currently trying to construct an F_2^+ centre laser using KCl.

The combination of simplicity, tunability, low pump power and potential frequency stability makes alkali halide lasers a promising prospect in the near infrared.

HL-A, the major histocompatibility system of man, which has its analogue, *H-2*, in the mouse, and also in many other species, is now known to contain many genes controlling cell surface determinants, immune response differences, some components of the complement system (in man C3 proactivator (Bf), C2 and probably C4) and perhaps other related functions connected in general with cell–cell recognition. The *HL-A* system was first defined by a series of antigenic specificities—identified by serological techniques using peripheral blood lymphocytes—which were assigned to two separate series (LA and FOUR) corresponding to two closely linked loci, now called *A* and *B* respectively, with multiple alleles. Although matching' for transplantation using these antigens, which was the original impetus behind their study, has turned out to be more difficult and complex than was hoped, knowledge of the wide range of important functions controlled by genes in the region has grown from these original serological studies. The earliest data on the recombination fraction between the *A* and *B* loci already indicated that the *HL-A* region probably included very many genes, at least hundreds, if not a few thousand.

The development of the *HL-A* system has been greatly stimulated by a series of international collaborative workshops started by D. B. Amos of Duke University, North Carolina, in 1964. These workshops, which involved exchange of reagents among a large number of participating laboratories and the combined analysis of the resulting data, have each been major turning points in the development of knowledge of all aspects of the *HL-A* system. Thus, the second and third workshops organised by J. J. van Rood of the University of Leiden in 1965 and by R. Ceppellini of the University of Turin in 1967, placed the definition of the first described antigens on a firm footing and established that they all belonged to a single system of closely linked genes. The fourth and fifth, organised respectively by P. Terasaki of the University of California, Los Angeles in 1970, and by J. Dausset of the University of Paris in 1972, established that two linked loci control the main serological specificities and, through a world-wide series of population studies, the universality of this genetic model and the general distribution of the antigens among the various major human population groups.

The aims of the sixth workshop organised by F. Kissmeyer-Nielsen of the University of Aarhus, culminating in the meeting in Aarhus, were the definition of specificities identified by the mixed lymphocyte culture (MLC) test and the improved serological de-

Histocompatibility testing international

from W. F. Bodmer

The 6th International Workshop on Histocompatibility Testing was held in Aarhus, Denmark, on June 29–July 5.

finition of specificities of the more recently described *C* locus, as well as of newer specificities of the *A* and *B* loci. The MLC reaction is measured by the proliferative response when cultured together of lymphocytes from different individuals.

A WHO nomenclature committee, which met immediately after the workshop, recommended that with the increasing number of loci being defined in the region, *HL-A* should be the name given to the whole region, while the individual loci within it will be called *A* (formerly the LA or first locus), *B* (formerly the FOUR or second locus), *C* (formerly AJ or the third locus) and *D* for the locus controlling the determinants identified by MLC typing. The probable order of these four loci is *D,B,C,A*. New loci of the *HL-A* region will be similarly named as they become clearly identified.

MLC typing
Following the discovery by F. Bach (of the University of Wisconsin) and D. B. Amos in 1967 that at least the majority of MLC reactions were controlled by genetic differences in the *HL-A* region, further work by Amos and others established the fact that the determinants of this reaction were controlled by one or more loci that were genetically separable from *A* and *B*, although closely linked to them. Subsequently, a number of laboratories clearly established that it was possible to use MLC reactions to a set of specially chosen lymphocytes to define MLC determinants, namely to do 'MLC typing'. For this the one-way test is used (in which one of the two sources of lymphocytes to be mixed is inactivated, for example by X rays or mitomycin, so it can only act as a stimulus for the other, which is not inactivated) and stimulators are chosen from individuals known to be homozygous for the *HL-A* region, usually on the basis of family studies. Because of the high level of polymorphism for the *HL-A* system, such homozygous typing cells are most readily found amongst the offspring of parents who are related. If a test cell does not show an MLC response to a given homozygous typing cell, then it presumably has the determinant carried by the typing cell. Such reactions to a series of typing

cells can be analysed following the same principles used for the analysis o serological reactions, to establish speci ficities defined by similar reactions t a set of typing cells. For the workshop fifteen collaborating laboratories from the United States and Europe, guidec by E. Thorsby of the University o Oslo, each used the same 62 carefull; chosen representative homozygous typ ing cells to type a panel of up to 10(responders.

The resulting data, which undoubt edly represent the most extensive s far collected on MLC determinants were coded in a standard format b; each of the laboratories and analysec centrally by A. Piazza of the Universit; of Turin, with the help of L. Lamn and F. Jorgensen of the University o Aarhus. There are many statistica problems involved in the assessmen of MLC reactions and in the definitio of positive and negative response: which were clearly revealed by thi combined analysis. The availability o such a large body of data, howevei was a great help in the more or les clear cut definition of a series of eigh determinants of the *HL-A-D* locus which were seen to correspond t various determinants previously define by one or more different laboratories Each *D* locus specificity could be identi fied by a cluster of up to six differen typing cells which, for the most part reacted together when the correspond ing determinant was present on responder cell. Family and populatio data suggested that these six determin ants behaved as if controlled by series of alleles at the *D* locu; although it is clear that, as in the cas of the serologically defined specificitie of the *A*, *B* and *C* loci, new data ma lead to 'splitting' of these MLC de terminants into two or more sut specificities, and indeed to splitting o the *D* locus itself. A particular featur of the *D* locus determinants, whicl was clearly confirmed by the workshop was their tendency to be in strong link age disequilibrium with *B* locus allele: Linkage disequilibrium is the tendenc; for alleles at different loci, usuall closely linked, not to be associated a random in a population. It is in genera the main cause of population associa tions between functions controlled b linked genes, and so is the probabl basis for most of the known HL-A an disease associations which have bee: interpreted as due to linkage disequilit rium between alleles of the *B* locus an alleles at a linked immune respons locus. Thus, it is, for example, th DW2 specificity (formerly LD 7a; which is closely associated with th serologically defined specificity B (formerly HL-A7) and also very sign: ficantly increased in frequency amon patients with multiple sclerosis.

Serology

The serological part of the workshop was based, as before, on an exchange of carefully selected sera among the participating laboratories. Each of the 73 laboratories, including one or more from every continent (except Antarctica) typed up to 250 cells with the same set of 178 sera. The populations of cells included the laboratories' own well-typed panels, some families, some 'exotic' population groups and also, in the United Kingdom as a convenient source of B lymphocytes, lymphoblastoid cell lines and cells from patients with chronic lymphocytic leukaemia (CLL).

The combined analysis of this large body of data, which was organised by Julia Bodmer of Oxford University with the help of Piazza and others, first of all clearly establishes the definition of five specificities of the C locus. Specificities of this locus, whose existence was first suggested by L. Sandberg of the University of Goeteborg and E. Thorsby and their collaborators in 1970 and which was later confirmed by A. Svejgaard, University of Copenhagen, and others, have so far been more difficult to define than those of the better known A and B loci. This is, in large part, because alleles of the C locus tend to be in strong linkage disequilibrium with those of the B locus and so easily confused with them. Eighteen antigens of the A locus and twenty-four of the B locus were recognised by the workshop sera These included better definition of a number of previously suggested specificities, often 'splits' of already defined antigens This splitting of antigens is a common phenomenon in HL-A serology mainly as a result of the existence of cross-reacting families of antigens which are seldom at first separated by the available antisera.

Ia-type specificities

A most important byproduct of the workshop was the simultaneous description by at least nine different laboratories of various approaches to the serological identification of Ia-type specificities. In the mouse the genetic region between the H-2K and H-2D loci (which correspond to HL-A-B and HL-A-A respectively) has been shown to contain, in addition to genes controlling immune response, further genes controlling a new set of serological specificities called Ia for immune associated Unlike the K and D, or HL-A-A, B and C antigens, the Ia antigens have a tissue distribution that is relatively specific, including especially B, but excluding T lymphocytes. Similar antigens were first described in man by van Rood and coworkers using inhibition of the MLC reaction as a screen and then immunofluorescence of

peripheral blood B lymphocytes. Other approaches to the identification of human Ia-type sera include in particular the use of B-derived lymphoblastoid cell lines and CLL cells, as well as partially purified peripheral blood B lymphocytes and immunisation between unrelated individuals identical at the HL-A-A, B and C loci. Ia-type antibodies are quite commonly found in the usual HL-A-A, B and C locus typing sera (which are mostly obtained from multiparous women who make these antibodies as a result of foetal–maternal stimulation) and were shown by W F. Bodmer of the University of Oxford and H. Dick of the Glasgow

Royal Infirmary and their collaborators to be present in just under one-third of the workshop sera. Several reports indicated, as might be expected, close association between Ia-type serological reactions and MLC determinants of the D locus. Clearly, serological Ia typing is much easier than MLC typing and so may become a powerful tool in disease association and other related studies. There is also the definite possibility that Ia specificities will be of greater direct importance for the problem of clinical transplantation than are the specificities of the HL-A-A, B and C loci.

This workshop was as exciting and

Hydrous minerals in meteorites

from David W. Hughes

THE water content of rocks, whether they be terrestrial or meteoritic, can provide an important clue to their place of origin. Meteoritic minerals are nearly always fresh and undecomposed —which contrasts with many of the water-containing products of weathering and erosion which occur in such profusion on Earth. By studying the chemical composition and paragenesis (the groupings of different types of minerals) of meteorites it is found that in the main they must have crystallised from a fiery melt which had an exceptionally low water content in contrast to the wet volcanic terrestrial melts which solidify to form igneous rocks. Only in type 1 and 2 carbonaceous chondrites is water reasonably abundant. These were formed at low temperatures and have not been subsequently heated above 350 °C. They are thought to have compositions very close to that of the primordal dust which coalesced to form the Solar System and they contain many primary volatile components. These meteorites are thought to be parental to other types which are formed by complicated thermal evolution processes and geochemical depletion reactions.

Ashworth and Hutchison in this issue of Nature (page 714) report having found hydrous minerals in the meteorite Nakhla, a diopside–olivine achondrite which fell in Egypt in 1911 and in the meteorite Weston (a chondrite which fell near Weston, Connecticut in 1807). Both are meteoritic types in which water is rare.

The water in Nakhla and Weston is in the form of iddingsite, a mixture of hydrothermal alteration products of olivine ($(Mg, Fe)_2 SiO_4$). The iddingsite is found as red-brown veins along cracks in the olivine. These veins were probably formed by shock deformation, and water present at this time perco-

lated down the cracks and caused mineral alteration.

Ashworth and Hutchison conclude that magmatic water must have been present during the formation of this shocked olivine, and that the meteoritic mineral originated on a body in the Solar System that had a hydrous atmosphere. There is however still the possibility that the meteorites were 'dry' when they left the parent body and that they picked up the water later. The water could also have come from an admixture of some carbonaceous chondritic material in with the meteorite; this however has not been chemically identified. The interaction between solar wind ions and meteoritic minerals causing hydrogen implantation is discounted because lunar breccias, which have been exposed to the solar wind for aeons, are generally anhydrous. That leaves terrestrial weathering as the alternative source of water. Was the hydrous mineral produced by the hydrolysis of primary lawrencite ($FeCl_2$) by water vapour in the terrestrial atmosphere? As Weston contains an order of magnitude more water than Apollo 16 rocks this requires a very high initial content of chlorine. Both Nakhla and Weston were observed falls and were collected soon after hitting the Earth. However as Nininger (Out of the Sky, Dover, 1952) points out, we never see a truly unweathered meteorite, the atmosphere through which they fall being nearly saturated with water—to say nothing of the air in the vicinity of the museum shelf on which they have been sitting for over half a century.

So the mystery remains—did the meteorites come from a wet planet or have they picked up their water later? It would be heartening to think that Earth has not been the only wet place in the life of the Solar System.

stimulating as its predecessors, reflecting the enormous effort devoted by Kissmeyer-Nielsen and his associates to its organisation and showing once again the value of such world-wide collaborative studies. The next workshop will be organised in Oxford in about 2 years' time and will have as its main theme the definition of human Ia specificities, their relation to MLC determinants and their significance for disease association and clinical transplantation. ☐

Reliability of molecular phylogenetic trees

from David R. Thatcher

IN principle a comparison of the primary structure of the same protein from a number of related organisms should provide evolutionary information of high precision. The amino acid sequence of a protein is a translated copy of the sequence of nucleotide bases in the structural gene and therefore is the one phenotypic character that is a direct reflection of the structure of the genome. The comparative morphology of amino acid sequences should therefore permit the deduction of some of the discrete mutational steps which have occurred during the evolution of an organism. Providing no genetic transfer has occurred and the gene has retained the same function throughout its history, a phylogenetic topology derived from amino acid sequence comparisons should represent the true ancestral relationships of the organisms expressing that particular gene. Molecular phylogenetic methods have the potential advantage of being able to distinguish evolutionary relationships where the classical methods of evolutionary biology do not produce a convincing answer, for example where the fossil evidence is controversial or absent or where there is little morphological diversity to compare.

In practice little new phylogenetic information has been derived from the construction of trees based on molecular evolutionary data and the method has received a somewhat hostile reception from other evolutionary biologists (these points are fully discussed in the excellent review of J. Williams in *The Chemistry of Macromolecules: Proteins*; Medical and Technical Publishers, 1974). The most damaging criticism proposed is that data based on a single structural gene cannot possibly reflect the evolution of the whole genome. Nevertheless, trees constructed by comparing sequences of vertebrate cyto-

chromes *c*, haemoglobins and fibrinopeptides are each more or less in agreement with the accepted phylogeny for this group, showing that the method at least works even if its precision is not as great as at first hoped.

The resolution of the sequence method is unquestionably restricted and if future projects are going to be attempted with an eye to solving particular phylogenetic problems, these limitations must be fully defined. These limitations are due to two main factors. First, to what extent is the assumption of parsimony justified at the molecular level? There is no absolute way of knowing the degree to which parallel, back or convergent mutations affect observed amino acid similarities. Second, if one accepts the most parsimonious solution as being the actual evolutionary history of a gene, the numerical problems involved in calculating this solution for even a small number of alternative topologies is formidable.

Peacocke and Boulter (*J. molec. Biol.*, **95**, 513; 1975) have begun to assess the extent to which these technical limitations have affected their conclusions on higher plant evolution. The evolution of a protein was simulated in a computer and the reconstruction of this hypothetical phylogeny was attempted using two different methods. The accuracy of each procedure was then estimated by determining the number of times a branch had to be moved in order to restore the original topology. The two methods employed were the ancestral sequence method of Dayhof (*Atlas of Protein Sequence and Structure*, 1972) and the matrix method of Moore, Goodman and Barnabas (*J. theor. Biol.*, **38**, 423–457; 1973). The ancestral sequence method infers the structure of nodal ancestral sequences as it generates a tree by adding one sequence at a time to the topology. New branches are added with respect to the most parsimonious sequences (real and ancestral) already in the tree. In the matrix method a distance matrix is calculated and an approximate tree is produced by successive pairwise clustering. This tree is then adjusted until hypothetical mutational distances (computed from the tree by comparing the mutational distances of two neighbours with the average mutational distance of all other members of the tree) approach the actual values of the original distance matrix. Applied to the model data the accuracy of the ancestral sequence method became progressively worse as the number of observed substitutions in the data set was increased. In contrast the matrix method, although less accurate than the ancestral sequence method at lower degrees of substitution, improved as the

variation between the sequences increased. Phylogenetic trees were then constructed from model data which varied to the same extent as the real data Boulter's group has accumulated on higher plant cytochrome *c*. The error observed in tree building with the model data and the ancestral sequence method ranged between 2% and 8% whereas the matrix method operated with an error of 9% to 15%. For a rapidly evolving protein like plastocyanin methods were equally successful in predicting the correct topology (error 8% to 12%).

Before molecular phylogenies are considered seriously by systematicists, some attempt must be made to quantify the errors inherent in each method; from the extent to which tree topologies may be influenced by sequencing mistakes to the probability of a given tree being the most parsimonious solution possible. Peacocke and Boulter have shown that an optimal amount of amino acid variation is required for the most accurate topological assignments by the ancestral sequence method. As structural genes have characteristic rates of evolution, which vary greatly from gene to gene, only a limited range of accurate phylogenetic information can be obtained from the study of a single gene.

Convincing evidence is obtainable but only by investigating the best gene for a particular phylogenetic problem and applying the numerical method most suited to the data. ☐

Consequences of hydrothermal circulation

from Peter J. Smith

LAST year, Lister (*Eos*, **55**, 740; 1974) made a strong plea for the testing of the hydrothermal circulation hypothesis using deep sea boreholes near oceanic ridges. His argument was that there is growing evidence that certain observations, notably in the fields of oceanic heat flow and ocean floor mineralisation, can only be explained in terms of the penetration of water to substantial depths (possibly several kilometres) in the new crust forming at ridge crests.

Presumably it is still too soon to expect any results to have emerged from such a proposal. In the meantime, however, indirect support for hydrothermal circulation continues to accumulate. Lee and Von Herzen (*Geophys. Res. Lett.*, **2**, 201; 1975), for example, have now reported 15 new heat flow measurements from the South Atlantic triple junction near 55 °S, 0 °E —the zone in which the boundaries of the African, Antarctic and South

American plates meet. Although the data are few, they show a distinct geographical correlation; on ridge crests flanking axial valleys the heat flow is high, in the depressions of fracture zones and axial valleys it is intermediate to low and on ridge flanks it is low. At one extreme, four values higher than 4.0 μcalorie $cm^{-2} s^{-1}$ were observed on the crests of three ridge segments, whereas at the other, a value of 0.4 μcalorie $cm^{-2} s^{-1}$ was found in a depression of an axial valley near its intersection with an adjacent fracture zone.

The problem with these and previous similar results from less complex areas is that they conflict with the conditions of steady state heat conduction, by which heat flow should be higher through depressions and valleys than through ridges. Variations in the thermal conductivity of the sediments in which the heat flow was measured would be one possible way of reconciling observation with conduction theory, but in the case of the South Atlantic triple junction such variations do not exceed 50% whereas heat flow values vary by at least an order of magnitude.

Lee and Von Herzen thus favour an explanation involving hydrothermal circulation in the cracks produced by thermal and/or tectonic tensional stresses near the spreading axis. According to this view, which is apparently the only one offering any hope at present, the high heat flow over a ridge crest reflects the topographically controlled ascending limb of the circulation system in the permeable basement rocks (although it could result from conductive cooling of the crust following the sealing of cracks generated at the spreading centre). The intermediate to low values in the axial valleys may then be attributed to the circulation's descending limbs. Similar values in fracture zone depressions are not quite so easily explained in detail, although reasons for cracking and subsequent hydrothermal circulation there are not difficult to envisage.

The only real difficulty is in accounting for the low heat flow over ridge flanks. One possibility is that the irregular topography here supports a locally controlled hydrothermal system which imitates the wider pattern. Thus hot water would ascend through elevated terrain and descend in depressed regions. The observed low heat flow would then result from a known sampling bias towards local sediment-filled topographic lows. A second possible explanation is that secondary circulation occurs in cracks reopened during the dehydration of rocks previously hydrated near the spreading axes. But either mechanism affirms the crucial role of hydrothermal circulation.

A similar conclusion has also been reached by Piper *et al.* (*Earth planet. Sci. Lett.*, **26**, 114; 1975) but in a quite different context. Piper and his colleagues have analysed (for major, trace and rare earth elements and uranium isotopes) an iron-rich (about 30%) deposit dredged from the upper flank of Dellwood Seamount in the north-east Pacific. What attracted them to the sample in the first place was its iron-richness, because oceanic deposits with high iron contents (20–35%) and high Fe/Mn ratios (3–75) have previously been associated with active ridge spreading. Indeed, in overall composition and mineralogy the new sample closely resembles other iron-rich deposits attributed to volcanic hydrothermal activity. But do the separate elemental compositions and distributions also support such an origin?

As Dellwood Seamount is close to the North American continent, an obvious possibility is that some of the elements in the sample are terrigenous, introduced into the oceans by rivers. This view may be rejected, however, partly because the major element composition differs from that of metal deposits from hemipelagic environments and partly because the Th content and Th/U ratio are much lower than those of typical river muds. Are, then, any of the elements derived from sea water? The fact that the rare earth element pattern and the $^{234}U/^{238}U$ ratio differ significantly from those of normal sea water suggests that this is unlikely, at least for the rare earths and uranium

isotopes (and probably for others too). Indeed, although the absolute concentrations of rare earth elements are much lower than those in oceanic sediments and basalts, the pattern of these elements is almost identical to that of ridge basalt.

Taken together, these observations can only be explained on the assumption that the unusual composition of the iron-rich deposit derives from a suboceanic source. And the only known way in which this source may be tapped is by hydrothermal circulation which leaches out the metals from flow interiors and transports them to the surface. Admittedly there is a problem. The $^{234}U/^{238}U$ ratio is not only much higher than that of normal sea water, it is also much higher than that generally found in iron deposits now forming near known active volcanic centres. In the case of the Dellwood deposit it is therefore also necessary to assume that ^{234}U is leached from the rock preferentially. The point is, however, that even this anomaly can be accommodated within a hydrothermal system. ☐

Constructing semisynthetic polypeptides

from D. G. Smyth

A SEMISYNTHESIS is one that utilises a fragment of a natural substance as a prefabricated unit in the construction of a larger molecule. The term does not include the preparation of simple derivatives of a natural protein nor of course does it cover the chemical synthesis of peptides from their building bricks, the constituent amino acids. The hallmark of a semisynthesis is that it involves the combination of two components, the one a fragment of a natural substance, the other a product formed by chemical synthesis. This description would include the preparation of ribonuclease S by association of the subtilisin-produced S-protein (residues 21–124 of ribonuclease) with a synthetic S-peptide (corresponding to residues 1–20). The combination of natural insulin A-chain with synthetic B-chain, or *vice versa*, would also qualify as a semisynthesis, as would the conversion of porcine insulin to human insulin by replacement of the B-chain octapeptide.

In the field of peptide synthesis, the idea that an intermediate fragment might be obtained by excision from a protein of known structure is attractive. Such fragments can be obtained in pure form and without racemisation by the action of proteolytic enzymes;

A hundred years ago

IN the Paris International Maritime Exhibition there is a small object deserving of notice. It is a platinum wire placed in a bottle and ignited by electricity from a bichromate battery. It is intended to be immersed in the sea, and the light emanating from it is said to attract an immense number of fishes. Experiments have been tried lately on the coast of the Côtes du Nord department with a fishing-boat, and have proved very satisfactory, on a bank of sardines. The glass must be green or black, otherwise the fish are frightened by the glare and do not follow the submarine light.

from *Nature*, **12**, 388, Sept. 2, 1875

but difficulties arise in activating the fragment for further use. This is illustrated in a semisynthesis of human β-MSH by Burton and Lande (*J. Am. chem. Soc.*, **92**, 3746; 1970), utilising the porcine hormone as an intermediate. Human β-MSH possesses four more amino acids than porcine β-MSH and a tetrapeptide was therefore synthesised with the intention of extending the NH$_2$-terminus of the porcine molecule. Unfortunately porcine β-MSH has two NH$_2$ groups, the α-NH$_2$ group at position 1 and the ε-NH$_2$ group at position 6, and the coupling reaction led to the formation of products with the tetrapeptide attached at more than one site. Inevitably the yield of the required α-linked hormone was low. In semisynthesis it is clearly important that, before coupling, all reactive side chains should be protected to ensure that only terminal residues are free to participate in the formation of peptide bonds. Herein lies the difficulty.

Offord (*Nature*, **221**, 37; 1969) has reported that carboxyl groups in peptides can be protected under mild conditions by reaction with phenyldiazomethane. This forms benzyl esters at the side chains of all aspartic and glutamic acid residues but it also esterifies the C-terminal carboxyl group; the latter, however, can be regenerated selectively by the action of an esterase. When the fragment is initially obtained from a natural polypeptide by the action of trypsin, the same enzyme can be used to remove the C-terminal benzyl group. Similarly NH$_2$ groups can be reversibly blocked in a precursor polypeptide before the required fragment is released by proteolytic cleavage. Provided the peptide was initially present within the sequence of the precursor and not at the NH$_2$-terminus, the enzymically released fragment will have a free NH$_2$-group at the N-terminus; the ε-NH$_2$ groups remain protected. By these reactions, one fragment can be prepared with only a C-terminal carboxyl group and another with only an N-terminal NH$_2$ group, appropriate to the coupling reaction. In this way, linking of the first peptide to the second can be made to take place specifically between the C-terminus of the one and the N-terminus of the other. While these reactions seem straightforward, it is true to say that few reports have appeared in the literature on the preparation of new polypeptides by the combination of natural fragments.

A semisynthesis of a different type has involved the preparation of an insulin in which the B1 phenylalanine was replaced by iodophenylalanine, with retention of biological activity (Offord, *Nature*, **227**, 718; 1970). To perform the conversion, the A1 and B29 NH$_2$ groups were protected by

trifluoroacetylation and the remaining NH$_2$ group at B1 was blocked by reaction with phenylisothiocyanate. The B1 phenylalanine residue was removed by treatment with trifluoracetic acid, giving rise to a fragment of insulin which lacked only the B1 residue. Coupling of iodophenylalanine to the insulin fragment was easily achieved. Obviously the semisynthesis of this homogeneous derivative is more practicable than a total synthesis of the specifically iodinated insulin from the constituent amino acids.

Dyckes, Creighton and Sheppard (*Nature*, **247**, 202; 1974) have described an intriguing semisynthesis of an analogue of trypsin inhibitor. The 58-residue polypeptide was cleaved specifically at a methionylarginine residue by cyanogen bromide, which converted the methionine residue to homoserine lactone and conferred weak acylating properties on the fragment. A peptide bond then formed spontaneously between the homoserine residue and the adjacent arginine residue, restoring

the intact polypeptide chain. The product, which carried a residue of homoserine in place of methionine, retained the inhibitory action of the natural molecule. Corradin and Harbury (*Biochem. biophys. Res. Commun.*, **61**, 1400, 1974) performed a similar experiment with cytochrome *c*, which has no stabilising disulphide bridges. They found that cyanogen bromide cleavage gave rise to two fragments which could reunite; again the homoserine analogue retained biological activity.

In the general case, cleavage of a polypeptide at methionine would not be accompanied by a tendency for the fragments to recombine. Only in situations where the three-dimensional structure of the cleaved molecule is the same or very similar to that of the natural molecule will the newly released termini be held in juxtaposition for intramolecular condensation.

These are early days in the development of semisynthetic procedures. Future applications will be awaited with interest. □

Between molecules and collision complexes

from our Chemical Physics Correspondent

IT is almost three years (*Nature*, **240**, 257; 1972) since I drew attention to the identification of (HF)$_2$ and expressed the hope that H$_2$OHF would also be identified in the gas phase. This has now been done by Bevan, Legon, Millen and Rogers (*J. Chem Soc. Commun.*, page 341; 1975) who find a clear-cut microwave spectrum near 14 GHz and 29 GHz.

It is the hydrogen of the HF which forms the hydrogen bond; the O .... F distance is 268 pm and the dipole moment is 12.8×10^{-30} C m (3 82 debye). There is an intensity alternation associated with the spin statistics of the two equivalent H attached to the oxygen, but it is not clear if the whole molecule is planar (point group C$_{2v}$) or whether the fluorine lies out of the H$_2$O plane (point group C$_s$). As expected the intensity seems to be proportional to the product of the partial pressures of each component and with an optimum total pressure of 100 Pa the lines are necessarily broad and such clear identification must have required the use of much experimental skill.

But though hydrogen bonds have been known for some time and such gas phase molecules have long been postulated, the extension of this work to the charge transfer species (CH$_3$)$_3$ N.ICF$_3$ is even more remark-

able (Legon, Millen and Rogers, *J. Chem. Soc. Chem. Commun.*, page 580; 1975) even though it is based on earlier infrared evidence (Mishra and Pullin, *Aust. J. Chem.*, **24**, 2493; 1971). For this species, which is a symmetric top, lines for *J* from 30 to 37 span 26 GHz to 33 GHz and are identified. With only one value of *B* for such a large molecule the structural information is not very precise, but suggests an N .... I distance of 293.2 pm. Habit sets the expression 'N .:.. I' with dots suggesting a non-bonded distance; but really the charge transfer complex has now a clear-cut identity and perhaps a full bond, based on charge transfer, should be shown.

And also unexpected is the spectroscopic detection, this time with molecular beam apparatus, by Harris, Janda, Novick and Klemperer (*J Chem. Phys.*, **63**, 881; 1975), of the rare gas species Ar.OCS. Both radiofrequency and microwave transitions were seen and they establish the structure as basically T-shaped with the argon adjacent to the carbon at a distance of 358 pm, slightly greater than the van der Waals' radius sum.

All of these molecules with self-respecting structures, lifetimes and dipole moments fill in the gap between true molecules and sticky collision complexes.

review article

Ion implantation

G. Dearnaley*

Ion implantation has proved an elegant and successful technique, and in the manufacture of silicon devices, is now being extended both for research and practical applications in other materials, such as metals.

ION implantation is the process whereby controlled amounts of chosen foreign species can be introduced into the near-surface regions of a material in the form of an accelerated beam of ions. The energies used normally lie between 10 keV and 500 keV, with corresponding penetrations ranging from 100 Å to 1 μm, depending also on the target material.

The technique has proved highly successful for the fabrication of semiconductor devices, in spite of being in competition with well established processes of thermal diffusion or epitaxy, and requiring a relatively expensive accelerator and vacuum equipment. Some 200 accelerators are now in operation throughout the world and this number is expected to rise 10-fold—far in excess of the number used for nuclear research.

There are several reasons for the success of ion implantation. Among the most important are the control and resolution offered by this technique. Both the total amount and the purity of the implanted material can be accurately controlled and monitored, in a way that is impossible, for example, with diffusion, in which surface phenomena determine the dose which diffuses in. Furthermore, the concentration of impurities as a function of depth can be controlled by means of the ion energy, so that it is feasible to implant a buried layer of dopant. But for practical purposes, a crucial feature of the technique is its compatibility with photolithographic masking. This means that the well directed beam entering the surface produces a doped region which can be given a very high lateral resolution using conventional masking techniques (the etching of apertures through oxide films by use of a photosensitive resin overlayer).

The process also avoids certain problems associated with other techniques. Implantation, and the subsequent annealing of damage, are completed quickly and at relatively low temperatures, avoiding the difficulties associated with lengthy exposure to high temperatures; it is also very clean, being carried out in a vacuum, and could in principle be highly automated.

Its versatility is a further advantage, for a single accelerator can be used for many doping and other processes in device manufacture, with a schedule that is easily varied in such a way as to aid product development or the production of short runs of specialised devices. In materials other than semiconductors, the advantage lies in the possibility of introducing essentially any required species and producing a treated layer which is integral with the substrate.

Physical processes

When ions enter a solid, they lose energy through elastic collisions and through electron excitations. A reasonably accurate theory of the process was developed by Lindhard,

*Address: Atomic Energy Research Establishment, Harwell, Oxfordshire OX11 0RA, UK.

Scharff and Schiøtt[1], and this is widely used to calculate ion ranges and range distributions. Some results for silicon are shown in Fig. 1, from which it can be seen that the ranges of commonly used dopants (boron, phosphorus) are compatible with the dimensions of present-day microelectronic components (100–1,000 nm) with ion energies of a few hundred keV. Since the semiconductors are crystalline, the phenomenon of ion channelling[2] introduces some difficulties: this is the enhanced penetration of ions travelling along open crystallographic directions, as a result of small-angle collisions with the atomic rows. We have been able to show that this is the cause of a "tail" which extends beyond the expected maximum range (Fig. 2) and various techniques have had to be developed to cope with this.

Most semiconductors are covalently-bonded materials, with rigidly defined bond lengths and bond angles. Under ion bombardment this structure is vulnerable to disordering and in most cases it is necessary to restore crystallinity by thermal annealing at 800–1,200 K for about 20 min. Otherwise, electrically-active defects will dominate the effects of the atoms introduced. Figure 3 shows a transmission electron micrograph of a wafer of phosphorus-implanted silicon after annealing at 700 °C. There is a large amount of localised strain visible as dark regions, but the superimposed electron diffraction pattern shows that between these the crystal is relatively perfect. Fortunately, the electron transport properties of the semiconductor are also very good and the carrier mobility in the implanted zone may approach that of bulk material at the same impurity concentration. Moreover, the carrier density will (in silicon) correspond to the number of phosphorus or arsenic atoms introduced, although for boron the degree of electrical activity is commonly less than 100% because of the formation of complexes such as SiB_6. In some applications, the electrical effects of defects induced by bombardment can be put to good use. Proton bombardment will raise the resistivity of GaAs by seven orders of magnitude[3], and is increasingly adopted for producing the isolation between neighbouring devices. The physical mechanisms involved are only just becoming clear: once again technology has provided a spur to physics. Another important process is that of causing unwanted metallic impurities, such as Au, Cu, Ni, to diffuse to defects introduced by ion bombardment[4]. This is the technique known as "gettering", important for achieving reproducible device performance and low diode leakage currents.

Ion-implanted silicon devices

We can now consider the various semiconductor devices to which ion implantation has successfully been applied, illustrating the advantages I have mentioned. The first important structures

## Ion implantation in silicon

Fig. 1 Ion ranges in silicon, as a function of atomic number, and the full-width at half maximum (FWHM) of the depth distribution, assumed to be Gaussian. ○, Projected range; ●, FWHM (projected).
to benefit dramatically from the technique were the metal-oxide-semiconductor (MOS) transistors. In these the conduction takes place at the surface of a silicon crystal, and is controlled by the voltage applied to a metal "gate" electrode, electrically insulated from the silicon beneath by a thin layer of thermally-grown SiO_2. Difficulties in aligning the elements of this structure were overcome by using the metal gate as a mask for implantation. Excellent registration of the "source" and "drain" (input and output) regions of the transistor was

automatically achieved with a consequent reduction in stray capacitance. Next, the surface conducting region was doped by ion implantation to the required value, while the material surrounding the transistor was maintained at a higher resistivity. By this means parasitic capacitances that load the input and output were significantly reduced. Finally, it was shown that the conducting "channel" could readily be buried so that electrons or holes would travel in good crystalline material rather than at the silicon–oxide interface where lattice defects

would interrupt their motion. These factors allowed the dimensions of MOS transistors to be reduced and their speed of operation to be dramatically improved.
Integrated circuits, sometimes containing many thousand individual transistors on a single square of silicon, have become extremely important for electronic systems ranging from pocket calculators to military defence installations, and they were stimulated intensively during the development of space satellites. Besides the techniques described above, two other applications of ion implantation have been found which proved even more beneficial. The threshold voltage, at which conduction of an MOS transistor commences, is governed by impurities in the oxide layer or at the oxide–silicon interface. Bombardment with low doses of ions (not necessarily group III or group V dopants) alters the threshold voltage[5] in a remarkably controllable manner (Fig. 4). Secondly, it is desirable to construct the two main types of MOS transistor (called "enhancement" and "depletion" mode devices) within the same circuit, so that one can act as a load for the other. The result is a considerable saving in power consumption, important in pocket calculators or electronic wristwatches, and so on. The necessary doping, to produce p-type regions, or "wells",

Fig. 3 Transmission electron micrograph of an ion-implanted silicon crystal, after thermal annealing, together with (inset) an electron diffraction pattern from the same region. The former shows a dense network of defects, while the latter reveals that the intervening matrix is crystalline.

however, that charge be transferred efficiently from one element to the next, and here the "buried channel" produced by ion implantation has proved highly effective, removing the charges from the region containing traps at the oxide interface. It seems likely that ion bombardment gettering will be useful for removing metallic impurities which trap mobile carriers.

Bipolar transistors, in which the active elements (emitter, base and collector) are buried within a silicon crystal, still account for the major part of the device market. At first it seemed that they would not benefit from ion implantation, since the performance of implanted transistors was not reproducible. It is now realised that this was due, in part, to the effects of the "tails" on implanted ion distributions (Fig. 2), which vary in extent from one crystal to the next and which influence the depth of emitter-base junctions. It was found in the USA (R. J. Scavuzzo, R. S. Payne, K. H. Olson, J. M. Nacci and R. A. Moline, unpublished paper presented at the IEEE Electronic Devices Meeting, Washington DC, 1972) that if arsenic ions are implanted to form the emitter a subsequent "drive-in" diffusion will yield a desirable concentration profile

Fig. 2 Penetrating "tail" observed in the distribution of radioactive phosphorus ions implanted into a silicon crystal in a direction well removed from major channelling axes or planes. This tail is due to scattering into channelling directions. ● $\gamma 13$–X. $7°$ to $\langle 11 \rangle$. 120 keV. 5×10^{12} cm^{-2}. ^{32}P. Room temperature. (– – – –) calculated from Lindhard et al.[1].

in n-type silicon for these circuits is best carried out by implantation. In the most recent development both enhancement and depletion mode devices are implanted, and computer memories with almost 19,000 transistors on a single silicon "chip" have been produced. A microprocessor with the general capability of a PDP-11 computer is expected to be introduced this year, packed on to a chip which is comparable in size with the first calculator microcircuits.

Even these achievements are overshadowed by the rapidly developing "charge-coupled devices" in which, by an extension of MOS technology, arrays of metal–oxide–silicon capacitors are used to store charge which can be transferred to the adjoining storage element, just as in a solid-state analogue of the obsolete "Dekatron" glow-discharge indicator tubes. The charges can be liberated optically, in which case the device acts as a scannable photo-detector array, already on the market in the form of hand-held TV cameras. Alternatively, the devices can be used to store and process analogue information. It is important,
Fig. 4 An example of threshold control in an MOS transistor achieved by boron ion implantation (after Sigmon and Swanson[6]). 30 keV implant oxide thickness ≈ 550 Å boron, 500 °C anneal. ●, Experimental.

with a reproducible distribution of electrically active donors. Other improvements have come from a better control of the size of residual defects (Fig. 3) which remain after annealing, and which can, if large, project through the junction with undesirable local effects on conduction. By a careful choice of annealing schedule these defects can be reduced to a negligible 10 nm or so in size. Excellent wholly implanted bipolar transistors have thus been produced in many laboratories, and this has led to a considerable upsurge in interest in ion implantation, which is now seen as an important process for practically all new device fabrication.

Specialised diodes, such as the variable-capacitance devices used for tuning purposes in radio and TV, or avalanche photodiodes which are fast, sensitive optical detectors, or nuclear particle detector diodes are all made more controllably by ion implantation. Indeed, yield improvements of two orders of magnitude have been reported for variable-capacitance diodes. However, these structures account for only a small fraction of silicon device output. A more promising development is in high-power rectifiers, in which ion implantation provides a close control of doping within a very thin layer. This thin layer can store very few trapped charges and hence a fast recovery is achieved without the need for the usual gold doping. 100-A, 150-V ion-implanted rectifiers are already on the market, and it is forecast that the process will be useful for diodes operating at up to 3,000 A.

Compound semiconductor devices

At first it was widely believed that ion implantation would speedily advance the fabrication of compound semiconductor devices, because it is in these materials that thermal diffusion is least satisfactory. Unfortunately this has not come about, for several reasons. In compounds, ion bombardment can create a wider variety of defects in which, for example, atoms are located on the wrong lattice sites. Some of these defects, after clustering, are thermally very stable, and the compound becomes unstable at temperatures below that required to restore order.

The problem then becomes one of finding a suitable encapsulating material which will prevent loss of the more volatile constituent during annealing. In GaAs (the most widely-used compound semiconductor) it has not proved easy to find a practicable means of encapsulation, but progress is being made along several ingenious routes. A good deal of exploration has been carried out to find the most suitable dopants, and Si^{4+} ions have been shown to provide a high degree of donor activity[7].

More immediate success was achieved in the inverse direction, that is that of destroying electrical conductivity in selected areas of semiconductor by ion bombardment. Modest doses

(10^{14}–10^{15} cm^{-2}) of protons will render GaAs, GaP or InP semi-insulating, in a manner that is very useful for isolating one device from its neighbour. In GaP, for example, the bombardment also turns the material opaque, and this has been exploited in a light-emitting diode array in which the individual elements are isolated both optically and electrically (A. R. Peaker, unpublished paper delivered at the European Solidstate Device Research Conference, Nottingham, 1974). Proton-induced defects are not very stable, however, since they probably consist of very small disordered regions and they are rather easily annealed out. There is a need for a less empirical approach to this useful process.

Equipment for ion implantation

The design and manufacture of ion accelerators and target chambers for ion implantation, in research and production, has become a sizeable industry, with an estimated world market of over £100 million over the next five years.

Some of the more useful ion sources for implantation purposes were developed originally for the separation of isotopes, where a simple, rugged source capable of delivering intense currents of a variety of ion species is also required. For research purposes it is advantageous to be able to change from one ion beam to another without elaborate clean-up procedures, while for industrial applications the reliable and efficient production of a few important ion species is paramount.

There are two possible configurations for the acceleration system: in one case ions are mass-analysed after reaching their full energy while in the other magnetic analysis is carried out after acceleration through only 20–40 keV and the selected beam is further accelerated to the required energy. The latter has the advantages that the high-voltage supply need not be well stabilised, and only the specific ions required are accelerated so that X rays resulting from back-streaming secondary electrons are minimised. Either the magnetic analysis system or the target chamber must be at a high potential, however—a feature which can pose a few design problems. Both these arrangements have been adopted in systems based on the Lintott accelerator. This equipment delivers the highest currents of any commercial machine, and consideration has had to be given to the consequences of target heating since a 1 mA beam at 100 keV dissipates 100 W and this power is not readily conducted from semiconductor wafers in vacuum. The solution[8] has been to manipulate many wafers rapidly through the beam, so spreading the heat dissipation, while also achieving a high degree of uniformity in the dose (ions per unit area). In this way, a throughput of several hundred 5 cm-diameter silicon wafers can be achieved in a day, and the process becomes very economical. In most research facilities, however, the ion beam is swept electrostatically over the face of a single fixed specimen, but it is not easy to achieve such a high degree of uniformity in dose. For example, neutral atoms resulting from collisions with residual gas are undeflected and give a central spot in the distribution.

Accurate current measurement, in the presence of secondary electrons and secondary ions, is not a trivial matter and comparisons between results obtained on different implantation systems can be surprising. Work is in progress to develop an absolute calorimetric ion collector, and to provide means of calibrating accurately an implanted specimen against a laboratory standard, using an ion backscattering technique at MeV energies.

Ion implantation of metals

During the past year or two it has become clear that ion implantation has important applications outside the semiconductor field, and an investigation has begun of the effects of implantation upon the surface properties of metals and alloys. The corrosion behaviour, electrochemical properties, coefficient of friction, wear resistance and bonding ability of metals are controlled by their near-surface composition. Novel

Fig. 5 The effect of yttrium implantation in a niobium-containing steel alloy, compared with that of alloyed yttrium, on the oxidation of the metal in CO_2 at 700 °C (after Antill *et al.*[11]). ○, 20/25/Nb; □, 20/25/Nb 0.13% Y alloy; △, 20/25/Nb 0.41% Y alloy; ●▲, Y implanted 20/25/Nb.
experiments on all these phenomena can be made by exploiting the ability to alter the surface composition in a versatile manner, and to monitor the migration of atoms initially confined to a shallow layer.

Thus at Harwell, we have studied the effects on thermal oxidation as a result of the implantation of a wide variety of ion species into titanium, zirconium and stainless steel[9]. The results in titanium and steel indicate a close correlation between the electronegativity of the impurity ions and the oxidation rate, but effects were reversed in the two metals. The behaviour of zirconium was quite different from that of titanium in spite of their proximity in the Periodic Table. There was no correlation with electrochemical properties but some indications of a trend with ionic size, which has been observed also in alloy studies. We inferred that these striking differences arise from the crystallographic properties of TiO_2 and ZrO_2. Crystallographic shear in TiO_2 is a powerful mechanism for eliminating oxygen vacancies, while in ZrO_2 the mechanical stress caused by volume changes upon oxidation is relieved by cracking and pore formation. The ionic size of impurities will influence this stress, and thus the degree of oxygen transport along fissures.

In these metals, bombardment by inert ions, or ions of the same species as the target produced little or no change in oxidation rate. But in the case of metals such as chromium or nickel, cation out-diffusion is the dominant process during oxidation and this seems to be inhibited by Cr^+ or Ni^+ bombardment, respectively.

This effect, together with the observation by Hartley[10] of a striking increase in wear resistance of ion-implanted steels, can tentatively be explained as a result of the lateral compressive stress generated by ion implantation. Such stresses can approach the yield stress of the material, and thus have a considerable influence on grain boundary phenomena and surface plasticity.

Besides these scientific studies, the practical possibility of

treating metallic components by ion implantation to improve their surface properties is arousing interest. Antill and others at Harwell have demonstrated[11] that implanted yttrium can be as effective as alloyed yttrium for inhibiting the high-temperature oxidation of an austenitic stainless steel in CO_2, without the drawbacks of a reduced bulk tensile strength and ductility. In this and other cases still under investigation the duration of the effects of ion implantation is remarkably long. This is due, in the case mentioned, to the fact that the yttrium remains near the metal–oxide interface. In other instances, and in wear modification, it could be that the initial phase of the corrosion or wear process is crucial in determining the subsequent pattern of behaviour.

In such practical applications the successful exploitation of ion implantation will depend upon economic factors, the geometry of the workpiece and the merits of alternative techniques. Novel configurations of ion accelerator and more versatile designs of ion sources will need to be developed, but the costs of the process seem likely to be acceptable for a variety of applications in both high and low cost systems.

Principles of protein–protein recognition

Cyrus Chothia & Joël Janin

Service de Biochimie Cellulaire, Institut Pasteur, 75015 Paris, France

The formation of the protein–protein interface by the insulin dimer, the trypsin-PTI complex and the αβ oxy-haemoglobin dimer removes 1,130–1,720 Å² of accessible surface from contact with water. The residues forming the interface are close packed: each occupies the same volume as it does in crystals of amino acids. These results indicate that hydrophobicity is the major factor stabilising protein–protein association, while complementarity plays a selective role in deciding which proteins may associate.

BIOLOGICAL molecules are able to recognise each other and form specific associations. These processes are fundamental

to biology and the nature of the interactions involved has frequently been discussed.

Recently X-ray diffraction analysis has provided detailed atomic information on several systems which involve protein–protein recognition and association. As a result of this we can now approach directly the problem of the nature of the interactions. We shall use here the known atomic structures of dimeric porcine insulin[1], of the bovine trypsin–pancreatic inhibitor complex[2,3] and of the αβ dimer of horse oxy-haemoglobin[4].

The association between protein subunits in these systems has been described in terms of Van der Waals' contacts, of electrostatic forces and of hydrogen bonds: that is, of point-to-point interactions. Here we analyse the contact regions between subunits in terms of surface area and of the volumes

occupied by residues, and show how these quantities, which can be interpreted from a thermodynamic point of view, account for the specificity and the stability of the associations.

Area and chemical nature of surfaces involved in protein–protein association

The concept of accessible surface area[5] describes the extent to which protein atoms can form contacts with the solvent. For a given atom it is defined as the area over which the centre of a water molecule can be placed while retaining Van der Waals' contact with that atom and not penetrating any other atom. Accessible surface areas are correlated with hydrophobic free energies[6].

Using available atomic coordinates and a computer program written by M. Levitt, we have calculated in the manner described previously[7], the total area accessible to water for each protein complex and for the isolated subunits. The surface area buried in the complex is then defined as the accessible surface area of one subunit plus that of the other subunit minus that of the complex (Table 1). This assumes that the free subunits have the same conformation as found in the complex. For the pancreatic trypsin inhibitor (PTI), the structure of which has been determined independently as the free molecule[8] and as the trypsin–PTI complex[2], we find that the small variations of conformation which do occur on binding have little effect on the estimation of the surface areas (Table 1).

Table 1 Changes in accessible surface area

Complex	Total accessible surface area (Å²)	Area buried in complex (Å²)	%	No. of residues involved*
Insulin dimer				
Monomer M1	3,400	530	16	12

β subunit	7,130	790	11	19
Total change in α β		1,720		

*Number of residues contributing more than 10 Å² to the surface area buried in the complex. In all cases residues which contribute less than 10 Å² make up for 2–7% of the total buried area.

†Value obtained as described in text. A value of 815 Å² was calculated using atomic coordinates for free PTI rather than the PTI moiety of the complex.

For each of the three interactions studied here, the association of the protein subunits leads to a reduction of the surface area accessible to solvent by more than 1,000 Å². The chemical nature of the groups involved is analysed in Table 2, which details the relative contributions of polar and non-polar atoms to the accessible surface areas of the molecules and to the interfaces. Eight aromatic residues occur in the insulin dimer interface (Tyr B16, Phe B24, Phe B25 and Tyr B26, from each monomer) making that interface a good deal more hydrophobic than the rest of the protein surface. This is less true of the αβ interface in haemoglobin, while the trypsin–PTI interface has essentially the same chemical composition as other parts of the protein surface which remain accessible to the solvent. Thus, a number of polar or charged atoms become inaccessible to solvent when the complexes form: Table 3 shows that most, if not all, form hydrogen bonds.

Protein interfaces are close packed

Richards[9] has shown that the volume occupied by an atom inside a protein molecule could be defined by tracing an

Table 2 Chemical character of protein surface

appropriate space-filling polyhedron (Voronoi polyhedron) separating that atom from adjacent atoms. This method was used to demonstrate that protein interiors are close packed[9] with individual amino acid residues occupying the same volume as they do in crystals of the amino acids themselves[7]. Using Richards' computer program in the manner described previously[9,7], we have calculated the volume occupied by residues buried in the interfaces: that is, by residues which are inaccessible to solvent in the complex but have a large accessible surface area in the isolated subunits. The results are summarised in Table 4, which also lists the volume occupied by residues in protein interiors and in crystals of amino acids. Table 4 shows clearly that residues occupy the same volume in protein interfaces, inside a protein or in the crystalline amino acid. The standard deviations are ~6% and a loose packing would cause a systematic tendency of the volumes towards higher values. The total volume of the residues cited in Table 4 for each complex, however, is in all cases within 1% of the corresponding volume calculated from crystalline amino acids. Thus the same rule applies to small organic molecules in the crystal state, and to amino acid residues in protein interfaces (or inside proteins): they close pack.

Free energy of protein association

The free energy of dissociation ΔG_D of a complex between two molecules is related to its dissociation constant K_D by:

$$\Delta G_D = -RT\ln K_D \qquad (1)$$

This equation implicitly refers to a standard state where all chemical species are 1 M, and attributes a free energy of zero to a complex with a dissociation constant of 1 M.

When two molecules associate, there is a loss of translational and rotational entropy which can easily be derived from

Table 3 Buried polar atoms and hydrogen bonds

statistical thermodynamics (refs 10 and 11 and our unpublished work) at least in the case of perfect gases. While this might appear quite irrelevant to macromolecules in aqueous solutions, Page and Jencks[11] have shown that the calculation gives reasonable estimates of the entropy lost by small organic molecules reacting in solution. Applying it now to the complexes studied here, we find that the entropy corresponding to three translational and three rotational degrees of freedom lost when two molecules associate amounts to 70–100 calorie $deg^{-1}mol^{-1}$, equivalent to a free energy, ΔG^s_D, of 20 to 30 kcalorie mol^{-1} at 27 °C (in the standard state). To form a complex with a

dissociation constant K_D, one must therefore provide a free energy at least equal to:

$$\Delta G^t_D = \Delta G^s_D + \Delta G_D \qquad (2)$$

Table 5 shows that weak but observable protein–protein interactions such as found in the insulin dimer require at least 25–35 kcalorie mol^{-1} of free energy, while the tight binding of PTI to trypsin or of the α and β subunits in haemoglobin needs 30–50 kcalorie mol^{-1}.

Origin of free energy of association

Can the structural analysis of the protein interfaces described above account for these large energies? What relative contribution does each type of interaction make to the association? Pauling[15] has argued that energy of association by proteins is due to the complementarity in structure and the resultant cooperation of weak forces (that is, H bonds and Van der Waals' interactions) over a sufficiently large area to produce a strong bond. An alternative model, due to Kauzmann[16], stresses the importance of hydrophobic energies, the association areas of proteins being viewed as surface patches of non-polar side chains brought together rather like hydrocarbon chains in lipid micelles.

Hydrogen bonds and Van der Waals' interactions

Thermodynamic evidence is against hydrogen bonds making a major contribution to the free energy of protein–protein interaction[17,18]. Although the enthalpy of breaking a typical amide H bond may be of the order of 4–5 kcalorie mol^{-1}

(ref. 19), the difference between a protein–protein H bond and the corresponding bond made with water in the dissociated complex can only be a fraction of this. It is unlikely that the four H bonds of the insulin dimer or even the 13 H bonds of the trypsin–PTI complex contribute more than 4–15 kcalorie mol^{-1} to the dissociation free energies.

Van der Waals' interactions are both much less energetic[20] and much more numerous than H bonds as they involve all pairs of neighbouring atoms. But as atoms making Van der Waals' interactions in the complex make similar interactions with water in the dissociated subunits, the overall contribution is small. Still, like hydrogen bonds, Van der Waals' interactions place severe restrictions on the structure of protein surfaces: to achieve the same interactions with each other as they do with water, the two surfaces must be complementary, and this is expressed in the close packing of residues, which we have described.

Hydrophobic contribution

We have ignored so far the effect of solvent entropy on the thermodynamic balance of the association: that is, the hydrophobic contribution. For this, we shall use an empirical correlation found between the accessible surface area of a solute and its free energy of transfer to a water solution. Such a correlation has been established for hydrocarbons and amphiphilic molecules[21,22], and also for amino acids[6]: for the latter, 1 $Å^2$ of surface area corresponds to 25 calorie mol^{-1} of hydrophobic free energy[7].

A free energy term favouring association is thus derived from the decrease in surface area accessible to water occurring when proteins associate. Using the values of Table 1, we calculate the hydrophobic contribution to the formation of the insulin dimer, of the PTI–trypsin complex and of the αβ dimer of haemoglobin. Table 5 shows that this contribution is very large in each case, and of the same order as the value of ΔG^t_D estimated above: in other words, the entropy gained by water due to the smaller accessible protein surface area is sufficient to compensate the entropy loss by protein molecules forming a complex.

Stability and complementarity

These results show that hydrophobicity is the major factor which stabilises protein–protein associations. Our estimates of the free energy required to make a stable complex indicate that each subunit needs to bury about 600 $Å^2$, corresponding to a hydrophobic contribution of 30 kcalorie mol^{-1} (for two subunits). In the case of the trypsin inhibitors this surface

Table 5 Free energy of protein–protein association

area is derived from only a small number of amino acid residues (ref. 3 and our unpublished work). As the hydrophobic contribution is entirely unspecific, it would lead to all kinds of incorrect interactions in a cell. The proper formation of hydrogen bonds and of Van der Waals' contacts, however, requires complementarity of the surfaces involved: they must be able to close-pack together, with the polar atoms properly positioned to make hydrogen bonds. Thus while Van der Waals' and polar interactions contribute little to the stability of the complex, they decide which proteins may recognise each other. Incorrect associations are forbidden by large unfavourable enthalpies due to poor packing and loss of hydrogen bonds made to water. These principles are likely to be also true of the interactions of proteins with small ligands, nucleic acids, and membranes.

Chloroplast DNA from higher plants replicates by both the Cairns and the rolling circle mechanism

Richard D. Kolodner* & K. K. Tewari

Department of Molecular Biology and Biochemistry, University of California, Irvine, California 92664

The chloroplast DNA (ctDNA) from pea and corn plants contains both Cairns type and rolling circle replicative intermediates. Denaturation mapping studies with pea ctDNA molecules have shown that the rolling circles initiate replication at or near the site where the Cairns replicative intermediates terminate replication. These results suggest that the rolling circles are initiated by a Cairns round of replication. A model for the replication of the chloroplast DNA is based on these results.

THE chloroplast DNAs from higher plants and the alga *Euglena* have been isolated as covalently closed circular molecules with molecular weights from 85×10^6 to 96×10^6 (refs 1–3). The replication of corn and pea ctDNA[4,5] has been shown to initiate with the formation of two displacement loops (Fig. 1b) similar to the displacement loops that initiate animal mitochondrial DNA (mtDNA) replication[5,6]. The two displacing strands are hydrogen bonded to the opposite parental DNA strands, they expand toward each other (Fig. 1c), and form a structure that looks like a Cairns replicative intermediate when the two displacing strands elongate past each other (Fig. 1d). We present here evidence that pea and corn ctDNA replicate by both the Cairns replication mechanism[8] and by the rolling circle mechanism[9]. Electron microscopic examination of pea and corn ctDNA have shown the presence of Cairns type and rolling circle type structures in both ctDNAs. Denaturation mapping studies on pea ctDNA have shown that the Cairns replicative intermediates elongate bidirectionally. The de-

naturation mapping experiment revealed that all the rolling circles initiated replication at the same site but could elongate in either direction from that site. The initiation site for the rolling circle round of replication was found to lie at or near the termination site of the Cairns round of replication, suggesting that the rolling circle replicative intermediates are initiated by the Cairns round of replication.

Structure of intermediates

To obtain replicative intermediates, the pea ctDNA was fractionated by centrifugation in ethidium bromide-caesium chloride density gradients[3,7]. The DNA was collected into three fractions; the lower band of closed circular DNA containing 20–25% of the total pea ctDNA, the middle band

T indicates the terminus of the Cairns round of replication which is 180° opposed to the origins of D-loop synthesis.

containing 10% of the pea ctDNA, and the upper band of nicked circular and linear DNA containing 65–70% of the pea ctDNA (60% of the upper band DNA was circular). The upper band DNA was determined to be ctDNA by its buoyant density in CsCl and its renaturation rate[3]. These fractions were examined in the electron microscope using the formamide
Fig. 2 Cairns replicative intermediates. *a*, A molecule that is 37% replicated and contains a single strand region (two small arrows) at one growing fork and a denatured region (large arrow) in the unreplicated portion of the molecule. *b*, A portion of a molecule that is 5.2% replicated and contains a single strand region (two small arrows) at one growing fork. *c*, A Cairns replicative forked molecule showing branch migration at one of the replicative forks (large arrow). The molecules were mounted for electron microscopy by the formamide technique[10,18]; the spreading solution contained 50% formamide, 0.1 M Tris, 0.01 M EDTA, *p*H 8.5, the hypophase contained 20% formamide, 0.01 M Tris, 0.001 M EDTA, *p*H 8.5, and the spreading was performed at 23 °C. Single-stranded and double-stranded ΦX DNA molecules were used as internal standards in all experiments. The bars indicate 1 μm.
Fig. 3 Rolling circle molecules. *a*, A molecule with a tail that is 19% of the length of the attached circle. There is a single-strand region at the growing fork that is 3 500 bases long (indicated by arrows). This molecule was mounted for electron microscopy using the conditions described in Fig. 2 *b* and *c*, Partially denatured molecules with tails that illustrate the two different denatured patterns at the tip of the tails. These molecules were mounted for electron microscopy under partially denaturing conditions using the formamide technique as previously described[18]. The spreading solution contained 77% formamide, 0.1 M Tris, 0.01 M EDTA, *p*H 8.5, the hypophase contained 47% formamide, 0.01 M Tris, 0.001 M EDTA, *p*H 8.5, and spreadings were performed at 23 °C. Single-stranded and double-stranded ΦX DNA molecules were used as internal standards in all experiments. *a*, Graphical representation of molecules in *b* and *c*. The boxes indicate the denatured regions, the asterisk indicates the circular part of the molecule that has been linearised. The unmarked free end is the tip of each tail. The bars indicate 1 μm.

technique to demonstrate single-stranded DNA[10]. Cairns type replicative forked structures were found in each fraction from two different DNA preparations (Fig. 2). Forty-five Cairns structures were measured and the extent of their replication ranged from 5.6 to 87%. Three per cent of the circular molecules in the lower band were Cairns structures and the extent of their replication ranged from 5.2 to 8.2%. The Cairns replicative intermediates made up an average of 5.7% of the circular pea ctDNA molecules in the middle band and the extent of their replication ranged from 7 to 50%. The Cairns structures consisted of 2.9% of the circular pea ctDNA molecules in the upper band and the extent of their replication ranged from 38% to 87%. In this study 3,118 circular pea ctDNA molecules were scored and it was calculated that 3.3% of the total circular pea ctDNA molecules consisted of Cairns replicative intermediates. The finding of Cairns replicative intermediates in the lower and middle bands of the caesium chloride–ethidium bromide density gradients, and the correlation between higher banding position and larger amounts of replication suggests that replication takes place on a covalently closed circular template, and is accompanied by nicking and closing cycles. Similar observations have been made in studies of the replication of mouse L cell mtDNA[11] and SV40 DNA[12].

The replicative intermediates of corn ctDNA were also studied. The total corn ctDNA was collected as a single fraction and 309 circular molecules were scored. Cairns replicative structures made up 4.5% of the total circular corn ctDNA molecules and the extent of their replication ranged from 9.4% to 70%. Cairns structures have also been found in *Euglena* ctDNA[13].

In the above experiments, monomer-length circular molecules with an attached double-stranded tail were also observed (Fig. 3a). In the pea ctDNA preparation, circular molecules with tails accounted for 4.9% of the circular molecules in the upper band, and 2.8% of the circular molecules in the middle band. No circular molecules with tails were observed in the lower band of pea ctDNA (<0.05%). The circular molecules with double-stranded tails made up 3.1% of the total circular pea ctDNA. The lengths of tails in the pea ctDNA ranged from 1.5 to 124% of the length of the attached monomer-length circular molecule. Circular molecules with double-stranded tails were also found in the preparation of total corn ctDNA that was examined. In corn ctDNA, 11% of the total circular molecules had tails attached to them. The tails in the corn ctDNA ranged in length from 2% to 140% of the attached monomer length circular molecule. Fifteen per cent of all rolling circle forms had tails longer than the unit length of ctDNA. The finding of tails that were longer than the attached monomer length circular molecule eliminates the possibility that the tails arose by breakage of a Cairns forked structure at a replicative fork. This suggests that the circular molecules with tails are rolling circle replicative intermediates[9].

Single-stranded regions in intermediates

A careful examination of the rolling circles and the Cairns forked structures in both pea and corn ctDNA showed that 77 to 81% of the growing forks in these molecules contained single-stranded regions (Figs 2a and b, and 3a). The lengths of these single-stranded regions were variable and ranged in length from 250 bases to 7,600 bases. The structure and frequency of these growing forks is presented in Fig. 4. In the Cairns structures, single-stranded regions could be observed at both of the replicative forks in a given molecule, which suggests that the Cairns structures grow bidirectionally. In unambiguously interpretable Cairns structures that contained single-stranded regions at both replicative forks, the single-stranded regions were located at positions that were *trans* with respect to each other (Fig. 4). In both the rolling circles and the Cairns structures, the single-stranded regions were located on only one daughter strand at each replicative fork. The single-stranded regions at the rolling circle growing forks were always found on the tail. These results indicate that at least one daughter strand at each growing fork is being synthesised discontinuously. The above observations do not eliminate the possibility that both daughter strands at each fork are being extended discontinuously, as in the case of T7 DNA[14] or *E. coli* DNA[15], since the failure to see gaps on both daughter strands of a growing fork would simply be a consequence of the 5' to 3' direction requirement of DNA synthesis[16].

Short single-stranded tails were observed (Fig. 2c) at some of

Fig. 5 Denaturation mapping of the replicative intermediates. DNA fractions containing replicative intermediates were mounted for electron microscopy under conditions of partial denaturation as described in the legend of Fig. 3. Under these conditions an average of 22% of each DNA molecule is denatured[18]. Three denaturation maps were constructed as described before[18] from the clean circular ctDNA molecules, from the circular part of ctDNA molecules containing double-stranded tails, and from the Cairns type of forked molecules. All three denaturation maps were very similar showing that all the molecules examined had an identical sequence. An example of such a denaturation map is represented by the histogram in this figure. The orientation of the replicated portion of 10 Cairns replicative intermediates in this denaturation map is represented by the horizontal lines (*a*). The arrows at the ends of the lines indicate the positions of the replicative forks. The tails of the rolling circle molecules were oriented in the denaturation map by comparing the denaturation pattern of the tail with both the denaturation pattern of the attached monomer length circular molecule and the denaturation map essentially as described by Schnös and Inman[19]. The orientation of the tails from 20 rolling circles are represented by horizontal lines (*b*). The single arrow on each line indicates the position in the denaturation map where the tail was attached to the circular molecule and represents the position of the replicative fork. The other end of the horizontal line (*b*) marks the position in the denaturation map where the end of each rolling circle tail maps. The small stars indicate the two origins of D-loop synthesis and the larger star indicates the origin of the rolling circle synthesis.

the replicative forks in pea and corn ctDNA replicative intermediates. These whiskers have been suggested to arise from branch migration at the replicative fork[17] and have been observed in the replicative intermediates from various systems[15]. Whiskers were observed at 17 and 15% of the rolling circle growing forks in pea and corn ctDNA, respectively. The Cairns structures in pea and corn ctDNA had whiskers at 13 and 15% of the growing forks, respectively. In addition to the whiskers, 12% of the pea ctDNA Cairns replicative intermediates found in the middle and lower bands had denatured regions in the unreplicated portion of the molecule (Fig. 2a). The relationship between branch migration and denatured regions in covalently closed replicative intermediates has been discussed elsewhere[7].

Denaturation mapping experiments

To study the pattern of the elongation of the Cairns forked structures and rolling circles, pea ctDNA was mounted for electron microscopy under conditions of partial denaturation[18]. Ten partially denatured Cairns replicative intermediates were ordered with respect to their position in the denaturation map of pea ctDNA molecules that were an average of 22% denatured[18]. The positions of the replicated portions of these molecules with respect to the denaturation map are illustrated in Fig. 5a. These partially replicated molecules have a pattern that would be expected if they all had initiated replication at the same place and that both replicative forks were being extended at the same rate. The initiation site of these Cairns replicative

intermediates lies at the same point in the denaturation map where displacement loops (Fig. 1b) were shown to map[7]. The termination site for the Cairns round of replication appears to lie at a site 180° around the pea ctDNA molecule from the initiation site (Fig. 5a).

The pea ctDNA rolling circles have also been studied by denaturation mapping. In the partially denatured pea ctDNA preparations, rolling circles with two distinct patterns of denaturation on the tip of the tail were observed. An example of each type is presented in Fig. 3. The two types of rolling circles appeared in equal proportion and no other types of denatured tails were seen. The two partially denatured rolling circles of Fig. 3b and c are represented as a line graph in Fig. 3d. This representation shows that the tip of the tail of these two molecules is mapped at the same site and that each tail extends in the opposite direction from this site. The positions of 20 partially denatured tails with respect to the pea ctDNA denaturation map are illustrated in Fig. 5. All the tips of the tails are mapped at the same site and the tails extend in either direction on the map from this site. In the rolling circle model of DNA replication the tip of the tail marks the site where the initiation of replication takes place[9]. The initiation of rolling circle replication at a unique site in the pea ctDNA is similar to the results found for E. coli phage P2 replication except that the P2 rolling circles elongate in only one direction[19]. It should be noted that the pea ctDNA rolling circles all initiate replication at a site that is at or near the site where the Cairns round of pea ctDNA replication was found to terminate, which suggests a connection between the two processes.

Model for replication of chloroplast DNA

The results presented here suggest a model for the replication of pea and corn ctDNA. This model is illustrated in Fig. 1. The ctDNA replication is initiated by the formation of two displacement loops whose displacing strands are complementary to the opposite parental strands of ctDNA (Fig. 1b). The two displacement loops expand towards each other and initiate the formation of a Cairns replicative forked structure (Fig. 1c and d). This initial stage of ctDNA replication has been discussed in detail[7]. The small Cairns forked structures expand bidirectionally (Fig. 1e) until termination takes place at a site that is 180° around the circular ctDNA molecule from the initiation site. Separation of the daughter molecules takes place yielding two circular molecules that each have a single-strand break or small gap at the same site located in opposite daughter strands (Fig. 1f). This part of the replication process is not well understood in any system, but it probably yields open circular progeny which are then sealed into closed circles[20]. In ctDNA the nicked circles could be sealed to closed circles or the 3'-OH of each nicked progeny molecule could be extended by a DNA polymerase molecule. This would displace a single-stranded tail (Fig. 1g) from the molecule and this tail could be filled in by discontinuous duplex synthesis to yield a molecule with a double-stranded tail (Fig. 1h). The tails might then be

converted to circular molecules by an intrastrand recombination event[21]. If both progeny from a Cairns round of replication initiated rolling circle synthesis, two types of rolling circles would be formed. In each case, the very tip of the tail would be mapped at the same site but the sequence of the two types of tails would extend in opposite directions from this site. This is the result that was observed in the denaturation mapping experiments with pea ctDNA rolling circles. Therefore, we feel that a Cairns round of replication is used to initiate a rolling circle round of replication in the ctDNA. A low frequency of Cairns structures was observed among the rolling circles that were shown to amplify the rDNA from Xenopus laevis[21] and both Cairns structures and rolling circles have been observed during E. coli phage λ DNA replication[22,23], suggesting a similar model of replication for these two DNAs.

It is interesting that the ctDNAs from pea and corn, two evolutionarily divergent plants, have similar modes of replication. Why should the higher plant ctDNAs require two modes of DNA replication, one of which is an amplification mechanism[21], and the other which is a duplication mechanism? Possibly it is related to a developmental aspect of higher plant chloroplast biogenesis that requires the rapid synthesis of a number of copies of ctDNA. The rolling circle mechanism might be used for this rapid synthesis of ctDNA while the Cairns mechanism might be used for normal duplication of ctDNA.

Soft X rays from Sirius

ON April 3, 4 and 5, 1975 the star Sirius (α CMa) was observed with the soft X-ray detector aboard the Astronomical Netherlands Satellite (ANS). The instrument consists of a parabolic collecting mirror which has at its focus a proportional counter with a 3.6-μm polypropylene window. It responds to X rays in the photon energy range 0.284–~0.2 keV. The projected area is 144 cm[2] which, allowing for reflectivity, counter efficiency

and so on, leads to a sensitive area of about 25 cm[2] at the carbon absorption edge (0.284 keV). The field of view is 34' FWHM circular. Further instrumental details are given in refs 1–3.

So that background could be subtracted, the observations were carried out in the offset pointing mode with the instrument alternately pointed at the source for 64 s and 40' away from the source for 64 s, the transition time being 16 s. Any ultraviolet contamination by light from the star can be determined by interposing into the light path a 0.5-mm MgF₂ filter which
Fig. 1 Counting rates of Sirius measured on April 4, 1975 with ANS soft X-ray (0.25 keV) detector in offset pointing mode: *a*, 0920 UT; *b*, 0930 UT. UV (X+UV), signal measured with (without) MgF₂ filter; on (off), on (off) source.

blocks out the X rays but which transmits ultraviolet radiation above about 1,100 Å. The photons responsible for the ultraviolet contamination come from the wavelength region between about 1,600 and 2,500 Å (because of the transmission properties of the foil plus coating, ultraviolet radiation below 1,600 Å can be neglected). By measuring twice, with and without filter, X radiation (X) can be distinguished from ultraviolet radiation (UV). In that way the ultraviolet response was determined by observations on a number of bright ultraviolet stars (R.M. *et al.*, unpublished). Figure 1 shows typical measuring signals on Sirius, with and without the filter. In Fig. 2 the source signal, corrected for background and averaged over the total observation time of about 1,300 s, has been plotted against the relative ultraviolet flux. The total counting rate from Sirius, without the filter, that is, signal X+UV, is more than 6σ above the observed ultraviolet counting rate. The excess counting rate has been interpreted in terms of X-ray flux from that star system (R.M. *et al.*, unpublished). Figure 2 also shows that

Fig. 2 Counting rates of various ultraviolet stars as a function of the relative ultraviolet flux at 2,000 Å after subtraction of background. Vertical error bars are 2σ in length and represent the combined uncertainty in the source and background data. The excess signals {(X+UV)−UV} of Sirius (α CMa) and Capella (α Aur) are 6σ and 5σ, respectively. ×, Signal without ultraviolet filter; ⊙, signal with ultraviolet filter; arrow, ultraviolet response.
Capella (α Aur), detected earlier as an X-ray star[4], gives a signal 5σ above background.

The counting rates from the other stars depicted in Fig. 2 can be wholly attributed to ultraviolet radiation. The observed counting rate of 0.58 ± 0.10 counts s⁻¹ and the instrumental sensitivity of 1.9 counts (photon cm⁻² keV⁻¹)⁻¹ give for Sirius an X-ray luminosity in the energy band 0.284–0.2 keV: $L_X = (9.1 \pm 1.6) \times 10^{27}$ erg s⁻¹. Sirius is a visual binary with at least two components: Sirius A (A1 V) and Sirius B (white dwarf). The rotation period is 50 yr, the present relative distance, *a*, of the two components is estimated to be about 30 AU.

The observations could be explained by invoking X-ray emission from a hot corona around Sirius A. Preliminary calculations show that such a corona would need to be heated up to a few million K. The energy required would exceed the convective energy by nearly two orders of magnitude, even considering the fact that the anomalous silicon abundance[5] would yield an enhanced, soft X-ray line emission. It could be questioned whether the X-ray emission could be produced by accretion on to the white dwarf of a stellar wind from Sirius A. To generate an X-ray energy of, say, 10^{28} erg s⁻¹ (this a very conservative lower limit), the accretion rate $\dot{M}$ must be at least $10^{-15} M_\odot$ yr⁻¹ $(GM_B\dot{M}/R_B \approx 10^{28}; \; M_B = 1.05 \; M_\odot; R_B \approx 0.01 R_\odot$ (ref. 6), *G* is the gravitation constant). If it is assumed that the stellar wind speed is twice the escape velocity of Sirius A[7], then (with $M_A = 2.2 \; M_\odot$, and $R_A = 1.75 \; R_\odot$; ref. 5), the accretion efficiency $(M_B/M_A)^2 \; (R_A/8a)^2 \approx 3 \times 10^{-10}$. Thus, a rate of mass loss from Sirius A of more than $3 \times 10^{-6} M_\odot$ yr⁻¹ would be needed to produce a total X-ray luminosity of 10^{28} erg s⁻¹. This is about 10^3–10^6 times the expected mass loss for an A-type main-sequence star[8]. Even the mass loss from the A2 Ia supergiant α Cyg, estimated from the Mg II resonance lines[9], is only $\sim 3 \times 10^{-10} M_\odot$ yr⁻¹. Thus, the mechanism of accretion probably fails to explain the observed X radiation.

Anomalous temporal behaviour of Her X-1

DURING January 1975 the Leicester Sky Survey experiment aboard Ariel V observed anomalous X-ray emission the during off state of Her X-1. Figure 1*a* shows the positive observations preceded by an extended period when no radiation was detected, a 3σ limit being shown by horizontal bars. The counting rates are averages over an entire satellite orbit and arise from photons in the range 2.4 to 19.8 keV. The counting rate scale may be converted to Uhuru units for a typical Her X-1 spectrum by multiplying by 1.27. Figure 1*b* shows that about half of the following on state was observed but not the actual turn on. If the turn on had occurred at phase 0.2 in the first observed cycle, the midpoint of the anomalous emission would have preceded the turn on by 16.5 d. A turn on extrapolated from
Fig. 1 Counting rate from Her X-1 during anomalous emission (a) and next regular on state (b). Vertical lines are mid-eclipse points, error bars are ±1σ random errors.

Copernicus data (A. C. Fabian, private communication), taken two 35-d cycles later, reduces this to 14 d.

Although Her X-1 was extensively studied with Uhuru, observations were concentrated on the on state so that the probability of detecting emission during the off state was low. The only other indication of low state emission[1] from Her X-1 also occurred approximately half way through the 35-d cycle and was estimated to have a strength of between 0.3 and 1.0 times the typical strength during the on-state. Also, the emission we observed showed considerable variation in intensity and when our observations ceased was at 0.4 of the average on state strength and still increasing.

The mechanism of mass transfer from primary star to the compact companion in binary X-ray source is crucial in determining the emission behaviour of the source on long time scales. The identification[2,3] of low mass star, HZ Herc, with the primary of the Her X-1 system suggests that the transfer is by Roche lobe overflow rather than by the stellar wind envisaged for the Krzeminski star/Cen X-3 system. In the former mechanism considerably more of the mass lost by the primary will be transferred to the secondary and the formation of the accretion disk is expected to be more orderly. Thus we anticipate that the long term temporal behaviour of Her X-1 will be simpler than that of, say, Cen X-3 where the density and ionisation state of the stellar wind have important roles in determining the activity and visibility of the X-ray emission[4].

The regularity of the extended low states of Her X-1 point to a clock-like mechanism with which the marching of the pre-eclipse dip seems to be connected (D. Gerend *et al.*, unpublished). These dips may be due to obscuration of the X-ray source by material at the point where the overflow hits the accretion disk[5] which itself may precess[6,7] and periodically prevent us seeing the still emitting source. This explanation may be contrasted with that involving 'wobble' of the neutron star which either periodically alters the direction of a sharply emitted X-ray beam[8] or actually causes the X-ray emission to be strongly modulated by giving rise to a geometrical mass gating action[9].

The presence of radiation from Her X-1 within the extended low places an additional constraint on these models, especially if the radiation could be shown to be a regular feature of the off state and to be always at a particular phase of it.

Whiskers and cosmic millimetre-wave sources

MANY extragalactic objects—N-type Galaxies, Seyferts and QSOs—are strong emitters of infrared and millimetre-wave radiation[1]. For Seyfert galaxies the most likely model for the 2–20 μm radiation involves a central source of primary radiation surrounded by a shell of solid particles, the dust absorbing the primary radiation and re-emitting it in the infrared[2]. There is independent evidence for the presence of dust in the nuclei of Seyferts including detections of differential reddening of [S II] lines[3]. The formation of dust could occur in the expansion phases following explosions of massive (or supermassive) stars[4] and the primary radiation may be in the form of ultraviolet photons, soft X rays or low energy cosmic-ray nucleons[5].

Dust particles invoked for these models have so far been assumed to be similar to solid particles which are deduced to exist in our own Galaxy. Nearly spherical grains with radii in the range 10^{-6}–10^{-5} cm could account for the observed 2–20 μm fluxes with reasonable mass requirements. A serious difficulty arises with regard to total grain mass if the same grains are to explain the observed millimetre and sub-millimetre wave radiation simply because of the low antenna efficiencies of very small particles at long wavelengths.

The total millimetre-wave fluxes of extragalactic sources and the peak wavelengths are somewhat uncertain. For Seyfert galaxies the average energy output at millimetre wavelengths is $\sim 3 \times 10^{44}$ erg s^{-1} and for QSOs a range 10^{44}–10^{46} erg s^{-1} is likely, the spectra probably peaking at $\lambda \sim 120$ μm. This value of the peak wavelength indicates a minimum grain temperature $T_g \sim 30$–50 K (depending on the wavelength dependence of the emissive efficiency). If T_g is the grain temperature at the outer edge of the shell, the flux in the range λ, $\lambda + d\lambda$ is

$$F_\lambda d\lambda \simeq \kappa_{abs}(\lambda) M_g \pi B_\lambda(T_g) d\lambda \tag{1}$$

where M_g is the total grain mass, $\kappa_{abs}(\lambda)$ is the mass absorption coefficient of grains, and $B_\lambda(T_g)$ is the Planck function. The maximum absorption efficiency of a small spherical particle being[6]

$$Q_{abs}^{max} \sim 10a/\lambda \tag{2}$$

in a typical case we find

$$\kappa_{abs}^{(sph)}(\lambda) \lesssim 30/4\lambda s \tag{3}$$

so that, taking $s = 2.2$ g cm^{-3},

$$F_\lambda d\lambda \lesssim 1.7 \times 10^{29} (T_g/\lambda^5) d\lambda \ (M_g/M_\odot) \text{ erg s}^{-1}$$

using equation (1) and the Rayleigh–Jeans approximation for $B_\lambda(T_g)$.

Taking $T_g \simeq 30$ K as a representative value, and setting $\lambda \simeq \Delta\lambda \simeq 1$ mm, we obtain

$$F_\lambda \Delta\lambda < 5 \times 10^{34}(M/M_\odot) \text{ erg s}^{-1} \tag{4}$$

for spherical particles. Thus, to explain a millimetre-wave output of 3×10^{41} erg s^{-1} for a Seyfert nucleus we require grain masses $> 5 \times 10^6 \ M_\odot$; and for $F_\lambda d\lambda \simeq 10^{44}$–$10^{46}$ erg s^{-1}, in the case of QSOs, we require grain masses exceeding 2×10^9–$2 \times 10^{11} M_\odot$. These grain masses must be regarded as untenably large.

These mass estimates are significantly reduced if long whisker grains of lengths 10^{-2}–10^{-1} cm are present in the emitting dust shell. For cylinders with length $l \gg a$, and at wavelengths $\lambda \leqslant l$ the mean mass absorption cross section for randomly oriented particles is approximately[7]

$$C_{abs}(\lambda) = \frac{4\pi a^2 l \sigma(\lambda)}{3c}\left\{1 + \frac{8K}{(K+1)^2 + 4(\sigma\lambda/c)^2}\right\} \qquad (5)$$

where $\sigma(\lambda)$ is the optical conductivity, K is the dielectric constant, and a is the cross-sectional radius. The second term is curly brackets is in general negligible compared with the first, and for graphite, where optical data are available up to millimetric wavelengths[8] $\sigma(1\,\text{mm}) \simeq 10^{15}\,\text{s}^{-1}$. Thus equation (5) gives a mass absorption coefficient

$$\kappa_{abs}^{(cyl)}(\lambda) \simeq 4\pi\sigma(\lambda)/3cs \qquad (6)$$

where s is the specific gravity of grain material, and using equation (3) we have

$$\frac{\kappa_{abs}^{(cyl)}(\lambda)}{\kappa_{abs}^{(sph)}(\lambda)} > \frac{4\pi\sigma/3cs}{15/2\lambda s}$$

$$\simeq 1.5(\sigma/10^{15})\,(\lambda/10^{-4}) \qquad (7)$$

For graphite with $\sigma(1\,\text{mm}) \simeq 10^{15}\,\text{s}^{-1}$, $\lambda \sim 10^{-1}$ cm we find the required mass estimates in the form of whisker grains are down by a factor $\sim 1.5 \times 10^3$. This gives grain mass estimates of $10^3 M_\odot$ for explaining the millimetre fluxes from Seyferts, and 10^6–$10^8 M_\odot$ for QSOs. The implied hydrogen masses $10^5 M_\odot$–$10^{10} M_\odot$ are now within the permissible range. Impure ice whiskers are expected to have a similar value of low frequency conductivity, so these mass estimates are also appropriate for ice whiskers, or formaldehyde polymer whiskers coated with impure ice.

The growth of formaldehyde whiskers in interstellar space has already been discussed by one of us [9,10]. Crystal growth in whisker form is also well known to occur in the case of graphite condensing in suitable laboratory conditions[11,12]. We will discuss the whisker growth process in greater detail elsewhere.

It may be argued that either formaldehyde polymers or graphite whisker growth could take place in conditions prevailing near the nuclei of Seyferts and QSOs. The former case arises where the ambient C/O ratio exceeds unity, and the latter where O/C exceeds unity. In the latter case, the oxygen uncondensed as H_2CO may be deposited as H_2O mantles on the formaldehyde whiskers. The maximum length l of whisker grains is determined by the condition for the exhaustion of condensable gas phase atoms in most cases of interest and is given by

$$l = (n_g/n_H)^{-1}(\pi a^2)^{-1}s^{-1}fm_A \qquad (8)$$

Here f is the fraction of condensable atoms (by numbers) relative to H, m_A is their mass per molecule, a is the radius of the grains (or base sites on grains) which act as condensation nuclei, and s is the specific gravity of the condensing solid. For interstellar type grains with $a \simeq 10^{-5}$ cm, $n_s/n_H \sim 10^{-12}$, $s = 2.5$, $f \sim 10^{-3}$, $m_C = 12m_H$ we find $l \lesssim 1\,\mu\text{m}$. Much longer particles could grow in the vicinity of galactic nuclei if lower n_g/n_H ratios and/or lower values of a are appropriate. Such situations could arise due to sputtering or evaporation of original grain nuclei in an explosive phenomenon, or simply from a low starting value of n_g/n_H. Grain lengths of 100 μm–1 mm required for our radiation model may thus be justified fairly easily.

The whisker growth process is extremely rapid, and could easily occur within the time scales of protostellar collapse. The existence of whisker grains in galactic protostellar clouds would allow extremely bright far-infrared sources with very low dust masses. For example, the millimetre emission from OMC1

could be explained with whisker grain masses of less than $0.02 M_\odot$.

Water in non-carbonaceous stony meteorites

WE report here on high-voltage electron microscope observations of the hydrous alteration products of olivine in an achondrite and an ordinary chondrite—two classes of meteorite in which hydrous minerals are rare. We argue that the Nakhla achondrite, and perhaps the Weston chondrite, contain water of extraterrestrial origin which was mobilised by mild shock deformation. The observations suggest that both meteorites have unusual volatile constituents.

Hydrous minerals are rare in meteorites other than types I and II carbonaceous chondrites[1]. It has been pointed out that iddingsite occurs in the 'diopside'-olivine Nakhla achondrite (T. E. Bunch and A. M. Reid, 1974 Meeting of the Meteoritical Society). Iddingsite is a disequilibrium mixture of products of the hydrothermal alteration of olivine, in which approximate hexagonal close packing of the oxygen ions is retained[2]. In the Nakhla achondrite it occurs mainly as red-brown veins in the large olivine grains. Using transmission electron microscopy we have examined a vein in material prepared by ion thinning[3]. The vein was found to have been formed as a result of alteration along a crack, which in turn is attributable to shock deformation since the adjacent olivine shows mosaicism and dislocation substructures characteristic of mild shock effects[4]. The fine-grained alteration product becomes colloidal towards the centre of the vein (Fig. 1a). The association with shock deformation supports the idea that the iddingsite is of extraterrestrial origin. The Nakhla achondrite is essentially an igneous rock which formed from a relatively oxidised melt, producing Fe^{+2}-rich silicates and primary magnetite; magmatic water is likely to have been present during its formation. The evidence for later mobilisation of the water by mild shock suggests that here leaching of rubidium may have been responsible for the radiometric anomalies[5,6] in which whole-rock specimens deviate from the 1.24 Gyr mineral isochron believed to represent the crystallisation age[5]. The presence of water suggests that the parent body was not outgassed earlier than 1.24 Gyr BP.

The Weston chondrite has similar iddingsite veins in olivine. Where olivine with only slight mosaicism is crossed by narrow veins (less than 1 μm thick), electron diffraction patterns were obtained showing a topotactic transition to a goethite-like condition, similar to that described in terrestrial iddingsite[2]. In the fine-grained matrix of the meteorite, we also found abundant iddingsite and similar material filling interstices. This accounts for the high content of bound water (0.98% by weight), in the bulk chemistry[7]. In Fig. 1b the relatively large crystal is olivine, with a rim of fine material which, by comparison with the vein occurrences, may be described as iddingsite. This material cements the grains in Fig. 1b. We found that the
Fig. 1 High-voltage (1 MV) electron micrographs showing meteoritic iddingsite. Insets are diffraction patterns from the fine-grained areas. *a*, The Nakhla achondrite (BM 1913,26) × 18,000—diffraction pattern comprises spots from olivine and rings from the alteration product; *b* and *c*, the Weston chondrite (BM 1920,349)—*b*, ×13,000; *c*, ×16,400.

alteration makes an important contribution to the mechanical cohesion of the Weston chondrite. Where relatively coarse, the material often has a morphology comprising matted laths (Fig. 1*c*), and gave diffraction patterns dominated by rings corresponding to lattice spacings of 2.46 ± 0.04 and 1.49 ± 0.05Å. Where strong, they were accompanied by other rings, consistent with patterns from randomly oriented crystallites of a clay phyllosilicate with $a \approx 5.2$ Å. Smaller grains tended to have equidimensional images, and diffraction gave pseudohexagonal arrays of diffuse spots comparable with basal diffraction patterns of the disordered phyllosilicate constituent in terrestrial iddingsite[2].

The Weston chondrite is mildly shock-lithified (J. R. A. and D. J. Barber, unpublished). If the water was present during the shock events, it would have been mobilised and could thus have produced the observed alteration. The possibility that the hydration occurred later should, however, be considered. The Weston chondrite (like the Nakhla achondrite) is an observed fall and, therefore, has not suffered normal terrestrial weathering, but it is reduced and porous, like the Apollo 16 'rusty rocks' in which hydrous minerals are thought to have been produced through the hydrolysis of primary lawrencite, $FeCl_2$, by terrestrial atmospheric water vapour[8]. The Weston chondrite contains, however, an order of magnitude more water than do the Apollo 16 rocks, and to attribute this to the lawrencite reaction requires an exceptionally high initial content of the volatile element chlorine; abnormal enrichment of extraterrestrial volatiles is found in the Apollo 16 rocks themselves[8].

Weston is a 'gas-rich' chondrite[9], which means that some individual grains suffered unshielded irradiation by the solar wind, resulting in the implantation mainly of hydrogen and helium. The observed alteration cannot, however, be attributed to the formation of water by reaction between mineral grains and solar wind ions, as lunar surface breccias are generally anhydrous. If aggregation of the grains occurred on a small atmosphere-free body[10,11], a magmatic source of reactive volatile elements is also unlikely. On the other hand, a likely source is a 'dust' component of type I and/or type II carbonaceous chondrite composition. Macroscopic inclusions of carbonaceous chondrite are certainly present in some gas-rich meteorites[10]. These meteorites probably formed during the terminal stages of accretion of their parent bodies, in an environment that was favourable for the incorporation of such inclusions[10,11]. Moreover, a carbonaceous chondrite component would carry water, because it would consist largely of hydrous phyllosilicates[1]. Because the hydrous minerals in the Weston chondrite were found on cracks and grain boundaries, it is unlikely that they could be unaltered grains from a carbonaceous chondrite source though such a source could have supplied the water for the subsequent alteration. If all the water in the Weston chondrite is from this source, the indicated minimum content of type I carbonaceous chondrite is 5% by weight, using the figure of 20% for the water content of type I material[1]; for type II, the corresponding minimum content in Weston is 7.5% by weight. These are minimum figures because water may have been lost during accretion. If the Weston chondrite does contain more than 5% of a carbonaceous chondrite component, it should be identifiable chemically. Neither the major element data[7] nor the Kr and Xe isotopic abundances[12] are, however, diagnostic of its presence. An attempt is being made to characterise any unusual component which may be present in the Weston chondrite. Until this has been done, the additional possibility that the Weston chondrite is from a body which had a hydrous atmosphere must also be left open. Whatever the source of the water, the pervasive alteration suggests that the matrix of the Weston chondrite incorporated an unusually large amount of chemically reactive material.

Lag times for oceanic responses to climatic change

RECENT studies of deep-sea sediment cores have defined changes in surface water circulation[1], in continental ice volume as recorded by oxygen isotope variations in foraminiferal tests[2], and in the corrosiveness of near-bottom water to calcium carbonate[3,4] during the past million years. These changes are all attributed to the major climatic changes that have occurred during the Quaternary[1,2,5,6].

Few of the studies have attempted to establish whether the various changes are synchronous, or whether there are leads and lags in the system[7]. Such information is critical in evaluating theories and models of climatic change, and in sorting out causes from effects. Thus, if bottom water changes precede surface water and ice volume changes during deglaciation, models like that of Newell[8] are favoured, whereas if the ice volume decreased first, an albedo-related cause is more likely.

To determine sequences of change, either extremely accurate time scales for the records of the oceanic system and the continental ice volume, or records of the two systems from the same core samples are needed. The latter approach eliminates problems of correlation or inaccuracies of time scales in different deep-sea cores, and is the approach used here.

The sediment core selected for detailed study (core Y69-106P, 2°59′N, 86°33′W, 2,870 m) was taken in the eastern equatorial Pacific, an area where the surface circulation varied significantly from glacial to interglacial times[9]. To establish a time scale throughout the core, a sedimentation rate model was constructed assuming that the rate of accumulation of quartz has been constant at the core location (a reasonable assumption given the depositional regime in the area[10]). The fact that calculated accumulation rates of quartz were constant to within 3% between points dated by three carbon-14 determinations, an $^{40}Ar/^{39}Ar$ age, and oxygen isotope and biostratigraphic boundaries of known ages, supports this assumption. Details of the model are given in ref. 10. Measurements of carbonate, opal, and quartz concentrations together with bulk density measurements were transformed by the model to give absolute accumulation rates (g cm^{-2} 10^{-3} yr) for the total sediment, calcium carbonate, opaline silica, and the remaining (non-biogenic, non-quartz) detritus during the past 450,000 yr.

Conversion of the raw calcium carbonate analyses to accumulation rates eliminates the problems inherent in working with concentration data. In the Pacific, changes in the concentration of calcium carbonate probably reflect changes in accumulation rate of carbonate particles, but in the Atlantic, fluctuations in

Fig. 1 Calcium carbonate and opaline silica accumulation rates (in g cm^{-2} 10^{-3} yr) and oxygen isotopic data from core Y69-106P.

Fig. 2 Calcium carbonate accumulation rate in core Y69-106P compared to oxygen isotopic analyses from core V28-238.

carbonate concentration are strongly influenced by variable dilution as a result of changes in the accumulation rate of terrigenous material[11].

Comparison of the silica and carbonate accumulation rate curves and the oxygen isotopic composition of foraminiferal calcite in Y69-106P (Fig. 1) suggests that climatic and oceanographic changes have not been synchronous. The accumulation rate curves for opaline silica and calcium carbonate during the past 150,000 yr are very similar (Fig. 1), but there seems to be a slight lag between the two curves during this period, changes in calcium carbonate accumulation preceding changes in opal accumulation rates. The calcium carbonate and opaline silica accumulation rates seem to be responding to the same changes in the driving mechanism, presumably climate, but the response times are different. The average lag time between change in carbonate and opal accumulation rate (Fig. 1a–f) is 2,600 yr.

The relation between the isotopic data and the other parameters is less apparent, but again the carbonate rate curve appears to lead, this time by 5,000–10,000 yr. Confirmation of this lead is provided by a comparison of the carbonate curve of Y69-106P with a more complete isotopic record from western Pacific core[2] V28-238 (Fig. 2). For the last three glacial maxima, the carbonate peak precedes the isotopic (ice volume) peak by about 5,600 yr.

Opal accumulation rates seem to be controlled by biological productivity in the surface waters[10,12] whereas changes in the carbonate accumulation rates reflect changes in the dissolution of calcium carbonate by bottom waters[3]. Thus the lags between changes in the calcium carbonate accumulation rates, the opaline silica accumulation rates, and the oxygen isotope analyses from core Y69-106P indicate that the following sequence of events occurred in the eastern equatorial Pacific during the transition from the most recent glacial to the present interglacial period (Fig. 1, a, a′, a″):

An increase in corrosiveness of the bottom water (indicated by a reduction in calcium carbonate accumulation rates), preceded a decrease in surface productivity (indicated by a reduction in opal accumulation rates), which in turn preceded the recession of continental glaciers (indicated by a reduction in the ^{18}O content of foraminiferal carbonate). The period covered by this sequence of events was about 5,600 yr with

about 2,600 yr (an average of events *a–f* Fig. 1) elapsing between the bottom water and surface circulation changes and 3,000 yr between the change in surface circulation and the recession of the continental glaciers. Because of the relatively wide spacing in time of individual samples from Y69-106P (the average sample interval is about 4,000 yr) these estimates represent maximum lag times.

If the lags between the carbonate and opal accumulation rate curves were random and independent, the probability of the observed succession in the six events *a–f* in Fig. 1 would be 0.016—highly unlikely. Rather, the observed changes seem to be systematic and are consistent with two recent models[8,13] of climatic change. Newell[8] has suggested that the termination of a glacial period is first marked by a decrease in the rate of formation or even stagnation of bottom waters (this would result in an increase in dissolved carbon dioxide in the bottom waters, leading to accelerated carbonate dissolution). He further suggests that the bottom water stagnation would be succeeded by reduced upwelling (leading to reduced opal deposition) and finally by wasting of continental glaciers. The data from core Y69-106P are in complete accord with Newell's model. If confirmed by data from other geographical areas, these results support continued development of the model and seem capable of providing accurate estimates of the lag times involved in the change of the oceanic and cryospheric systems from glacial to interglacial modes.

Strain resulting from adhesive action of water in capillary bridges

WE report here on the measurement of adhesive forces of thin films of water between glass plates. Our approach differed

Fig. 1   Displacement, d*b*, in a deformable isolated capillary. (From surface-energy considerations.)

**Fig. 2**   Interference fringe pattern obtained by a mechanical loading of 20,482 dyne.

from the traditional method of measuring the force necessary to rupture the liquid film in tension[1-3]; we used interferometry to measure the elastic strains produced around the bridges. The main pupose of the study was to assess the degree of agreement between measured adhesive forces and those predicted by classical capillary theory.

When a surface-energy consideration is applied to a liquid bridge between a deformable capillary wall and a rigid capillary wall, the work done by the force F during an increase, d*b*, in the distance b (Fig. 1) is equal to the energy of wetting and the elastic bending energy of the capillary wall:

$$F\mathrm{d}b = (\gamma_{SV} - \gamma_{SL})\mathrm{d}A_{SL} + \gamma_{LV}\,\mathrm{d}A_{LV} + \mathrm{d}U \qquad (1)$$

where γ is an interfacial energy, A an interfacial area, and the subscripts S, V and L denote solid, vapour and liquid, respec-

Fig. 3   Interference fringe pattern obtained by capillary adhesion. An adhesive force of 9,510 dyne is measured.
tively; U is the bending energy in the capillary wall. From the Young–Dupre equation, $\gamma_{LV}\cos\theta$ can be substituted for $(\gamma_{SV} - \gamma_{SL})$ with θ being the contact angle of the liquid on the

capillary wall. The theory of bending of plates[4] gives:

$$dU = Fdb/\cos(s\pi/a) \qquad (2)$$

When $s \gg b$, the term $\gamma_{LV}dA_{LV}$ is negligible, and by using β to represent $s\pi/a$ equations (1) and (2) can be combined to give

$$\frac{F}{\pi s^2}(1 + \frac{1}{\cos\beta}) = \gamma \cos\theta\frac{2}{b}, \qquad (3)$$

which indicates a linear relationship with a slope of $\gamma \cos\theta$.

A helium–neon laser beam was directed normal to two parallel glass capillary walls separated by a metal spacer 2 μm thick. Deflections of the deformable wall under applied forces gave rise to interference fringe patterns which are linearly related to the magnitudes of the applied forces. Mechanical loading was used to produce fringe patterns for calibration (Fig. 2).

Fringe patterns were obtained with water bridges having diameters of 0.04, 0.070, 0.12 and 0.13 cm (Fig. 3). Next, the forces of adhesion were calculated based on the calibration.
Fig. 4 The relationship of $(F/\pi s^2)(1 + 1/\cos\beta)$ (ordinate) and $2/b$ (abscissa) for a deformable glass–water capillary system. The experimental value of $\gamma \cos\theta$ is 73.9 dyne cm^{-1}, compared with a predicted value of 72 dyne cm^{-1}.

Using these results, Fig. 4 was plotted. The slope of the linear regression line is 73.9 dyne cm^{-1} which, from equation (3), would be equal to γ since θ was near zero. This close agreement with the surface tension value of water supports the correctness of equation (3). The results indicate that the surface energy of wetting can account for the elastic strains observed.

Three-coordinated magnesium in dehydrated offretite

OFFRETITE is a rare natural zeolite whose synthetic equivalent, zeolite O, is commercially important as a molecular sieve[1]. Its aluminosilicate framework is topologically related to that of erionite[2], an abundant natural zeolite[3]. The catalytic properties of molecular sieve zeolites have been ascribed to framework-bound protons, strong electrostatic fields, and oxygen vacancies in the framework[4]. As befits the small radius of Mg^{2+} ions (0.049 nm for four-coordination, 0.072 for six-coordination and 0.089 for eight-coordination)[5], Mg normally occurs in six-coordination with oxygen and hydroxyl, though four, five and eight-coordinations occur infrequently (for example, four-akermanite: $Ca_2MgSi_2O_7$, Mg–O = 0.1876 nm; five-grandidierite: $(Mg,Fe)Al_3O.BO_4.SO_4$, 0.2176, 0.2054, 0.2040, 2×0.1970; farringtonite: Mg_3PO_4, 0.196, 0.197, 0.201, 0.206, 0.214; eight-pyrope: $Mg_3Al_2Si_3O_{12}$, 4×0.2196, 4×0.2342)[6]. We report here on the occurrence of three-coordinated Mg in dehydrated offretite, which should produce a strong electrostatic effect on adjacent sorbed molecules.

*Numbers in brackets are atom designation numbers.

Hydrated offretite[7] $(K_{1.1}Ca_{1.1}Mg_{0.7}Si_{12.8}Al_{5.2}O_{36}.15H_2O)$ contains a K ion in each cancrinite cage, a pentahydrate of Mg in each gmelinite cage, and hydrated Ca ions in the main channels. Electron microprobe analysis of a new crystal, from Mount Simiouse, France, showed that this had $K_{1.04}Ca_{1.04}Mg_{0.95}Al_{5.2}Si_{12.8}O_{36}$ atoms in each cell. The crystal was dehydrated in a silica capillary for 22 h at 500 °C and 10^{-5} torr before sealing. Using MoKα radiation, 4,700 intensity measurements at room temperature yielded 514 independent non-zero diffractions in P6̄m2, a 1.3229(5), c 0.7338(4) nm. Least-squares refinement yielded the coordinates shown in Table 1.

The stereo plot (Fig. 1) shows Mg occupying the centre of a single six-ring where it is bonded to three oxygens at 0.208(1) nm. The six-ring is very distorted to accommodate this short distance and the other three oxygens are displaced outwards to 0.288(2) nm. Some weak bonding may occur to these three oxygens, but the strong disparity in the distances implies that the Mg is effectively three-coordinated. Each Ca ion lies between two six-rings which are distorted so that three oxygens from each give near-octahedral coordination at 0.2619(8) nm. Each K ion lies at the middle of a distorted eight-ring with four oxygens at 0.3258(7) as nearest neighbours and two more at 0.3350(6) nm. All the cation–oxygen distances are longer than the values expected from simple ionic theory and distances found in most silicates (for instance, Ca–O = 0.24; K–O = 0.27; and predicted Mg–O for three-coordination is less than 0.19 nm). The mean Al, Si–O distance of 0.1631 nm is less than the value of 0.165 obtained by interpolating the Al/Si ratio of offretite between the data for anhydrous framework silicates[8]. This suggests that the bonding in the framework of the dehydrated zeolite is stronger than in normal silicates and that the bonding
Fig. 1 Stereoplot of dehydrated offretite. Ellipses drawn at 30% probability level.

between extraframework cations and framework oxygens is weaker.

The Mg ion of dehydrated offretite should have a strong electrostatic field around it, and sorbed molecules should be strongly attracted to form a complex. Perhaps catalytic properties would result. In the dehydrated structure[9] of mazzite, which is another zeolite, Mg was tetrahedrally coordinated to three oxygens of a six-ring plus a fourth oxygen species which might be either a water molecule or a hydroxyl ion. Perhaps addition of one water molecule to each Mg ion would result in a similar coordination in offretite. Disproportionation of a water molecule into a hydroxyl ion and a proton could occur, with the latter condensing with a framework oxygen to yield a framework hydroxyl. The latter might be a Brønsted-acid catalyst (see, for example, ref. 4).

The unusual coordination of Mg in dehydrated offretite results from the spatial restrictions posed by the topology and geometry of the aluminosilicate framework. The four-rings cannot accommodate the Mg ion because of electrostatic repulsion from the Al,Si ions, and the centre of a six-ring offers the best of a set of bad options. Because of spatial restrictions the six-ring cannot pucker sufficiently to yield a near octahedral coordination, though it can pucker to give a triangular coordination. Thus the Mg ion, which would have had a reasonable coordination in the hydrated zeolite, becomes forced into an unusual coordination. A similar situation occurs in dehydrated Type A zeolites, in which transition metal ions have been found in three-coordination at or near the centre of six-rings[10,11].

Full details, including the nature of an erionite intergrowth, will be published elsewhere.

Effect of glass dissolution on corrosion measurements

BOROSILICATE glass is widely used in electrochemical and corrosion studies because of its transparency, rigidity, ease of fabrication and, in particular, its resistance to chemical attack. Some disadvantages of the use of glass at very high temperatures, such as its solubility and the risk of solution contamination in autoclave studies of aqueous electrochemical processes, have been pointed out by Jones and Masterson[1]. In a previous communication[2] from this laboratory it was reported that at temperatures of 80 °C and above, appreciable dissolution of silica from glass can occur and that, in the corrosion of zinc, appreciable amounts of zinc pyrosilicate hydrate are present in the corrosion products. Later[3], figures for the silica contamination of distilled water held in glass vessels at 90 °C were quoted and the possible implication of glass dissolution on the corrosion behaviour of mild steel discussed.

Contamination of aqueous solutions by the test vessel is obviously undesirable in the acquiring of any standard corrosion data and this is particularly so in corrosion rate studies, since silicates—especially metasilicates—have an appreciable inhibitive action on metallic corrosion even when present in low concentrations. Since most of the experiments on the influence of temperature on corrosion rate—at least up to 100 °C and on occasions even above—have been conducted using glass test vessels considerable doubt must be placed on the validity of data obtained in this way.

Comparisons have been made of the corrosion behaviour of abraded mild steel sheet in distilled water at 90 °C using in the one case new 200 × 35 mm test tubes and condensers in borosilicate glass, as normally supplied commercially to laboratories, and in the other case equipment of similar geometry made in transparent fused quartz. Test specimens 30 × 25 × 0.8 mm were fully immersed in 60 cm³ of triply distilled water (pH 5.5, conductivity 84 µS m⁻¹) with the specimens resting on the bottom of the tubes at an angle of about 30° to the vertical. A slow stream of washed air was bubbled through the water just below its surface throughout the test. Specimens were tested in duplicate in separate vessels for periods of 28 and 100 d with the temperature maintained at 90 ± 1 °C throughout the test period.

Within the first few hours of immersion the specimens in glass were subjected to highly localised attack with hardly any rust in the water, whereas those in the quartz tubes had undergone more general corrosion, with the production of an appreciable amount of suspended rust. This difference in appearance of the specimens and the waters in the two types of vessel was maintained throughout the 100-d test period (Fig. 1). Measurements of dissolved monomeric silica, as determined by the colorimetric molybdate method, made on water after 8 d in similar tubes but without specimens present gave values of ~10 p.p.m. SiO_2 in water from glass but <2 p.p.m. SiO_2 in
Fig. 1 *a*, Mild steel specimens in quartz and glass tubes after 28 d at 90 °C. Right, quartz tubes and "rusty" water; left, glass tubes and clear water. *b*, Specimens after removal from these tubes.

water from quartz vessels. Corrosion product was removed from specimens after test by cathodic treatment in 5 % H_2SO_4 + 0.1 % quinoline at 75 °C. Curves of weight loss as a function of time are shown in Fig. 2 and the appearance of typical specimens after removal from the test vessels but before removal of corrosion product are shown in Fig. 1.

We suggest that the presence of enhanced quantities of silica in the water in new glass vessels has resulted in a partial inhibitive effect on the corrosion process. The reason for the higher rate of silica dissolution from glass than from pure silica (quartz) is presumed to be the result of an initial dissolution of alkali metal ions from the glass producing local alkalinity which will facilitate subsequent dissolution of the Si–O network. The corrosion effects observed are, however, not thought to be associated with pH changes in the bulk of the water since the maximum pH values found in glass vessels—without specimens present—were only 7.1 after 28 d and 7.6 after 100 d.

These results have wide implications for corrosion tests in hot waters and will influence conclusions relating to the effect of temperature on the corrosion behaviour of steel, and pro-

Fig. 2 Corrosion–time curves for abraded mild steel in distilled water at 90°C. *a*, Specimens in quartz tubes; *b*, specimens in glass tubes.
bably other metals, in these conditions. Because of the attenuation of corrosion rate with time shown in these experiments, the effect of glass dissolution may have a considerable bearing on the value, or even the existence, of a temperature for maximum corrosion below 100 °C.

Following the 28-d tests the glassware was cleaned in hot HCl, followed by thorough washing in water, and the tests repeated. The corrosion rates then measured over 28-d were similar to those obtained in quartz vessels, and furthermore, the amounts of silica dissolved from these used vessels were lower than those from new vessels. In view of the uncertainty of the effectiveness of any conditioning treatment, however, we consider it inadvisable to rely on this approach to avoid silica contamination of hot waters. We therefore recommend the avoidance of glass vessels for any accurate determinations of corrosion rates in such conditions.

Further work is in hand to determine the magnitude of the effects observed at temperatures below 90 °C.

Unique form of tool-using in two gastropod molluscs (Trochidae)

TOOL-USING, the ability to manipulate an object as a functional extension of the body, has been described in a number of vertebrate and invertebrate species[1]. Although earlier workers regarded it as an indication of insight learning, its significance as a behavioural adaptation[2,3], possibly arising through the novel use of a pre-existing behaviour pattern[4], has been stressed in recent studies.

We report here a form of tool-using in two species of prosobranch gastropod, *Tegula brunnea* and *T. funebralis*, both of which inhabit the intertidal region on the Pacific coast of the US. This behaviour, unlike previously reported instances of tool-using, functions to alter the position of the organism itself rather than displace or modify an extraneous object, and to the best of our knowledge has never been observed in nature or reported from other laboratory studies.

Approximately 30 specimens of both species of *Tegula* (5.8–11.9 g) were collected by the Peninsula Marine Biological Company, Sand City, California, and maintained in our laboratory in a 30 gallon refrigerated Instant Ocean aquarium at 10 °C. They readily fed on brown kelp (*Egregia*).

When the snails were inverted, the propodium was extended over the edge of the shell and engaged in a brief period of probing. If they had access to a solid substrate or an object heavy enough to support their weight, the propodium adhered to the support and pulled the shell over in a manner similar to that reported for other gastropods[5,6]. A gravel substrate consisting of limestone pebbles having an average weight of 0.23 g and an average diameter of 6.0 mm could not sufficiently support the weight of an inverted snail. The prehensile anterior tip of the propodium would grasp a stone and lift it from the aquarium floor. Instead of releasing it immediately, however, the stone was conveyed in a posterior direction to the end of the foot through a series of alternate, retrograde undulations of the sole. This pattern is also typical of the normal locomotory movements of these species[7]. More stones were similarly procured and transferred to the posterior and median portion of the foot where they were accumulated (Fig. 1*a*). The continued
Fig. 1 *a*, Inverted specimen of *T. brunnea* in the process of transferring small stones to the posterior portion of the foot where they are accumulating. Note that the propodium is flexed downward and is ready to probe the substrate for another stone. The diameter of the widest whorl is approximately 2.5 cm. *b*, Inverted specimen of *T. brunnea* that is using a small flat stone as a shovel to gain the leverage to right itself on the sandy substrate.

upward flection movements of the propodium in acquiring stones and the rotating movements of the snail body with the additional weight afforded by the retained stones resulted in the gradual displacement and eventual righting of the snails. If larger stones approximately 35 % of the snail's weight were selected by the foot and extended to the side, the shell was induced to roll and the snail was promptly overturned. When an elongate stone was used, righting occurred by pushing it against the substrate in a shovelling fashion during the contortions and twisting movements of the snail body (Fig. 1*b*). Thus, these species of *Tegula* achieved the leverage necessary to bring the foot closer to the substrate by shifting their centre of gravity upward by the added weight of the retained stones and were able to restore themselves to an upright position.

The righting efficiency was affected and perhaps influenced by the nature of the supporting substrate, the position of the shell on the substrate, and the size of the stones used. There was little or no difference between the overall behavioural pattern of the two species, observed on approximately 60 occasions.

Both *T. brunnea* and *T. funebralis* possess a relatively heavy, turban-shaped shell which tends to overturn them after they have been dislodged from the substrate. The righting ability of these species of *Tegula* is significant as inverted snails unable to right themselves could not feed and would be particularly subject to predation by carnivorous echinoderms such as *Pisaster*, to which these species of *Tegula* respond by rapid flight movements[8].

T. funebralis, which has a patchy distribution on the Pacific coast of the US, is found in large numbers on moderately exposed rocky shorelines and is only encountered rarely in sandy areas[9]. At Mukkaw Bay, Washington, *T. funebralis* is particularly abundant in areas in which small cobbles and pebbles are present rather than solid bench rock[10,11]. From our observations of the Washington state coastline a few years ago, these small cobbles are several centimetres larger than the small stones used in our aquarium study. But as the snails move down the beach they may encounter substrata on which stone manipulation may have some adaptive significance. This would be particularly true in areas in which small stones or gravel would accumulate—for instance, on the bottoms of tidal pools and between larger rocks.

It has been suggested that the large operculum of strombid gastropods may have evolved partly to compensate for the lack of a large, long foot which could be used for righting movements[7]. We suggest that the stone manipulation as a form of tool-using may have similarly evolved as a compensatory behavioural adaptation.

Significance of dorsoventral abdominal vibration among honey-bees (*Apis mellifera* L.)

IN observation hives worker honey-bees may often be seen to perform a behaviour pattern called dorsoventral abdominal vibration (DVAV)[1], the jerking dance[2], or shaking[3]. It has been suggested[4-6] that it serves to prepare bees for flight, mainly on the grounds that the only occasions on which queen honey-bees are vibrated (subjected to DVAV) are before their orientation and mating flights and before swarming. But conclusive evidence has not been provided, and von Frisch regards the function of DVAV as still being obscure[2]. Gahl[7] also leaves this question open.

The African bee, *Apis mellifera adansonii* L., is eminently suitable for study because, unlike European races, it has the habit of absconding if the nesting site becomes unfavourable for some reason. If DVAV does promote flight it should reach its highest level in a colony about to abscond, as this represents an extreme case of flight activity in which all the bees leave the nest together.

Detailed observations were made on two colonies in two-frame observation hives, one of which consisted of about 4,500 workers and the other of about 3,000. On the day of absconding the queens were not vibrated at all and the frequency of DVAV among the workers was extremely low. During numerous scans of the whole hive usually only one bee, and often none, could be seen performing DVAV at any time. DVAV is thus not a prerequisite for flight of either queens or workers.

This conclusion received support from observations made possible by another behavioural characteristic of the *adansonii* bee. In favourable temperature conditions foragers may be active at very low light intensities and the number leaving a hive often reaches the diurnal peak shortly after first light. In a colony of approximately 3,500 bees this exodus of foragers was compared on two occasions with the first DVAV performances
Fig. 1 Frequency with which a queen honey-bee was vibrated during a swarming cycle. *a*, First queen cup cell constructed. *b*, First egg laid in a cup cell. *c*, First queen cell sealed. *d*, Colony swarmed on March 20, 1975. *e*, Queen departed with swarm at 1204. The observation hive contained three Langstroth brood frames and the bees numbered 9,500–10,000 at the time of swarming. DVAV frequency was sampled for 90 min each day until the first queen cell was sealed. On the day of swarming recording was continuous.

of the day after the usual nocturnal cessation of the behaviour. In both cases well over 1,000 bees left the hive before the first DVAV was recorded. These observations do not agree with those of Allen[5] on European bees, in which it seemed that DVAV among workers probably preceded the first flights of the day.

As maximal flight activity was associated with minimal DVAV frequency in the above examples, it was postulated that DVAV is a flight inhibitor and not a flight activator as suggested by Hamman and Allen[4-6]. These mutually exclusive hypotheses were tested as follows.

Allen has shown that the frequency with which a queen is vibrated rises to a peak on the day of swarming[3]. It might reasonably be predicted from the activation hypothesis that this frequency would remain high right up to the time of the queen's departure with the swarm, whereas the inhibition hypothesis predicts that it would have to drop sharply before the queen could fly. Figure 1 shows that during the last 5 h before departure of a swarm the DVAV frequency did, in fact, decline rapidly. Compared with the peak of 291 vibrations h[-1] on the previous day there were only 25 during the last hour before swarming. Of these, only one occurred during the last 20 min. A similar result was obtained in a second trial and it agrees closely with a previously uninterpreted observation[1] that vibrations of the queen ceased altogether 30 min before a colony swarmed.

More direct evidence in favour of the inhibition hypothesis was obtained during a study of the behaviour of a virgin queen reared by a colony of about 1,500 bees. From the time of her emergence until the destruction of the last rival queen cell more than 8 h later this queen was not seen to be vibrated at all and she moved rapidly over the combs during the whole of this period except when being fed. She was first vibrated less than half an hour after the last queen cell had been attacked when, during a 6-min period, several bees vibrated her a total of twelve times. After the first three she slowed down considerably and after the next nine she stopped altogether for the first time. Thereafter, her activity diminished markedly (Table 1).

After repeating these observations on a second virgin queen with essentially similar results, it was concluded that DVAV is not exclusively a flight inhibitor, but a non specific activity inhibitor. It seems, furthermore, that one of its functions is the regulation of a queen's responses to the presence of queen cells. This latter conclusion was borne out by events recorded in two colonies that changed the direction of their behaviour from swarming to absconding.

Both colonies occupied two-frame observation hives and consisted of an estimated 4,500–5,000 bees. In the first, one sealed and two unsealed queen cells were discovered on December 17, 1974, but the colony was prevented from swarming by 4 consecutive days of overcast weather with intermittent rain and on day 5 the queen cells were destroyed. Figure 2 shows the frequency with which the queen was vibrated both during this

Fig. 2 Frequency with which a queen honey-bee was vibrated during a change in behaviour from swarming to absconding. *a*, Swarm cells discovered. *b*, Swarm cells destroyed. *c*, Colony attempted to abscond, but was prevented by a queen excluder at the hive entrance. *d*, Colony absconded after removal of the queen excluder.

period and on the following days until the colony absconded. The destruction of the cells coincided with the virtual cessation of DVAV, but it was not observed whether the queen initiated the attacks on them. In the second colony, however, the queen was seen to attack two of the three sealed queen cells present following a sharp drop in the frequency with which she was vibrated. In this case the cause of the change in behaviour was unknown, the weather being favourable to swarming at the time.

In view of these observations, it seems that the response of a mated queen to the presence of swarm cells is very similar to that of a virgin to rival queen cells. She is strongly motivated to destroy them, but is prevented from doing so by a reduction in the level of her activity through the agency of DVAV. The observed increase in the frequency with which she is vibrated as the swarming cycle progresses probably reflects her increasing tendency to attack the swarm cells as their occupants mature.

Table 1 Relationship between DVAV, presence of rival queen cells and movement of a virgin queen

Observation period		No. of occupied queen cells	No. of times queen vibrated	Movement of queen	
Starting time	Duration (min)			Duration (min)	%
0530	30	4	0	30	100
0824	30	3	0	30	100
1005	15	3	0	15	100
1100	10	3	0	10	100
1200	10	2	0	10	100
1307	30	2	0	30	100
1416	30	0	22	24	80
1540	10	0	4	7	70
1605	10	0	0	3	30
1705	10	0	0	2	20

Further evidence in favour of the inhibitory effects of DVAV on both queen and worker honey-bees, and the results of investigations into several of its functions will be reported in detail elsewhere.

Occurrence of "pockets" of very small cells in adipose tissue of the guinea pig

THE concept of hyperplastic obesity, wherein the excessive number of cells in the adipose depots is thought to originate during overnutrition in early life, has evolved in the laboratories of Hirsch[1], Salans[2] and Björntorp[3]. The estimation of the number of adipose cells relies on (1) a measurement of total body fat and (2) a measure of the mean cell size. The two methods most commonly used for measurement of cell size are based on the microscopic examination of cells in a piece of fixed tissue[4], or on sorting of cells in to size ranges by an electronic cell counter after dispersion of the tissue into a free cell suspension[5].

An advantage of the microscopic method is that the disposition of cells within the tissue can be observed directly. In general it seems that cells of different sizes, whether they follow a normal or a polymodal distribution, are randomly distributed throughout the tissue. Nevertheless our studies have revealed a distinctly heterogeneous distribution of fat cells in different adipose tissues of the guinea pig. We shall describe the occurrence of isolated "pockets" or clusters of cells very much smaller than the general size range within the tissue.

In these studies the guinea pigs were of the Frant strain, 3 months old, fed *ad libitum* Oxoid modified diet 18, with cabbage twice a week.

For cell sizing, a modification of the microscopic method of Sjöström *et al.*[4] was used. From each tissue site, four frozen sections (100 μm) were cut and in each section 10 cell diameters were measured in one direction and then 10 in another direction perpendicular to the first. Each measurement was the maximum diameter obtainable by focusing through the section. The volume of each cell was calculated by computer making the assumption that adipocytes are spherical[4,6]. No assumptions have been made about the distribution of the diameters, but the volume of each cell has been individually calculated and an average obtained from all the cells observed.

The volume of the adipocyte is essentially the volume of the triglyceride contained in it[4,5]. The proportion of tissue occupied by adipocytes is represented by its triglyceride content, determined gravimetrically after ether extraction.

We have defined a pocket as a cluster of four or more cells distinctly smaller than the general size distribution within the tissue (Fig. 1a and b). The clusters, which are sometimes seen around blood vessels, have been observed in all the tissues examined (three subcutaneous sites: interscapular, anterior and posterior abdominal, and three deep sites: parametrial or epididymal fat pads and perirenal adipose tissue). The following discussion relates only to the frequency of pockets in fat taken from the posterior abdominal region of a female guinea pig. No attempt has been
Fig. 1 *a*, Small pocket and surrounding "normal" cells. *b*, Large pocket and surrounding "normal" cells.

made to quantify pocket frequency at other sites although qualitatively it seems to vary from site to site.

Pocket frequency was determined by examining 10 serial sections of 100 μm thickness in a block of tissue measuring 6 × 11 × 1 mm (66 μl). All cells in a section were scanned and all pockets noted. In this particular block there were 90 pockets containing an average of 5.67 cells per pocket (maximum 9, minimum 4). Therefore there were 510 pocket cells in the tissue block.

The mean cell diameter of the "pocket cells" was 59 ± 11 (s.d.) μm (Fig. 2a) and of the "normal cells" 173 ± 31 (s.d.) μm (Fig. 2b). These data correspond to a cell volume of 0.11 nl (0.10 μg triglyceride per cell) for "pocket cells" and 2.72 nl (2.48 μg triglyceride per cell) for "normal cells". There is no overlap in the size ranges of the two population samples.

The triglyceride content of the tissue was 91 ± 3.1 % (± s.d. on six determinations). The volume of the tissue block occupied by fat cells was therefore 60.060 μl.

The number of cells in the 66-μl block of tissue is essentially the volume occupied by cells divided by the mean volume per cell. The presence of pocket cells complicates the calculation because of the difficulty of determining mean cell volume. The calculation has been done three ways.

(1) The volume occupied by "normal" cells is obtained by subtracting the volume occupied by 510 "pocket" cells from the total volume of tissue occupied by fat cells. The number of "normal" cells in this space is therefore 22,093 and the total number of cells is 22,603.

(2) If the observer recognises the existence of pocket cells but chooses to ignore them, the total cell number would be underestimated by 490 or 2.2 %.

Importance of fixed sections in the study of adipose tissue cellularity

IN the study of obesity in human subjects and animal models attention has recently been directed to the size and number of cells in adipose tissue. Measurements of fat cell sizes have led to the classification of hypertrophic, hyperplastic or mixed forms of obesity in animals[1] and man[2]. A study of the literature concerning animals, however, reveals wide discrepancies in reports of the degree of hypertrophy or hyperplasia contributing to the expansion of fat mass observed in genetically[3,4] or experimentally obese animals[1,5–10]. These discrepancies have arisen not only because different species and strains of animals were used and different fat depots were sampled, but also because different methods were used to determine fat cell size and number.

Two of the most popular methods used for determining fat cell size are the osmium fixation of fat cells[11] and the sizing of isolated cells prepared by collagenase digestion[12,13]. Both methods can be used to determine the distribution of cell sizes within a population and will yield a value for the mean cell diameter of the population. Neither method, however, gives any information about the *in situ* distribution of cell sizes or the
(3) If the observer includes a pocket of, say, four cells in his measurements, the calculated mean cell diameter would thereby be reduced and the total number of cells would be overestimated by 622 or 2.8%.

The results of this study reveal a distinct population of small adipocytes in the adipose depots of the guinea pig. Their mean volume per cell is only 4% that of "normal" cells and they represent only 2.3% of the cell population in terms of numbers and constitute only 0.09% of the volume occupied by adipocytes. The error introduced therefore, by inclusion or omission of these cells during the microscopic determination of cell size is small. The paper by Ashwell *et al.* which follows[7] indicates, however, that the pocket phenomenon is more widespread than hitherto realised and we cannot rule out the possibility that in some tissues the frequency may be much higher rendering the microscopic method of determining mean cell size of dubious value.

But the results do highlight the desirability of microscopic examination of adipose tissue. Techniques based on sorting cells after digestion of the tissue would certainly reveal polymodality but would not distinguish between random occurrence of small cells throughout the tissue and the clustering of small cells in pockets as observed here. Moreover by detailed microscopy it may be possible to determine whether the pockets themselves are randomly distributed in the tissue, or whether their association with blood vessels is more than fortuitous. This raises the question of interpretation of the pockets in terms of tissue development. Preliminary observations suggest to us that pocket frequency decreases with age and this may indicate the pockets represent loci of most recent fat cell recruitment from a bed of pre-adipocytes. This possibility is being investigated by autoradiographic examination of tissue exposed to tritiated thymidine.

histological or pathological changes that might occur in the adipose tissue. We have studied numerous samples of adipose tissue from various sites of genetically obese mice and their lean littermates, and we propose that examination of fixed sections is essential if maximum information about adipose tissue cellularity is required.

Figure 1 shows a low power photograph of a fixed section of subcutaneous adipose tissue from a 4-month-old genetically obese mouse (C57BL.6J.ob/ob). The black circles show "pockets" of small cells which have developed between areas of larger cells. Figure 2 shows a high power photograph of one pocket. These pockets are particularly evident in the perirenal and subcutaneous fat depots and are not quite so obvious in the epididymal or parametrial depots. We have examined fat from obese mice from 4 to 40 weeks old and have seen pockets at all ages in obese mice.

A photograph with a final magnification of ×210 showing the same field as Fig. 1 was used for sizing the fat cells. A representative area of large cells and pocket cells was chosen and this contained 153 cells. Cell diameters were measured with a ruler in two directions for each cell: the maximum diameter and the diameter perpendicular to this. The average of these two diameters was calculated and three determinations of mean cell diameter ±s.e.m. were made. For all cells, mean cell diameter was 70.5 μm ± 2.96; for normal cells, mean cell diameter was 89.2 μm ± 2.66; for pocket cells, mean cell diameter was 28.3 μm ± 0.72.

Several studies of adipose tissue development have concentrated on development of the gonadal fat pads (for example, ref. 14) probably because these are a very convenient source of tissue. Our observations on obese mice and also on normal rats have convinced us that the gonadal fat pads are unrepresentative

of other fat depots in animals and are certainly unrepresentative of human adipose tissue. Conclusions drawn from their study should be interpreted with caution. The photographs of fixed sections leave no doubt that pockets of small cells exist in some fat depots and it is tempting to speculate that these pockets represent loci for new fat cell formation. The development of adipose tissue has usually been studied in young growing animals and so far there is no general agreement as to the origin of fat cell precursors. Some investigators believe that fat cells arise from ordinary fibroblasts and others believe that they arise from special connective tissue cells, distinct from fibroblasts (see review in ref.15). A detailed study of the location of these pockets of small cells should yield more information in this field.

We thank Miss Janet McKenzie for the photomicrographs and Dr M. Cawthorne, Beecham Research Laboratories for obese mice.

Pattern of fat and lean tissue deposition in children

THERE is evidence[1] of a prolonged change in body composition in children who have been overfed during the first year of life, and it has been suggested[1,2] that there may be a critical period for fat deposition and adipocyte formation. We have examined published data on growth and body composition of normal children, and have found that these reveal cyclical changes in fat and lean tissue deposition which confirm the existence of critical periods, and offer an explanation for the observed changes in body composition.

From tables of average body weight extending from 13 weeks after conception[3] and from birth to 17 yr (ref. 4), we have calculated increments in body weight per unit time (ΔM). Similarly, the increments in body fat mass (ΔF) can be calculated from data on average body composition at various ages[3,5]. The difference between ΔM and ΔF at any given age is taken to be the change in lean tissue (ΔL). Figure 1 shows how the proportion of lean tissue deposited ($\Delta L/\Delta M$) varies with age throughout the growth period.

The changes shown are large and cyclical, and are unlikely to be artefacts in spite of the use of data from different sources for the pre- and postnatal periods. In early and midfoetal life, the deposited tissue is almost entirely lean, but fat deposition is favoured nearer full term. Throughout the first year of life, fat deposition predominates, but the proportion of lean rises to a maximum again at about 4 yr, when very little of the weight gained is deposited as fat. This cycle is repeated twice more,
Fig. 1 Variations with age in the ratio between lean (ΔL) and fat (ΔF) deposition in normal males aged from 26 weeks after gestation to 16 yr.

We have now developed the model so as to simulate energy balance and body composition changes during growth. Instead of a fixed ratio of lean to fat tissues, the time sequence of ratios shown in Fig. 1 is programmed into the model. Initially, the various parameters were adjusted so that when the energy intake is made to follow the sequence of values at different ages recommended by FAO/WHO (ref. 6), the body weight and composition remain close to the standard values from which Fig. 1 was derived.

The model was then used to study the effects of departures from the recommended energy intake. Thus, for example, Fig. 2 shows the deviations from expected weight and fat content which result from over- or underfeeding by 20% during the first year after birth. Note that the effects on body composition are marked, and that they persist throughout the following 9 yr of 'normal' feeding even though total body

with a return to predominantly fat deposition during the period between 6 and 10 yr, lean again between 12 and 14 yr (the period of the adolescent growth spurt), finally swinging back to fat deposition at 17 yr. In adults, changes in body composition consequent on experimental underfeeding, indicate that the lean–fat deposition ratio varies from about 50% for 'lean' types of individual down to 5% for 'obese' types.

In a computer model, which simulates weight maintenance in the adult, food intake energy is compared each day with energy expended for maintaining metabolic activity and for physical work (P.R.P. and A.E.D., unpublished). When positive, the difference is deposited as fat and lean tissue in proportions which are fixed for a particular physiological type of person (that is, tending to be 'lean' or 'obese'). If the daily energy balance is negative, sufficient tissues are mobilised to make up the deficit, but still in the same proportions. The model uses a random number generator to simulate the effects of daily variations in intake and expenditure, and predicts the time course of changes in body weight and composition that will result from feeding specified levels of daily energy intake.

Fig. 3 Predicted deviations from expected mass for age when ratio of lean–fat tissue deposition is altered by $\pm 10\%$, and a normal calorie intake is given. $\triangle$ and $\bigcirc$, Fat and total body masses with a 10% reduction in the lean–fat ratio. $\blacktriangle$ and $\bullet$, Fat and total body masses with a 10% increase in lean–fat ratio.

weight rapidly returns to near the expected values. This confirms clinical findings by emphasising the importance of over- or underfeeding during early life.

The programmed sequence of lean–fat tissue deposition ratios can also be changed. Thus, Fig. 3 shows the effects of changes $\pm 10\%$ imposed on all the values shown in Fig. 1, while maintaining energy intakes at the normal recommended levels. The upward shift produces a lean, ectomorphic individual; the downward, a plump endomorph. As has been mentioned above, there is experimental evidence that leanness or obesity in adults is associated with different values of the ratio $\Delta L/\Delta M$, and these studies support the idea that changes in the 'settings' of the ratio may explain many of the observed features of the development of ecto- and endomorphy in children. The metabolic mechanisms and the degree of genetic dependence of the ratios are unknown, but will clearly be important areas for future research.
Fig. 2 Predicted changes in body mass in children who have been given a 20% deficit or excess in calories from birth to 1 yr and then a normal calorie intake. Changes are shown as percentage of expected mass for age. $\triangle$, and $\bigcirc$, Fat mass and total body mass with excess calories. $\blacktriangle$ and $\bullet$, Fat and total body mass with a calorie deficit.

Eosinophils as mediators of antibody-dependent damage to schistosomula

WE have reported previously[1] that damage to schistosomula can be assayed by measuring release of ^{51}Cr from labelled larvae. Using this technique, we have shown that schistosomula can be damaged by a combination of normal human peripheral blood leukocytes and of heat-inactivated sera from patients infected with *Schistosoma mansoni*[1]. We now present evidence that the eosinophil is substantially the most active mediator of damage in normal peripheral blood, but that cells from eosinophilic patients are relatively inactive.

Schistosomula were prepared by allowing *S. mansoni* cercariae to penetrate mouse skin *in vitro*[2], and were stored overnight at 4 °C before labelling with ^{51}Cr as previously described[1]. Sera from five patients infected with *S. mansoni* were used as sources of anti-schistosomular antibody in different experiments. These sera had previously been tested for cell-dependent cytotoxic activity to schistosomula, and dilutions (1/24 to 1/90) were chosen which had given at least 50% cytotoxicity in the presence of unpurified leukocytes at an effector to target ratio of 2,000 : 1 over an 18-h incubation period. All sera were inactivated at 56 °C for 1 h before use, and were diluted in HEPES-buffered Eagle's minimal essential medium containing 10% heat-inactivated

foetal calf serum (MEM/FCS). Effector cells from uninfected laboratory workers were prepared from heparinised blood by sedimentation of 5 volumes of blood with 1 volume of 4.5% dextran in phosphate-buffered saline for 30 min at 37 °C. Cells from the leukocyte-rich supernatant were washed twice in MEM/FCS, and were subjected to various purification procedures before testing for cytotoxicity. Eosinophil counts in the peripheral blood of the four normal subjects studied ranged from 90 to 240 mm^{-3}. Unpurified leukocyte-rich preparations after dextran sedimentation contained 3–6% eosinophils. The cytotoxicity test was carried out in 7×38 mm sterile plastic tubes : each of four replicate tubes contained 0.1 ml of labelled schistosomula (500 ml^{-1}), 0.1 ml of diluted serum, and 0.1 ml of effector cells at various concentrations. After overnight incubation, half of the supernatant was withdrawn, and percentage isotope release was calculated from the count rates in both the pellet and the supernatant tubes. Statistical analyses were carried out on the logarithmically-transformed percentage isotope release data, using multifactorial analysis of variance and Duncan's multiple range tests[3]. Each of the experiments described here was repeated at least three times, with comparable results.

Titration of unpurified peripheral blood leukocytes for their ability to induce release of ^{51}Cr from schistosomula in the presence of antibody revealed that isotope release was proportional to the logarithm of the effector to target ratio over a range of ratios from 50 : 1 to 5,000 : 1 (Fig. 1). The high ratios required presumably reflect the multicellular nature of the target organism.

Subsequent attempts to purify the effector cell showed that cytotoxic activity was progressively lost during repeated cycles of incubation with carbonyl iron and magnetic extraction. Although recent work[4] has shown that some antibody-dependent effector cell activities in the mouse may be removed by incubation with uncoated but not with protein-coated carbonyl iron particles, this finding was initially taken to imply that the effector cell was phagocytic. It was then found that after centrifugation of the starting effector cell preparation over Ficoll–Hypaque[5], the cells recovered from the pellet were approximately 10 times more active than those recovered from the interface (Fig. 2). For example, pellet cells induced 33% isotope release at a cell to target ratio of 90 : 1, whereas for the interface cells a ratio of 1,020 : 1 was required to induce the same level of release. The differential counts for the two cell preparations (legend to Fig. 2) show that the pellet preparation contained 88% polymorphonuclear cells (PMN) and 12% mononuclear cells (MN), whereas the interface contained 9% PMN and 91% MN. From these differential counts, it can be calculated that the ratio of PMN to targets in the preparation of pellet cells which gave 33% release

Table 1 Reduction of cytotoxicity after pretreatment of effector cells with ANS or AES

Treatment	Complement	ANS + complement	AES + complement
Ratio of total effector cells to targets required for 30.5% isotope release	530	1,000	3,200
% reduction in cytotoxicity per added cell	0	47	83.5
% eosinophils killed	5	20	80
% neutrophils killed	5	100	10
*Ratio of viable eosinophils to targets in preparations giving 30.5% release	20	32	26
*Ratio of viable neutrophils to targets in preparations giving 30.5% release	302	0	1,728

*Based on a differential count in the complement control of 4% eosinophils, 60% neutrophils, and 36% mononuclear cells.

Fig. 1 Titration of effector activity of unpurified peripheral blood leukocytes, containing 62% neutrophils, 5% eosinophils and 33% mononuclear cells. Abscissa: $\log_{10}$ ratio of unpurified effector cells to target schistosomula. Ordinate: percentage isotope release from schistosomula after 15 h incubation. Analysis of variance: "dilution" effect $P < 0.001$ ($F = 16.7:9$ and 30 degrees of freedom). Multiple range tests:"antibody alone" significantly less ($P < 0.05$) than 200:1 ratio and all higher ratios.
Fig. 2 Titration of effector activity of partially purified polymorphonuclear leukocytes and mononuclear cells. Cells from the leukocyte-rich supernatant of a heparinised, dextran-sedimented peripheral blood preparation were washed twice in MEM/FCS and overlayed on 10 ml of Ficoll-Hypaque[b]. This preparation was centrifuged at 400g for 40 min, and the interface layer and the pellet were washed twice in MEM/FCS before dilution and testing for cytotoxicity in the presence (————) or absence (— — —) of antibody. ●, Pellet cells, containing 8% eosinophils, 80% neutrophils and 12% mononuclear cells; ■, interface cells, containing 0.7% eosinophils, 8% neutrophils and 91% mononuclear cells. Analysis of variance: ("with antibody" only): "purification" effect $P < 0.001$ ($F = 100.6:1$ and 30 degrees of freedom). Interaction "purification" × "cell dilution" $P > 0.05$ ($F = 0.92:4$ and 30 degrees of freedom), indicating that the slopes of the titration curves are not significantly different.

was almost identical to the PMN to target ratio in the interface preparation which gave the same level of release (79 : 1 and 89 : 1 for the pellet and interface preparations respectively). In contrast, the ratios of MN to targets in these two preparations differed by two orders of magnitude (11 : 1 and 928 : 1 for the pellet and interface preparations respectively). Therefore, for a mononuclear cell to be responsible for damage, there would have to be a 100-fold selective purification of that particular mononuclear cell into the pellet. No evidence for this was available from other systems: it was therefore concluded that the active cell was a member of the PMN series. Since, however, both neutrophils and eosinophils were enriched to a comparable extent in the pellet (legend to Fig. 2), it was not possible at this stage to conclude which type of PMN was active.

The anti-human eosinophil serum (AES) and anti-human neutrophil serum (ANS)[6,7] were then used in an attempt to identify the particular PMN involved. Unpurified affector cells were treated with AES or ANS and complement, and after subsequent washing were titrated for antibody-dependent cytotoxicity to schistosomula (Fig. 3 and Table

1). The AES and ANS reagents were also tested for direct cytotoxicity to purified neutrophils[7] and eosinophils[8] by Trypan blue exclusion (Table 1). The number of total effector cells in each preparation required to induce equivalent levels of isotope release was calculated from Fig. 3. Since the release induced by the AES-treated preparation was so low, the level chosen for comparison (30.5%) was that induced by the AES-treated sample at the highest cell concentration tested. From the total number of cells required, the reduction in cytotoxic activity per added cell could then be calculated for each preparation (Table 1). This reduction was related to the reduction in viable eosinophils, but not to the reduction in viable neutrophils. Equivalent levels of isotope release were induced by preparations containing comparable numbers of viable eosinophils, whereas there was no relationship between isotope release and the number of viable neutrophils (bottom two lines of Table 1). Since the starting preparation contained 4% eosinophils and 60% neutrophils, it could be calculated that each eosinophil was at least 27 times more active than each neutrophil in mediating cytotoxicity. Furthermore, the sum of the inhibitions induced by AES and ANS alone was greater than 100%, and part of the ANS effect may be artificial, since it may have been attributable to competitive inhibition of eosinophil cytotoxicity against antibody-coated schistosomula by the large numbers

Fig. 3 Reduction of cytotoxicity after pretreatment of effector cells with AES and ANS. Unpurified leukocytes from a heparinised, dextran-sedimented peripheral blood preparation were washed twice in MEM/FCS. Aliquots were treated with MEM/FCS alone (●), with AES absorbed once with neutrophils and four times with erythrocytes, at a 1/10 final dilution (▲), or with ANS absorbed four times with erythrocytes, at a 1/10 final dilution (■). All preparations were incubated for 30 min and washed once with MEM/FCS. Fresh guinea pig serum (1/6 final dilution) was then added, and the preparations were incubated for a further 45 min at 37 °C before washing and testing for cytotoxicity to antibody-treated schistosomula. Analysis of variance: "antiserum effect" $P < 0.001$ ($F = 22.2:2$ and 36 degrees of freedom). Interaction "antiserum" × "cell dilution" $P > 0.05$ ($F = 2.35:6$ and 36 degrees of freedom), indicating that the slopes of the titration curves are not significantly different.

of antibody-coated neutrophils present in the preparation. This argument does not apply to the AES effect, since the numbers of antibody-coated eosinophils present in the AES-treated preparation would be too small to inhibit the much larger numbers of neutrophils. The inhibition induced by ANS therefore was more likely to be artificial than that induced by AES.

In contrast to these results, cells from three patients with marked eosinophilia (21% to 38%) induced by schistosomiasis or other helminth infections did not show the increase in cytotoxic activity which would be predicted if all eosinophils were equally active. One interpretation is that eosinophils from such patients may be blocked or inactivated by the immune complexes that elicited the eosinophilia. This possibility is now being tested.

These findings indicate that the major, and possibly the only, cell type in normal human peripheral blood capable of inducing antibody-dependent, complement-independent damage to schistosomula is the eosinophil. Other mechanisms for damaging schistosomula in vitro have been described[2,6-11], but the eosinophil-mediated reaction described here is potentially of particular importance in the light of subsequent findings (A.A.F.M., K. S. Warren and P. A. Peters, unpublished) that administration of AES abolishes resistance to reinfection in mice infected with S. mansoni. The observations described here, therefore, not only reflect a new eosinophil activity, but may also provide a useful model for analysing one mechanism of immune damage to schistosomula that does have relevance in vivo.

Mediation of serum-induced changes in cyclic nucleotide levels in cultured fibroblasts by cyclic nucleotide phosphodiesterase

CELL cultures of untransformed fibroblasts can be maintained in a stationary or relatively quiescent state by adjusting serum concentrations to suboptimal levels[1]. Addition of excess serum to quiescent cell cultures causes a rapid decrease in the intracellular concentration of cyclic AMP and a rapid increase in cyclic GMP levels[2-5]. These alterations in cyclic nucleotide concentrations precede the

Fig. 1 BHK 21/c13 cells from surface cultures in 75 cm² Falcon tissue flasks were washed once with Eagle's minimal essential medium (MEM) containing 1% foetal calf serum. After trypsinisation (0.25% trypsin) cells suspensions were made in MEM and 1% foetal calf serum. 1 × 10⁶ cells were seeded in 75 cm² Falcon culture dishes with 10 ml of MEM and 1% foetal calf serum and were incubated for 48 h at 37 °C. All cell cultures were then supplemented with an additional 10% foetal calf serum and incubated for the indicated times after which they were collected by scraping and centrifugation at 500g for 10 min. The cells were washed twice in Hanks' balanced salt solution; homogenised in 40 mM Tris (pH 8.0), and cyclic AMP and cyclic GMP phosphodiesterase activities determined according to the methods of Thompson and Appleman[9,10]. Four culture dishes were pooled for each enzyme activity determination. The cyclic nucleotide activity is shown in pmol per mg protein per min. These data illustrate the results of a typical experiment. a, Cyclic AMP phosphodiesterase activity measured at a cyclic AMP concentration of 1.0 µM; b, cyclic AMP phosphodiesterase activity measured at a cyclic AMP concentration of 50 µM; c, cyclic GMP phosphodiesterase measured at a cyclic GMP concentration of 1.25 µM.

changes in macromolecular synthesis (such as RNA, protein and DNA synthesis) and growth induced by serum, and constitute one of the earliest steps in the sequence of events before the initiation of growth. The mechanism responsible for altering cyclic nucleotide concentrations in response to serum or other growth stimuli has not been elucidated however. We show here that a rapid alteration in cyclic nucleotide phosphodiesterase activity occurs when serum is added to quiescent fibroblasts and demonstrate that this alteration could mediate the changes in cyclic nucleotide levels.

Figure 1 illustrates the changes in phosphodiesterase activities seen after addition of 10% foetal calf serum to BHK 21/c13 (BHK cells, 1 × 10⁶ cells per dish) cultured in media containing 1% foetal calf serum. Fig. 1a shows a 4–5-fold increase in cyclic AMP phosphodiesterase activity, measured at 1 µM cyclic AMP concentrations, within the first 15 min of serum addition. The total cyclic GMP
Fig. 2 Cells from ten culture dishes (1 × 10⁶ cells per 75 cm² grown and collected as described in Fig. 1) were pooled, enzyme activities determined, and Lineweaver–Burk plots analysed. ●, Cells in 1% serum for 36 h; ○, cells that received 10% foetal calf serum for the final 30 min of incubation.

phosphodiesterase activity is shown to be reduced threefold at this time (Fig. 1c). Fig. 1b demonstrates an increase in total cyclic AMP phosphodiesterase activity after the addition of 10% serum. We have found that the cyclic AMP phosphodiesterase activity at zero time measured at 1 μM cyclic AMP may vary depending on the time of incubation in the 1% serum media and the serum lot used. An average increase of 3.5-fold (four experiments having a range of 2.8–5.3-fold increase) was seen, however, after addition of 10% serum.
Fig. 3 Cells were prepared as described for the experiments in Fig. 2 with the exception that some cultures were incubated in cycloheximide (0.2 mM) for three hours before the addition of 10% serum. *a*, Cells in MEM with 1% serum and cycloheximide for the final 3 h incubation; *b*, additional 30 min incubation in 10% serum with no cycloheximide; *c*, same as in *a* except that after a 3 h preincubation in cycloheximide 10% serum was added to the cultures for the final 30 min.

Kinetic analysis of cell homogenates showed that the cyclic AMP phosphodiesterase of the cells incubated in medium containing 1% serum had an apparent K_m of 15 μM cyclic AMP (Fig. 2). Cyclic AMP phosphodiesterase activity from the cells which had been incubated for an additional 30 min in medium with 10% serum, however, showed activity with anomalous kinetic behaviour and apparent K_m values of 3 and 20 μM cyclic AMP. A 5-fold decrease in the K_m of cyclic AMP phosphodiesterase was evident within 30 min after the addition of serum to quiescent BHK cells.

To determine whether protein synthesis is required to obtain a serum-induced cyclic AMP phosphodiesterase
Fig. 4 Culture dishes (1 × 10⁶ cells per plate) were incubated for 36 h. At zero time 10% serum was added to the plates and at the indicated times cells were collected for cyclic AMP determinations. To determine cyclic AMP content, the medium was poured from the plate and 0.05 N perchloric acid was added before scraping the cells from the plates. Cyclic nucleotide concentration was analysed by the radioimmunoassay according to Steiner *et al.*[11] as modified by Thompson and Williams[12].

activity with a greater apparent affinity for cyclic AMP, BHK cells were incubated as described for Fig. 2, except that during the 3 h before the addition of 10% serum either cycloheximide (0.2 mM) or a vehicle control was added. Following this treatment, cultures were either retained in 1% serum or had 10% serum added for the final 30 min incubation. The Lineweaver–Burk analysis[6] of the homogenate activities from cells undergoing these treatments is shown in Fig. 3. The phosphodiesterase activities of the cells maintained in 1% serum in the presence of cycloheximide have a lower affinity (higher apparent K_m) for cyclic AMP than do the cells receiving 10% serum in the presence of cycloheximide (comparison of Fig. 3a with b and c). Analysis of the quiescent cells receiving additional serum did not reveal any differences in kinetic profiles between the vehicle control cells and those that received cycloheximide (Fig. 3b and c). These data indicate that the rapid change in substrate affinity of the cyclic AMP phosphodiesterase activity seen in quiescent cells in response to growth-promoting concentrations of serum takes place in the absence of protein synthesis.

Cyclic AMP levels decrease rapidly following the addition of 10% serum to quiescent BHK cells. The decrease in cyclic AMP levels is evident within 15 min after addition of serum (Fig. 4) and correlates with the increase in activity of cyclic AMP phosphodiesterase measured at 1 μM cyclic AMP (Fig. 1). Schröder and Plagemann reported that serum contains a cyclic nucleotide phosphodiesterase[7]. We also detected phosphodiesterase activity in foetal calf serum but

the data suggest little if any contribution of this enzyme to our experimental results. First, the specific activity of the serum enzyme using micromolar substrate concentrations of cyclic AMP in the assay is not sufficient to account for the changes in cyclic AMP phosphodiesterase activity seen in BHK cells after serum addition unless the cells did selectively extract all of the serum enzyme activity. Second, the serum enzyme can also hydrolyse cyclic GMP but we found a decrease in cyclic GMP phosphodiesterase activity in response to the addition of serum. Finally, previous studies with surface cultures of confluent BHK cells demonstrated a reduction in total phosphodiesterase activity when these cells were diluted to a lower density in 10% foetal calf serum[8].

These data support our hypothesis that substrate affinities of the cyclic AMP phosphodiesterase activities are altered as a response to certain conditions that affect cell growth[8]. These same conditions result in a concomitant, rapid and transient change in intracellular cyclic nucleotide levels. Thus, the substrate affinity as well as the amount of phosphodiesterase could be involved in regulation of cyclic nucleotide concentrations. Alterations in substrate affinity of the enzyme may be an important early step preceding cyclic nucleotide changes and altered growth states.

Evidence for immunoreactive somatostatin in the endocrine cells of human foetal pancreas

Somatostatin has been identified as a hypothalamic factor inhibiting the release of growth hormone[1,2] by acting directly at the level of adenohypophysial cells. It also acts on pancreatic endocrine cells[3,4] to inhibit the secretion of glucagon and insulin. Immunohistochemistry has localised somatostatin in the median eminence[5-7] as well as in discrete cells of the Langerhans islets of several species[8,9]. The origin of pancreatic immunoreactive somatostatin poses a problem. It has been demonstrated that neither nerve fibres, nor nerve endings with immunoreactive somatostatin are found in the adult pancreas[9]. Therefore it has been suggested that the somatostatin detected in the pancreas does not

result from absorption by these cells of somatostatin synthesised elsewhere (in the central nervous system for instance) but is produced by the pancreatic cells (probably A1 cells) themselves[9]. The results reported here show the presence of immunoreactive somatostatin in the pancreas of normal human foetuses and one totally anencephalic human foetus.

The pancreases were removed from 6 to 24-week-old human foetuses obtained immediately after legal abortion, or from deceased premature infants. After fixation for 2 or 3 d in Bouin–Holland fluid, without acetic acid, and with 5% saturated Hg sublimate added, the tissues were carefully washed in water, then dehydrated and embedded in

Fig. 1 Serial sections of a single islet of normal human 16-week-old foetus after application of *a*, anti-somatostatin; *b*, anti-glucagon; and *c*, anti-insulin.

paraffin. Sections (5 μm) were used after fixing on to glass slides with 0.5% aqueous gelatin.

Hormones were detected in the cells using immunofluorescence. Anti-somatin[9], anti-glucagon[9] and anti-insulin were used as antisera. Immunofluorescence was detected by the indirect method with the aid of sheep anti-rabbit-γ-globulins conjugated with fluorescein isothiocyanate (Pasteur Institute, Paris). In all cases, the antisera were saturated with the particular proteins used in the coupling of antigen. The specificity of the immunofluorescent reaction was ascertained by studying the inhibition of the reaction by homologous and heterologous antigens (somatostatin, glucagon, insulin).

Figure 1 shows the reaction of the normal 16-week-old foetus endocrine cells with the three antisera. Three types of cells were distinguished—somatostatin-containing cells and glucagon-containing cells were often located in the islet periphery, insulin-containing cells, in the islet centre (Fig. 1*a*, *b* and *c*). Different cells reacted with each serum.

No immunofluorescent reaction was seen with antisomatostatin and anti-glucagon before 10–11 weeks of gestational age and before 12 weeks of age with antiinsulin. At the third month, the fluorescent cells are located close by or in the wall of branching ducts embedded in connective tissue of the pancreatic parenchyma. After this time, they are located in islets.

Figure 2 shows the endocrine pancreatic cells of an anencephalic 7.5-month-old foetus reacting to antisomatostatin. Immunofluorescence was also observed with anti-glucagon and anti-insulin. The cells were smaller than in the normal foetus. A fluorescent reaction was never observed

with anti-somatostatin either in nerve fibres or in nerve endings throughout the pancreas.

In the human foetal pancreas, inhibition of the immuno-fluorescent reaction was seen only after adding somatostatin in a concentration equal to 400 $\mu g\,ml^{-1}$ of undiluted antiserum. Glucagon and insulin do not interfere with the immunocytological binding of somatostatin antiserum. Similarly, only insulin inhibits the immunofluorescence reaction caused by insulin antiserum, and only glucagon inhibits the immunofluorescence reaction caused by glucagon antiserum. No reaction was obtained using normal rabbit serum in place of the antisera.

It has been demonstrated and reported elsewhere[7,9], that the anti-somatostatin serum used here does not react with any of the following peptides—LH-RH, TSH-RH, ocytocine, lysine vasopressin, neurophysin, glucagon, insulin, secretin and the tetrapeptide Thr–Phe–Thr–Ser, common to somatostatin, glucagon and insulin. These data and the study of inhibition of the immunocytological reaction show that the fluorescence is most certainly attributable to the presence of somatostatin in the pancreatic cells. Therefore it

Fig. 2 Anencephalic human 7.5-month-old foetus pancreas. Cells containing immunoreactive somatostatin in two adjacent islets were detected by anti-somatostatin.

may be concluded that human foetal pancreas somatostatin occurs by 11 weeks of gestation.

The presence of somatostatin-containing cells in the islets of normal human foetal pancreas agrees with the recent observation of a somatostatin activity detected by bioassay in aqueous extract of foetal rat pancreas[10]. Also, the presence of glucagon-containing cells at 10–11 weeks of gestation and of insulin-containing cells at 12 weeks is consistent with the presence of the same hormone as demonstrated by radioimmunoassay for glucagon[11,12] or insulin[13,14] and by morphological techniques[15,16], all of these in human foetal pancreas. It has been suggested that the somatostatin-containing cells were the A1 cells[9]. Indeed, these cells have been identified in the human foetal pancreas from about the third month[16].

Whether pancreatic somatostatin participates in some mechanism involved in the central control of glucagon and/or insulin secretion in the human pancreas during intra-uterine life is still unknown.

The data reported here demonstrate that somatostatin is not an exclusively hypothalamic hypophysiotrophic peptide and may be synthesised elsewhere.

Scrapie incubation time can exceed natural lifespan

IN mice injected with mouse-passaged scrapie, the earliest rise in titre of agent is found in organs of the lymphoreticular system —irrespective of whether the injection is intracerebral or by a peripheral route[1-4]. The titre of agent in the spleen, for example, can rise fairly quickly to a moderate plateau level and subsequently starts to increase progressively in the brain, where it reaches, during the clinical phase, a greater concentration than elsewhere. These generalisations are based on work in various laboratories with agent strain–mouse strain combinations having relatively short incubation periods in the range 150–300 d after injection of high doses of agent. Evidence of replication in the spleen is therefore an indication that the animal will eventually develop scrapie if it lives long enough.

The detailed titre levels and time sequences for the start of replication in the spleen depend on the strain and dose of agent, on the genotype of the mouse and its age at injection, and on the route of injection[5,6]. In particular the gene *sinc* (alleles, s7 and p7) is important in controlling agent replication and the details vary widely for different strains of agent[7]. It has been shown with ME7 agent, that in mice homozygous for p7 there is a delay of about 4 weeks before replication starts in the spleen after injection of 10^4 C57BL intracerebral LD_{50} units of agent whereas in *sinc*[s7] mice the delay, if any, does not exceed 3 d; the respective incubation periods in these examples are approximately 300 d and 160 d.

Table 1 Number of infectious units of agent in spleen and incidence of clinical scrapie in C57BL mice injected intraperitoneally with various concentrations of 22A and, for comparison, incubation periods and incidences for the same doses given intracerebrally

Dilution of VM 22A-infected brain*	22A dose† injected	Intraperitoneal injection						Intracerebral injection

ND, Not determined.

For each agent strain–mouse strain combination, incubation period increases as dose is decreased and is longer after intraperitoneal than intracerebral injection. Even with intracerebral injections it is difficult to determine the titration endpoint for some agent–mouse combinations because the incubation period at the lower doses is of the same order as the lifespan of the mouse. Thus, with 22A agent in C57BL mice (sinc^{s7}) individual incubation periods range from about 450 d with 10^{-1} 22A-infected brain homogenates to about 670 d with the 10^{-5} dilution, and many of the apparent survivors are senile by this stage (Table 1: estimated $\log_{10}$ C57BL intracerebral LD_{50} Reed–Muench titre is -4.6). In these senile mice there is an element of uncertainty in the histological criteria for deciding whether a mouse is dying of scrapie or of old age because there is an overlap in the range of histological lesions of scrapie and those caused by brain ageing[8]. Assay of agent in the spleen provides a potential means of resolving the dilemma of whether, in the type of example given, titre is being underestimated by cases of scrapie in the 'next higher dilution' not having the opportunity to appear during the normal lifetime. To assay this efficiently would require using another genotype of mouse in which the particular agent replicates much more rapidly, which in the case of 22A agent would be VM mice (sinc^{p7}). The following experiment shows that this approach is practicable in even more extreme circumstances.

C57BL mice were injected intraperitoneally at weaning with various saline dilutions of 22A-infected VM brain homogenate. One female and one male mouse in each dilution from 10^{-2} to 10^{-5} was killed at 60, 100, 300 and 600 d after injection and the spleens removed for assay. The assay involved intracerebral injection of groups of weanling VM mice with 10^{-1} C57BL spleen homogenates, which were not centrifuged, and estimating the titre from the incubation period[9]. The results for the female spleens are shown in Table 1; preliminary results (not given) for male spleens show the same general pattern.

In addition, some C57BL mice in each dilution group were observed for signs of scrapie: all the mice given the 10^{-1} dose developed typical symptoms and lesions but in the lower dilutions none developed unequivocal signs. When individuals were senile or showing equivocal signs of chronic neurological illness they were killed and their brains examined histologically, as were the brains of all those killed earlier for spleen assay. None of the mice in the 10^{-2} to 10^{-5} groups had typical scrapie lesions, but one of the four mice in the 10^{-2} group (killed 709 d after injection) presented some difficulties in deciding that the lesions were probably caused by ageing—the spleen of this mouse had 50–100 VM intracerebral LD_{50} units 22A mg^{-1}. The only other mouse brain in the whole experiment which presented such difficulties was from the 10^{-2} group male killed at 600 d for spleen removal. It is possible therefore that scrapie was partly responsible for the equivocal symptoms and lesions seen

in a minority of the 10^{-2} group. If only clinical cases of scrapie are used as the basis for calculation, the estimated intracerebral titre is 1,000 times higher than that for the intraperitoneal route but this reduces to about 50 times higher if allowance is made for animals with agent in the spleen.

The results of the spleen assays form a clear and consistent pattern, with agent only being detectable in the two higher-dose groups and being detected earlier in the 10^{-2} group than the 10^{-3} group, but even then no agent was detected in the spleen until at least 100 d after injection. It is not yet known whether agent is present in the spleen for a few days immediately after injection and then cleared, but it seems unlikely that agent first recovered at 300 d is part of the original inoculum, slowly accumulating there. The reason for this long absence from the spleen is unknown and it could even be an artefact of insensitive assay systems. The crucial point will be whether agent can be detected elsewhere in the body during this interval and in which organs. Until these points are settled it would be quite inappropriate[4] to refer to this interval as an 'eclipse phase' and without direct evidence it should not be assumed that this, or other, conventional virological categories apply to scrapie[10].

If incubation can exceed lifespan with scrapie there seems to be no reason why this will not occur with other members of this group of diseases. It is therefore possible that a greater number of individuals are infected with one of the agents causing transmissible encephalopathies or dementias, such as Creutzfeldt–Jakob disease in man, than the number of cases which occur. Such individuals are, presumably, potential sources of infection, especially where tissue transplantation is involved[11].

Translational control in the mealworm, *Tenebrio molitor*

ONE of the best known examples of translational control in a eukaryotic system comes from studies on the mealworm, *Tenebrio molitor,* in which control of the synthesis of adult cuticular proteins at the translational level has been proposed[1-7]. From experiments using actinomycin D, it was concluded that the mRNAs for some of the adult cuticular proteins were synthesised by the first day of pupation[1]. To translate these mRNAs *in vitro* on first day polysomes, however, the tRNA and enzyme from 6 to 7 d pupae were required[2-4]. Ilan *et al.* gave further evidence for a leucine tRNA which seemed to be controlling the translation of the mRNAs and the synthesis of which seemd to be in the control of juvenile homone[3-7]. But our own studies of *Tenebrio,* reported here, lead us to question this translational control model.

We decided to look at changes of tRNAs during the development of *Tenebrio* and compare them with changes observed during the development of *Drosophila*[8-10]. Transfer RNA and aminoacyl-tRNA synthetases were extracted by the methods described previously[8]. Aminoacylation conditions were established that would give plateau levels of charging by 10 min. We found the conditions used by Ilan *et al.*[4] for aminoacylating leucine tRNAs gave a very slow rate of charging chiefly because of the relatively low affinity of the *Tenebrio* leucyl-tRNA synthetase for leucine, the monovalent cation requirement and the ATP–Mg^{2+} ratio used. We found the K_m of the enzyme for leucine to be 20 μM. This compares with an even higher K_m (200 μM) reported by Ilan and Ilan[7].

Using the improved aminoacylating conditions, the amounts of the leucine tRNAs as well as other tRNAs were determined in both early pupae and late pupae (pharate adults) (Table 1). When compared with either phenylalanine or tyrosine tRNAs, there was no significant change in the total acceptance of leucine by tRNA preparations from these two developmental stages. Even though there was not the expected net increase in the acceptance of leucine there could have been a new leucine tRNA formed with a concomitant decrease in the other isoaccepting species. To examine this possibility, ^{14}C-leucyl-tRNAs from both early and late pupae were chromatographed on reversed-phase 5 columns by methods described previously[8]. The profiles of the leucyl-tRNAs from larvae, first-day pupae, last-day pupae and adults aminoacylated with a last-day pupal aminoacyl-tRNA synthetase preparation, were

virtually identical (Fig. 1). The same result was obtained using last-day pupal microsomal enzyme[4] as well as larval, first-day pupal and adult aminoacyl-tRNA synthetase preparations. This was surprising in view of the results of Ilan and Ilan that indicated the synthesis of a new leucine tRNA[5,7].

We, therefore, went back to the conditions used by Ilan *et al.* for the aminoacylation of the leucine tRNAs (Fig. 2).

Fig. 1 Chromatography of ^{14}C-leucyl-tRNAs from different developmental stages of *Tenebrio.* Aminoacylation was performed as described in the legend of Table 1 using last-day pupal aminoacyl-tRNA synthetase preparations. Chromatography of leucyl-tRNAs on RPC-5 columns was performed as described previously[8]. *a,* Larval; *b,* first-day pupal; *c,* last-day pupal; *d,* adult.

**Table 1** Acceptance of amino acids by first-day and last-day pupal tRNAs

Amino acid	pmol amino acid accepted per A_{260} unit of total tRNA		First-day/last-day
	First-day pupal	Last-day pupal	
Leucine	55.3	51.5	1.07
Phenylalanine	26.3	25.4	1.02
Tyrosine	24.7	22.7	1.09

Transfer RNA and aminoacyl-tRNA synthetases were prepared as described previously[8]. Last-day pupal aminoacyl-tRNA synthetase was used. The aminoacylation conditions for leucine tRNAs were 50 mM Tris-HCl, pH 7.5, 10 mM KCl, 8 mM ATP, 5 mM $MgCl_2$, 5 mM 2-mercaptoethanol, 50 μM ^{14}C-leucine, 1 mg ml^{-1} enzyme preparation and 0.5 mg ml^{-1} tRNA. The conditions for the aminoacylation of phenylalanine and tyrosine tRNAs were the same except 50 mM KCl, 4 mM ATP, 10 mM $MgCl_2$ and 25 μM ^{14}C amino acid were used.

The plateau level observed clearly represents incomplete charging and could not be used to estimate the amount of leucine tRNA present. We also chromatographed the ^{14}C-leucyl-tRNA obtained in these conditions on RPC-5 columns (Fig. 3). It is apparent that peak 1 and peak 2 are poorly charged in relation to peak 3. Similar results were obtained when aminoacylation was performed in conditions where the amino acid or enzyme was limiting.

These results immediately suggested an explanation for the differences between our results and those of Ilan *et al.*[3-7]. As aminoacylation in suboptimal conditions can give rise to different isoacceptor profiles, any comparison of tRNAs from different developmental stages can only be performed when rapid complete charging is achieved. The charging conditions used by Ilan *et al.*[4] produced rates that
Fig. 2 Rates of aminoacylation of larval tRNA with leucine under varying conditions. ▲, Aminoacylation in the conditions described in the legend of Table 1; ●, aminoacylation conditions were similar to those described by Ilan *et al.*[4]; 50 mM imidazole, *p*H 7.0, 10 mM MgCl$_2$, 4 mM ATP, and 4 μM ^{14}C-leucine.

gave plateau levels only after about 50 min, and the results presented here indicate that charging under such conditions is incomplete especially for certain leucine isoaccepting tRNAs. Another problem with any analysis of aminoacyl-tRNAs using dual labels[5,7] is that the concentration of the differently labelled amino acids in both charging mixtures must be identical and the comparison made reciprocally to avoid isotope artefacts[11]. This is especially true when the labelled amino acid substrates are used at concentrations that are well below the K_m value of the aminoacyl-tRNA synthetase. The observed differential charging rates could produce apparent control during the translation of mRNAs *in vitro*, due not to lack of a particular tRNA but to incomplete aminoacylation.

Another weakness in the evidence for translational control of adult cuticular protein relates to the amino acid

Fig. 3 Chromatography of larval ^{14}C-leucyl-tRNAs aminoacylated in different conditions. *a*, Aminoacylated in the conditions described in the legend of Table 1; *b*, aminoacylated in conditions similar to those used by Ilan *et al.*[4], and described in the legend of Fig. 2.
composition of these cuticular proteins. It has been claimed by Ilan *et al.*[4,6], apparently on the basis of published analyses on the beetle *Agrianome spinicollis*[13], that adult *Tenebrio* cuticles are high in tyrosine (20%) whereas pupal cuticles have 'low tyrosine'. This difference was used as an index of the synthesis of adult cuticular protein *in vitro*[4]. It has been shown by Anderson *et al.*[12] that the adult cuticle has in fact less tyrosine (4.6%) than pupal cuticle (9%). This, therefore, invalidates the use of high tyrosine content as an index of adult cuticular protein synthesis.

The ability of actinomycin D to mimic the action of juvenile hormone suggests control at the transcriptional rather than the translational level[14–16]. Our results would support this in that we have found no evidence for a novel leucine tRNA that might control the translation of preformed mRNA for adult cuticular protein. We feel that the suboptimal conditions used to aminoacylate the leucine tRNAs, coupled with the differential rates of charging of the leucine isoacceptor tRNAs, explains much of the data that originally led Ilan *et al.*[4] to suggest a translational control mechanism.

We thank Dr G R. Wyatt for reading the manuscript. The work was supported by the National Research Council of Canada and the Rockefeller Foundation.

Extraordinary pigment composition of a prokaryotic alga

WE report an anomalous unicellular alga with a prokaryotic cellular organisation like that of a blue-green alga, but with a pigment composition characteristic of green algae and higher plants.

Synechocystis didemni Lewin is a unicellular marine alga so far found only associated with colonial ascidians (*Didemnum* spp.) on the coasts of Baja California, Mexico[1]. Under the light microscope it looks like a blue-green alga, and by electron microscopy of thin sections we have confirmed that the cellular organisation is prokaryotic, without membrane-limited nucleus, plastids or mitochondria (ref. 2 and R. A. L. and M. Schulz-Baldes, unpublished). Typically, blue-green algae—photosynthetic prokaryotes which can evolve oxygen when illuminated—contain at least one red or blue bilin pigment (phycoerythrin or phycocyanin) and only one chlorophyll, *a*, *S. didemni*, however, is leaf-green in colour, apparently
Fig. 1 Spectral absorption curves of solutions of *S. didemni* chlorophylls in ether, provisionally identified as *a* and *b*. For details of extraction and separation methods, see Table 2.

lacks bilin pigments, and contains two chlorophylls, *a* and *b*— features characteristic of green algae and land plants. Preliminary evidence for this unique combination of a prokaryotic organisation with a pigment complement so far only known in eukaryotic plants has been published elsewhere[2]. We offer here confirmation of the presence of chlorophylls *a* and *b*, together with other lipid-soluble (but no water-soluble) pigments.

So far it has not proved possible to culture cells of *S. didemni*; consequently we had to analyse living material collected from the wild. In March 1975, didemnid colonies bearing *S. didemni* were gathered in a tropical lagoon on Isla S. José, Baja California from dimly illuminated mangrove roots (maximum light intensity around noon, 300–500 lx; water temperature about 20–25 °C). The surfaces were brushed as described[2], and the algal cells removed were concentrated by centrifugation. We collected three lots of algal cells, each of a few hundred milligrams (wet weight). The pigments from small subsamples were extracted and examined chromatographically on the day of collection; the rest of each sample was stored at −20 °C for careful examination in the laboratories of the Scripps Institution of Oceanography several days later. (There was no reason to believe that storage in this way effected any appreciable change in the pigment composition of the samples.)

After thawing, the cells were washed in water, and the supernatant, essentially colourless, was examined for possible traces of bilin pigments. An absorption spectrum revealed no

evidence for any pigmented material of this sort. The lipid-soluble pigments were then extracted and examined by thin-layer chromatography (TLC) and spectrophotometry (Fig. 1 and Tables 1 and 2).

The evidence for the existence of chlorophyll *b*, as well as *a*, in *S. didemni* seems unequivocal. This second green pigment cochromatographed with chlorophyll *b* from the chlorophyte *Codium fragile* and exhibited absorption maxima (Table 2) and band ratios typical for *b* (ref. 3). In the two samples examined the ratio *a:b* was found to be comparable with that of other algae which contain *b* (Table 1). The presence of *b* in our preparations could hardly be attributable to contamination of the samples by other algae, as microscopic examination revealed that the cells in our suspensions were almost all *S. didemni*, with no evident chlorophytes or euglenophytes. There was a small proportion (less than 1%) of diatoms or diatom debris, but these were mainly empty frustules, and only a few retained pigmented contents. The second chlorophyll of diatoms, *c*, has an R_f and other properties quite dissimilar from those of *b*. No *c* was detected in our material.

The predominant carotenoid in *S. didemni* is β carotene, representing some 65% of the total absorption attributable to yellow pigments. This proportion is higher than that normally encountered in chlorophytes (for example, 15% for *Chlorella pyrenoidosa*, which also has α carotene), but is close to that found in certain cyanophytes (for example, 46% for *Anacystis nidulans*[5], 63% for *Microcoleus vaginatus*[6]). The other carotenoids of *S. didemni* were presumably xanthophylls, perhaps including myxoxanthophyll. The amounts were insufficient for critical analysis, which must evidently await the availability of much larger quantities of cell material, if and when this can be obtained in culture.

Although it has been generally accepted that all photosynthetic cyanophytes (blue-green algae) possess bilin pigments, in an unidentified blue-green alga associated with ascidians of the Great Barrier Reef little or no phycocyanin or phycoerythrin was detected[7]. It has also been generally accepted that blue-green algae lack *b* (ref. 8), although spectral data from blue-green algal mats collected in Yellowstone Park indicated that about 15% of the chlorophyll was present as *b* (ref. 9). Since those algae had grown at temperatures above 48 °C, they could hardly have been contaminated by chlorophytes or euglenophytes, none of which has been reported to grow in such hot water. Among the predominantly filamentous algae Inman[9] noted the presence of *Synechococcus lividus* (Chroococcales) and of "a unicellular green alga, probably *Chlorella* sp.". From what we now know of such habitats we can be almost certain that the latter alga was *Cyanidium caldarium*, which does not contain *b* (ref. 10).

In the original description of the type species of the genus, *Synechocystis aeruginosa*[11], the cells were described as being of a blue-green colour. Drouet and Daily[12], who re-examined Sauvageau's material, reported that it contained cells which seemed to belong to the Chlorococcales (Chlorophyta); but it is hard to believe that Sauvageau could have mistaken a unicellular cyanophyte in this way. Further conclusions may only be drawn after examination of the pigments of an authentic

Table 1 Comparative pigment data for *S. didemni* and other algae

	Phycobilins (g per 10^{14} cells)	Chlorophylls		*a:b*	β carotene/ total carotenoids	Calculated from data in ref.

Cell counts were made with a Levy haemocytometer. Carotenoids and chlorophylls were estimated spectrophotometrically using standard extinction coefficients[3,13].

Table 2 R_f values and absorption maxima (nm) of *S. didemni* pigments

R_f on sucrose (TLC)	Colour	Acetone	Solvent Ethyl ether	n-Hexane	Identity
0.92	Yellow	425, 452, 480	—	420, 448, 475	β carotene*
0.72	Blue-green	430, 662	431, 662	—	Chlorophyll *a*
0.61	Orange	425, 451, 480	—	—	Unidentified xanthophyll
0.48	Yellow-green	457, 645	452, 642	—	Chlorophyll *b*
0.19	Yellow	440, 470	—	—	Unidentified xanthophyll
0.02	Orange	445	—	—	Unidentified xanthophyll

*Failed to separate from authentic β carotene (from *Daucus carota*) in a mixed chromatogram on Al_2O_3 + MgO developed with 6% ethyl acetate in n-hexane[22].

Pigments were extracted by sonicating the cells in a small volume of cold acetone. Cell residues were removed by centrifugation, and the pigments from the supernatant were transferred to ethyl ether by addition of cold, saturated saline. The ether extract was concentrated under N_2 and subjected to TLC on sucrose, using 1.3% n-propanol in ligroine (boiling point 63–75 °C)[21].

strain of *S. aeruginosa* (we are attempting to obtain a culture of this species from the Department of Genetics, University of Moscow), and of the pigments of other cyanophytes grown in natural conditions, notably those encountered by *S. didemni* in mangrove swamps and by other species which survive in hot springs.

In conclusion, we have confirmed that natural collections of *S. didemni* contain chlorophylls *a* and *b*, β carotene, at least three xanthophylls, and no demonstrable water-soluble phycobilin pigment. In these respects it seems to be unique among cyanophytes which have been examined to date.

We thank Dr F. T. Haxo for advice and guidance with the chromatography, and the Foundation for Ocean Research for making the RV Dolphin available for collecting material.

Neuronal plasticity and recovery of function in a polyclad flatworm

NEURONAL recovery of function, although well known in the lower metazoa, has received comparatively little attention or critical investigation. We have been able to demonstrate not only recovery of function but also the recruitment of pathways mediating aspects of feeding behaviour in the marine polyclad flatworm, *Notoplana acticola*. Unlike some freshwater planarians which regenerate lost parts readily and may even grow new brains, polyclads have limited powers of regeneration and the brain seems to be essential for any repair which takes place[1]. Three aspects of feeding behaviour were utilised in this study. When a normal intact flatworm is presented with food (dead adult brine shrimp) at its posterior laterial margin, that part of the

margin in contact with the food is extended and grips the shrimp. This local response is followed by an ipsilateral turning and contraction which brings the anterior margin in contact with the food which it grips and then passes the shrimp towards the midventral mouth. After feeding on two or three shrimp, the worms are satiated and no longer respond to the presence of food. Both turning and satiation are altered when the brain is removed. Decerebrate animals do not turn, the local response is prolonged, and the food is passed directly to the mouth where it is swallowed. After the stomach is filled the worms continue to collect food which is piled under the mouth. This localised feeding response (LFR) continues to occur as long as food is presented. The presence of the brain is necessary to inhibit the LFR as well as to initiate turning and satiation.

If a cut is made from the midline to the margin right through the entire body, that portion of the animal ipsilateral to and posterior to the cut will act as if it is decerebrate. The contralateral side, however, will still turn and with distension of the stomach this side will ignore offered food. A single animal can then be used for both experiment and control.

Table 1 Recovery of turning behaviour component of feeding in *N. acticola*, following a cut across one side of the body severing the nerve plexus

Treatment	Experimental side			Control side

Cut (experimental side)	4.3	95.7	92	92.3	7.7	91
Healed	94.9	5.1	99	97.9	2.1	94
Cut (control side)	79.8	20.2	84	0.0	100.0	90

N, Number of observations; T, turning reflex.

Ten animals were used and, except for the initial test, approximately ten responses from each side were obtained. Sides were tested alternately. Animals were kept in small fingerbowls, 11 cm diameter and containing approximately 2.5 cm seawater. The water was changed every 2 d but the inner surface of the bowl was not wiped clean. This is critical as animals will not feed until a layer of slime has been deposited on the surface of the container[2]. Dishes were not aerated and were maintained at ambient room temperature which fluctuated between 18 and 20 °C. With sufficient food animals can be kept indefinitely and will even grow. In each experiment 10 animals were used. Pairs were placed in separate dishes and allowed to acclimatise to the containers for 48 h before the start of the experiment. Individuals in a pair could be identified by size or slight colour differences.

Animals were tested for the turning response by being offered food on alternate sides (Table 1). Normal animals always turned to the side stimulated. During the course of the experiments described here food was always removed before it could be ingested. One side of each animal was cut (the experimental side) and the two sides were tested with food 20 h later. Nine of the ten animals now responded with LFR on the experimental side although one individual still turned in four of eleven tests. The control side turned in 92% of the tests and used LFR the other 8%. These animals were then retested 49 h after the cut had been made, by which time the edges seemed to have rejoined. When food was offered to the experimental side the animals turned 95% of the time. During these tests five LFRs were recorded from four of the animals. The recovery of turning behaviour

Table 2 Recovery and recruitment of feeding behaviour in *N. acticola*

Treatment	Experimental side			Control side		
	T(%)	LFR(%)	N	T(%)	LFR(%)	N
Normal response	100.0	0.0	100	—	—	—

Healed	92.1	7.9	98	97.9	1.1	98
Recut (exerimental side)	72.1	27.8	103	100.0	0.0	86

Ten animals were used in these experiments, approximately ten readings were obtained from each animal.

could be accounted for in either of three ways. Functional connections could have been re-established across the lesioned zone. Secondly, new or unused pathways across to the contralateral side could have been recruited. Finally, mechanical coupling across the wounded area might have elicited activity from stretch or other sensory receptors which could then evoke the turning response. Histological examination showed that the severed nerves had become reconnected (Fig. 1). To see whether contralateral pathways were being recruited, the animals were cut across the control half slightly anterior to the previous cut on the experimental side. As might be expected the control side responded with LFRs to each food presentation. Eight of the animals turned toward food presented to the experimental side but two animals used LFRs consistently. The reappearance of LFRs suggested that in some cases recruitment of alternative pathways occurs. This was tested in a second series of experiments.

Fig. 1 Reconnected nerve trunks 49 h after lesion. Large nerve trunk running through the section had been cut at a branch point. Arrows are arranged on either side of the healed scar. Note apparent disorganisation within nerves across the scar. Bar, 200 μm.

Ten animals were set out as before and tested for turning, which they all did. A cut was made across one side and they were tested for turning 19 h later. The experimental sides used LFR 94% of the time. Two of these animals did turn, one in two out of thirteen tests and the other in four of eleven tests. Table 2 shows that when the cut had rehealed 46 h later all the animals turned to the experimental side with only occasional LFRs. Once these readings were taken the original cuts were reopened and the animals retested 16 h later. Following the initial cut turning had only been recorded 5.6% of the time before healing but when the cut was reopened turning was recorded 72.1% of the time. The difference between these two results is statistically significant ($P < 0.001, \chi^2$ test). All of the animals turned but seven also gave occasional LFRs. Turning behaviour to the reopened cut sides differed from that recorded after the cuts had healed. There was a considerable latency between contact and the initiation of turning which could last as long as 20 s in the reopened animals, whereas it was usually only 1–5 s in healed animals. The fact that animals still turned following reopening of the cut suggests that mechanical coupling is not a factor in turning elicitation. Histological examination of the reopened lesions indicated that in all but one case the nerves on the healed side had been completely resevered.

These results suggest quite strongly that functional connections can be made between severed portions of the nerve trunks and also that alternative, perhaps pre-existing, pathways can be recruited as well. Although such systems may have been suspected in these primitive systems previously, this seems to be the first time that such recovery of function has been clearly demonstrated.

Influence of haemoglobin type on the induced ovulation rate in sheep

HARRIS and Warren[1] first reported haemoglobin (Hb) polymorphism in sheep; they separated a fast moving Hb A, and a slower moving Hb B, which were controlled by a single pair of alleles yielding three phenotypes—AA, BB and AB (ref 2). Several investigators have subsequently reported on the influence of Hb type on the reproductive performance of sheep. Evans and Turner[3] found that Merino ewes of Hb types BB and AB were more fertile and had a greater proportion of multiple births than AA ewes; subsequent investigations have confirmed this observation[4]. In a study of Australian Merino ewes grazing oestrogenic clover pastures Obst *et al.*[5] reported that AA and BB ewes were significantly more fertile than BB animals, suggesting that the A gene is associated with some factor which protects against the deleterious effects of plant oestrogens. We report observations in Indian Bikaneri ewes and suggest an association between Hb type and the ovarian response to exogenous gonadotrophins.

Seventy-eight adult multiparous Bikaneri ewes were classified according to their Hb phenotypes to give 12 AA, 36 BB and 30 AB animals. They were all kept in identical conditions of housing and management, and oestrus was detected by raddled vasectomised rams at 0900 daily; the day of onset of oestrus was classified as day 0. The BB and AB animals were subdivided into four groups and were injected with either 0, 500, 750 or 1,000 IU of pregnant mare serum gonadotrophin (PMSG,

Table 1 Influence of Hb type on ovarian response to PMSG in Bikaneri ewes

			Mean number of ovulations ($\pm$s.e.)				
PMSG level (IU)		0		500		750	1,000

BB	6	1.0	10	1.6$\pm$0.33 (3)	12	2.08$\pm$0 077 (11)	8 3.5$\pm$0.717 (7)
AB	6	1.0	8	1.25$\pm$0.070 (2)	8	3.0$\pm$1.20 (6)	8 5.25$\pm$2.20 (8)

n, Number of observations

Figures in parentheses indicate the number of animals which responded to PMSG treatment. Only those animals which had two or more corpora lutea in the ovaries were considered to have responded.

Gestyl, Organon) intramuscularly on the 13th day after oestrus. There were insufficient AA ewes to form more than two groups, which were either untreated or given 1,000 IU PMSG. The number of ovulations in response to this gonadotrophin treatment was assessed by counting the corpora lutea at laparotomy on the 5th to 7th day of the cycle following PMSG injection (Table 1).

None of the AA animals responded to the higher dose of PMSG, whereas there was a significant response ($P < 0.01$) of the AB and BB animals which was dose dependent (χ^2 test). The variation in the response of AA, BB and AB animals to 1,000 IU PMSG treatment was significant ($P < 0.01$) while between BB and AB animals was not significant (χ^2 test).

The ovulation rate of mammals is thought to depend primarily on the amount of gonadotrophins released into the blood[6] rather than in changes in ovarian sensitivity to gonadotrophins[7]. The results of the present study strongly suggest that the number of follicles which will ovulate may also be determined by ovarian sensitivity. In analogous studies in mice, genetic differences in ovulation rate have been attributed to differences in ovarian sensitivity[8-10].

Bindon et al.[11] reported that in a flock of Merino ewes selected for fecundity the ovarian response to a standard dose of PMSG was significantly higher in the group with the higher incidence of multiple births. Since response to PMSG is partly dependent on the endogenous gonadotrophin concentrations[12,13], a higher concentration of endogenous gonadotrophin in the BB or AB ewes may be responsible for the higher ovulation rate to PMSG. This possibility seems to be remote, however, since, irrespective of the Hb type, the incidence of twinning in the Bikaneri ewes is exceptional (2–3%). It may well be that the rate of secretion of endogenous gonadotrophin in BB and AB ewes may be lower than in AA ewes. Recent studies have revealed a significant variation in the peripheral plasma LH concentrations between ewes of same breed but of two different strains[14]. It also remains to be determined whether the sensitivity of BB and AB ewes to other hormones is also higher than that of AA ewes.

The results of this study suggest that haemoglobin type may provide a simple means of selecting sheep for increased sensitivity to gonadotrophins, and may also explain some of the variability in response to standard doses of gonadotrophin encountered in practice[15,16].

Implication of absence of HCG-like gonadotrophin in the blastocyst for control of corpus luteum function in pregnant rabbit

IN the primate, the corpus luteum formed after ovulation has a relatively short life span. If the ovum becomes fertilised, however, the presence of the embryo in the uterus leads to 'rescue' of the corpus luteum and a prolongation of its functional life[1]. Circumstantial evidence suggests that this is achieved through the elaboration of a luteotrophic substance (chorionic gonadotrophin) by the trophoblastic cells of the implanting embryo[1,2]. Based on differences in the plasma progesterone levels of pregnant and pseudopregnant animals, a similar situation has been proposed for the rabbit[3]. In support of this, the blastocyst fluid from 6-d pregnant rabbits has been reported to contain a substance similar to human chorionic gonadotrophin (HCG), by a radioreceptor assay[4], and a substance similar to luteinising hormone (LH), by a heterologous radioimmunoassay[5]. Our study was initiated to identify definitively the source of the HCG-like substance in the rabbit blastocyst. Using a highly sensitive *in vitro* bioassay method we have examined the concentration of HCG-like material in the serum throughout pregnancy and in the blastocyst from days 4 to 7 of pregnancy. We report here that the rabbit blastocyst does not contain or secrete any gonadotrophin which has significant HCG-like activity.

New Zealand White rabbits were mated and killed 4–6 d later. The uterine horns were removed and flushed from the oviducal end with physiological saline to expel the embryos, which were immediately transferred to incubation vials. The surrounding saline was aspirated and appropriate materials added for incubation. To obtain blastocyst fluid without loss of any critical material, the following procedure was adopted. Uterine horns removed on days 6 and 7 of pregnancy were wrapped in aluminium foil and frozen rapidly by immersing in an acetone–dry ice mixture. The uteri were then partially thawed, dissected longitudinally and the frozen blastocysts transferred to centrifuge tubes. After thawing, the blastocysts were ruptured, centrifuged and the supernatant obtained. The
Fig. 1 Testosterone production by isolated mouse testes. Mice (70–80-d-old) were killed by cervical dislocation and the testes removed. After decapsulation the testes were rinsed with cold saline and placed in 16×50 mm glass vials containing 1 ml incubation medium (Krebs–Ringer bicarbonate buffer, pH 7.4, with 0.1% glucose) and graded doses of HCG or samples. HCG (10,600 IU mg⁻¹) was added in 100 μl incubation medium with 0.1% bovine serum albumin (●). Using saline, blastocysts were flushed out from the uterine horns of 6-d-pregnant rabbits and immediately transferred to incubation vials. The blastocysts were either left intact (▲) or punctured (△) with a needle and the blastocoel fluid allowed to escape. All points were assayed in quadruplicate. Incubations were carried out at 34 °C in a metabolic shaker at 150 cycles min⁻¹ in an atmosphere of 95% O₂–5% CO₂. After 4 h incubation aliquots of incubation medium were diluted and stored at −20 °C until the determination of testosterone by a direct radioimmunoassay⁶.

endometrial surface was scraped with a blade and the material coating the endometrium as well as part of the endometrium obtained. This was weighed, homogenised with 10 volumes saline, centrifuged and the supernatant obtained. The *in vitro* bioassay for HCG- and LH-like substances was based on the steroidogenic response of the mouse testes⁶,⁷.

Figure 1 shows the testosterone production by decapsulated mouse testes. A dramatic increase in testosterone production was obtained with 20 pg of HCG (biological activity 10,600 IU mg⁻¹). When testes were incubated along with day 6 blastocysts, up to four freshly-obtained blastocysts did not stimulate testosterone production. This was the case for intact blastocysts as well as for blastocysts which were disrupted and the blastocoel fluid allowed to escape into the medium.

The steroidogenic response of a highly sensitive mouse Leydig cell preparation was used to evaluate the HCG-like activity (Fig. 2). Pregnant rabbit serum obtained 2 h after mating gave a dose–response curve parallel to that of HCG. In this system 200 μl day 7 blastocyst fluid or 100 μl of day 6 blastocyst fluid did not show any HCG-like activity. Saline extracts from 10. mg endometrial scrapings from 6- and 7-d-pregnant rabbits also showed no activity. To ascertain whether blastocysts secrete HCG-like material, embryos were flushed out of the uterus on day 4 of pregnancy and preincubated for 21 h. Leydig cells were then added and incubation continued for a further 3 h. No evidence for the secretion of HCG-like material was noted.

The Leydig cell preparation was used to measure HCG-like activity in the rabbit serum throughout pregnancy. By 0.5 h after coitus there was a 100-fold increase in the HCG-like activity (Fig. 3). After reaching maximum levels at 2 h *post coitum* the activity declined by 4 h and had returned to premating levels by 24 h. The levels remained low throughout pregnancy and did not rise above the premating levels. The recovery of HCG added to sera or blastocysts was quantitative.

These results demonstrate that coitus is followed by a rapid increase in the serum HCG-like activity which reaches a peak in 1 to 2 h and then decreases quickly to premating levels, at which it remains throughout pregnancy. The post-coital LH levels measured by radioimmunoassay show a similar pattern⁸. No significant HCG-like activity could be detected in the blastocysts between days 4 and 7 of pregnancy. Haour and Saxena⁴, using a radioreceptor assay, reported that on day 6 of pregnancy the concentration of HCG-like material in the blastocoel fluid was tenfold higher (87 ng ml⁻¹) than that in the serum (6–8 ng ml⁻¹). They also reported that the plasma levels of HCG-like material in the 6-d-pregnant rabbit was significantly higher than that in the non-pregnant animal. Results of the present study which are based on a highly sensitive *in vitro* bioassay do not confirm the results obtained by radioreceptor assay. This discrepancy is probably related to the different methods used. Comparison of the radioreceptor assay with radioimmunoassay and *in vitro* bioassay has shown that the radioreceptor assay was subject to nonspecific interference by plasma proteins⁹.

In the rabbit, a reflex ovulator, mating induces ovulation and corpus luteum formation. If the ova are not fertilised a pseudopregnancy of 17 d duration follows. The corpus luteum of pseudopregnancy shows regressive changes by day 12. Most of the evidence suggests that the non-pregnant rabbit uterus produces a luteolytic substance, presumably a prostaglandin, which limits the duration of corpus luteum function¹⁰. The biological evidence for the existence of a luteotrophic substance derived from the conceptus before day 10 of pregnancy is equivocal. Using a competitive protein-binding assay plasma progesterone levels were reported to be significantly higher in pregnant rabbits during the preimplantation stages than in pseudopregnant animals at similar stages³. A radioimmunoassay, however, showed no such differences¹¹.

The significance of the detection of HCG-like substance by indirect immunofluorescence on the surface of mouse embryos

Fig. 2 Testosterone production by mouse Leydig cell preparation. Four mice were killed by cervical dislocation and the testes removed. After decapsulation they were rinsed with saline and placed in a beaker with 25 ml medium 199 (Difco) containing 2% foetal bovine serum. Testes were chopped into small pieces with scissors and stirred for 10 min at room temperature on a magnetic stirrer. The medium was then filtered through a fine nylon mesh and centrifuged at 600g for 15 min at 4 °C. The supernatant was discarded and the cells resuspended in 25 ml medium. A portion (0.25 ml) of the cell suspension was added to tubes containing 0.1 ml standards or samples. HCG (●) was dissolved in the incubation medium. Serum obtained 2 h *post coitum* (○) from two rabbits was pooled and diluted with incubation medium. Blastocyst fluid (vertical bar) from 7-d-pregnant rabbit was lyophilised and reconstituted in the incubation medium to half its original volume. The rest of the procedure was as in Fig. 1 except that the incubation time was reduced to 3 h; stippled column, control.
Fig. 3 Serum levels of HCG-like material in the pregnant rabbit measured as in Fig. 2. Blood samples (3–4 ml) from the marginal ear vein were collected before mating, at frequent intervals after mating and at less frequent intervals throughout pregnancy. The high HCG activity at 1 and 2 h *post coitum* (*a*) represents the presumptive LH peak. The levels are much lower throughout pregnancy (*b*, note change in scale).

during the morula stage but not during the blastocyst stage is not clear[12]. A role for HCG in the protection of the foetus against attack by the maternal immunological system has been suggested[13]. Perhaps substances resembling HCG reported to be present in the unimplanted mouse and rabbit embryos play a role in the immunological system but are not gonadotrophins.

We thank the NIH for HCG (CR117) and for financial support.

Fig. 1 Synergy between N and C primed T cells, Spleen cells were treated with a cytotoxic rabbit anti-mouse B cell antiserum, prepared by repeated injection (3 or 4) of anti-θ treated spleen cells which had been depleted of dead cells[22] and red cells[23]. About 10[8] cells were injected at 2-weekly intervals, half intramuscularly emulsified in Freund's, and the rest intravenously. B cell contamination after treatment with the antiserum and complement ranged from 0–3% in replicates. Significant helper cells to OFd were only induced provided OFd primed T cells, or a mixture of N and C-BSA primed spleen cells were used. The dots above the bars indicate the upper limit of the standard error.

T–T interaction in the generation of helper cells *in vitro*

THE interaction of different cell types is now widely recognised as being of fundamental importance in the generation of many different immune responses[1,2], and occurs in many species. Several broad groups of interactions have been described—between macrophages and lymphocytes[3,4], between T cells, B cells (and macrophages) in antibody production[1,3,5] and between subpopulations of T cells in the graft versus host responses[6], and in the generation of cytotoxic T cells[7-10].

Levy and her colleagues have reported that the antigen performic acid oxidised ferrodoxin (OFd), derived from *Clostridium pasteurianum* has only 2 major antigenic determinants located in the carboxyl and amino terminal regions of the molecule[11]. They reported that cooperation between cells primed to the determinants situated at the COOH- (C-hapten) and at the NH_2-terminus (N-hapten) is necessary for the generation of a proliferative response of guinea pig lymph node cells *in vitro* to the whole antigen, OFd [12,13], but not for the expression of hypersensitivity reactions. Having recently described a system for the development of helper cells *in vitro*[14], we wanted to

determine whether the T helper cell response to OFd required cooperation between two populations of T cells, in analogy with other cooperative proliferative response to OFd[11].

By using the chemically defined determinants of OFd either linked together as in the whole antigen, or separately, coupled to bovine serum albumin (BSA), it was possible to prime cell populations *in vivo* to both or to either of the individual determinants and subsequently to use these cells *in vitro* to test for cell interaction during the development of helper cells to OFd. Cells were initially cultured for 4 d in the presence of OFd to generate helper cells directed towards OFd, and then small numbers of these cells were transferred to a second culture where, in the presence of excess B cells and macrophages and with dinitrophenylated-OFd (DNP-OFd) helper cells directed towards OFd would augment the plaque forming cell response to DNP. Here we describe the use of three distinct experimental approaches which have previously been used to study T–B interactions. They demonstrated that the interaction of two T-cell subpopulations is essential for the development of helper cells to OFd *in vitro*.

The first approach was the classical one of synergy, which

Fig. 2 Effect of excess N or C hapten on the response to OFd. Either bovine serum albumin (BSA) or N-BSA or C-BSA was added to cultures of OFd primed T cells containing OFd (1 μg ml⁻¹) and KLH (0.1 μg ml⁻¹) N-BSA, C-BSA or N or C-S-BSA (made with succinylated BSA) and N or C poly-D-glutamic acid (PDG) all suppressed the helper response to OFd. Substitution ratios of the preparations used ranged from 10–20 N or C groups mol⁻¹. These were made as described previously[12]. All these compounds were toxic in high concentrations, with nonspecific diminution of the KLH response beginning at 30 μg ml⁻¹ of N or C-PDG, and 100 μg ml⁻¹ of N or C-BSA, or succinylated BSA. The inhibition results shown were with 10 μg ml⁻¹ of N or C-BSA. Inhibition was also found with 1 μg ml⁻¹ of N or C-BSA, but not with 0.1 μg ml⁻¹. Dot above the bar graph indicates the standard error. Dark bar represents the response to DNP OFd, the unshaded bar represents the response of the same cultures to TNP KLH.

implies that a mixture of two cell populations yields a response substantially greater than the sum of the two individual populations. Over the past year, four series of mice have been used for these experiments, each series comprising three groups of mice, which were primed with either the N or the C hapten conjugated to BSA (that is N-BSA), or with OFd. Spleen cells from these mice or mixtures of cells primed to N-BSA or C-BSA were cultured with OFd. Typical results are shown in Table 1 and Fig. 1. Experiments 1 and 2 of Table 1 show that cells primed to N-BSA or C-BSA do not yield significant numbers of helper cells. Mixtures (1:1) of these cells, however, produced responses as good as OFd primed cells and sometimes significantly better (Fig. 1). Since neither N nor C primed cells yield measureable help, it is not possible to calculate the exact degree of synergy, but this can be estimated to be at least 25-fold, and often 500-fold (Table 1). That the interacting N and C primed cells were T cells is shown by experiment 2 of Table 1 and Fig. 1, which indicates that nylon wool filtered spleen cells (<10% B), or anti-B and complement-treated spleen cells (<3% B) cooperated even more efficiently with B cells than helper cells obtained from unpurified spleen (experiment 1). Experiments

with anti-θ antisera verified that the helper cells were, as usual, T cells (data not shown).

Inhibition of cooperative responses by unconjugated carrier or hapten has been reported both *in vitro*[16] and *in vivo*[15]. Responses that do not involve cell cooperation are not blocked in this way[16]. Thus, the effect of adding N-BSA or C-BSA on the response of OFd primed T cells to OFd was ascertained. Figure 2 shows that the addition of 10 μg ml⁻¹ of N-BSA or C-BSA suppressed the response to 1 μg ml⁻¹ OFd. Significant but not complete suppression was obtained with 1 μg ml⁻¹ N-BSA or C-BSA (data not shown). Analogous results were obtained with N or C hapten coupled to poly-D-glutamic acid, or to succinylated BSA (data not shown). As control, the helper cell response to KLH was also assayed with the same pool of helper cells, to exclude the possibility that the suppression of the OFd response in the presence of N or C-BSA was due to nonspecific toxicity.

Fig. 3 Antigen induced suicide with radiolabelled N or C-BSA. This was performed in a way similar to that of Byrt and Ada[24] and Pearson *et al.*[13]—BSA, N or C-BSA were radiolabelled with ¹²⁵I using the chloramine-T method, 2–10 μg of each compound was labelled with 1 mCi of carrier-free ¹²⁵I-iodide (Radiochemical Centre, Amersham). Primed T cells (10⁸) (purified by nylon wool) were incubated with 1 μg ¹²⁵I-labelled antigen for 1 h at 0 °C in HEPES-buffered Eagle's medium (sometimes containing azide) then washed three times through foetal calf serum, and left overnight at 4 °C before culture with OFd and KLH, together with the addition of 5×10⁵ anti-T and anti-B serum treated peritoneal macrophages per culture. Dark bar represents response to DNP OFd. Unshaded bar represents the response to TNP KLH. Dot above bar graph indicates the upper limit of one standard error of the mean. Results shown are with 10⁵ helper cells from suicided or mixed back helper cell cultures, which were subsequently cultured with normal spleen cells and DNP OFd or TNP KLH. Specific suicide of the response occurred with ¹²⁵I-N-BSA or ¹²⁵I-C-BSA. It is interesting that mixing the two suicided populations completely restored the response to OFd. These experiments were performed as a helper cell dose-response titration, using 5×10⁵, 10⁵ and 2×10⁴ helper cells. For simplicity, the results with 5×10⁵ and 2×10⁴ are not included, as they corroborated those shown.

Table 1 Synergy between N- and C-primed T cells in the generation of helper cells to OFd

Cells cultured	Helper cell induction			Cell cooperation	
	Treatment	Antigen	Helper cells transferred	Antigen	Anti-DNP response (AFC per culture)
(1) OFd primed spleen	nil	OFd	10^5	DNP OFd	173± 22
N-primed spleen	nil	OFd	10^5	DNP OFd	13± 10
C-primed spleen	nil	OFd	10^5	DNP OFd	0
N-+ C-primed spleen (1 : 1) —	nil —	OFd —	10^5 —	DNP OFd	217± 33
				DNP OFd	3± 43
				DNPPOL	553±160
				nil	27± 33

—	—	—	—	DNP OFd	127± 25
				TNP T$_4$	920±110
				nil	113± 54

CBA mice bred at University College or at the ICRF Animal Unit at Mill Hill were used at 70–210 d of age. For use as donors of primed spleen cells, they were injected intraperitoneally with 25 μg of OFd, N- or C-BSA emulsified in Freund's complete adjuvant. Usually the N or C hapten was conjugated to succinylated BSA. 15×10^6 spleen cells were cultured with 1 μg ml^{-1} OFd for 4 d to yield helper cells. Cell recoveries were variable from 10–45%, but averaged 30%. Washed viable (Trypan blue exclusion) cells from these cultures were mixed in the numbers indicated with 15×10^6 unprimed CBA spleen cells and 1 μg ml^{-1} DNP OFd and cultured for a further period of 4 d before assay for anti-DNP antibody forming cells using the Cunningham technique[14]. Preliminary experiments had indicated that the two periods of 4 d and 1 μg ml^{-1} of antigen were optimal. Eleven experiments of the type shown as experiment 1 have been performed. No helpers were obtained with N or C primed cells at other times of culture (1–6 d), or other concentrations of OFd.

In experiment 2, spleen cells from OFd, N or C primed mice were passed through nylon wool columns[20] to purify T cells. Contamination with B cells, as assessed by fluoresceinated rabbit anti-mouse Ig antibody was 5–9% in replicate experiments. Because the nylon wool columns also remove macrophages, essential for helper cell induction[21] 5×10^6 peritoneal exudate macrophages (obtained 3 d after the injection of starch), purified by treatment with anti-B serum and complement[21] were added to each helper cell culture. The exact degree of synergy is difficult to estimate, as neither N nor C primed cells yield detectable help A crude approximation of the degree of help may be obtained by comparing the smallest numbers of (N and C) mixed cells which provide help, for example, 2×10^4, with those unmixed that do not, for example 5×10^5, giving a synergy ratio of greater than or equal to 25. DNPPOL (dinitrophenylated polymeric flagellin) and TNPT$_4$ (trinitrophenylated phage T$_4$) are thymus-independent antigens

The technique of radioactive antigen-induced suicide was also used to verify the requirement for both N-hapten and C-hapten reactive cells to generate helper cells to OFd. Incubation of OFd primed spleen cell or purified T cells with highly radioactive (^{125}I-labelled) N or C-BSA suppressed the helper response to OFd. In contrast, the responses of the same cell pool to KLH was unimpaired. ^{125}I-BSA was not suppressive. Mixing the N-suicided and the C-suicided populations (each of which should contain an intact population of cells directed against the other hapten) restored the OFd helper response to normal levels, thus providing further evidence for a cooperative interaction between the two hapten reactive cells.

Three independent experimental approaches have thus all indicated that N and C reactive T cells interact to generate helper cells to OFd. It seems then that there is T–T interaction in the development of helper cells, just as in other T cell responses—the graft versus host response[6] and the T killer response[7–10]. Other studies also support our evidence for T–T interaction in the generation of helper cells. Either anti-lymphocyte serum (ALS) treatment or adult thymectomy (ATX) markedly reduces the thymus-dependent antibody response to tobacco mosaic virus[17]. Furthermore, Hunter, Kappler and colleagues have also shown that both ALS and ATX diminish helper responses to sheep red cells, but that both procedures are needed to abolish the helper response[18,19]. Our studies *in vitro*, using keyhole limpet haemocyanin as antigen, indicated that defined populations of T$_1$ and T$_2$ cells purified from the spleen (by treatment with ALS and by adult thymectomy respectively) do not yield helper cells unless mixed together (unpublished data), in contrast to normal spleen which contains both T$_1$ and T$_2$ cells. Thus the interaction of subpopulations of T cells is of importance in the generation of helper cells, just as it is in the development of graft versus host and the cytotoxic response.

We thank Mrs M. Dunkley, Miss E. Creaghe and B. de Souza for assistance.

Concurrent inhibition by chlorpromazine of concanavalin A-induced lymphocyte aggregation and mitogenesis

A PLANT lectin from extract of Jack bean (concanavalin A) is known to initiate transformation *in vitro* of T lymphocytes into large, proliferating blast-like cells[1]. Knowledge of the mechanism whereby con A induces such changes is incomplete, but a necessary first step seems to involve the binding of con A to receptors on the surface membrane of the lymphocyte. Within minutes of binding of a mitogen, recognisable alterations in lymphocyte surface membrane physiology have been noted. These include increased phospholipid incorporation into the membrane[2], increased fluxes of ionic potassium[3] and calcium[4], and increased uptake of nucleosides[5], sugar[6], and amino acids[7]. In addition, con A has been reported to increase the fluidity of lymphocyte membranes after binding[8]. Internalisation of con A is not required for lymphocyte activation so that con A binding to the lymphocyte surface membrane of T cells seems to be sufficient to induce blastogenesis[9].

Less attention has been paid to the fact that con A also induces an aggregation or clustering of mononuclear cells following its addition to *in vitro* culture. At optimal mitogenic concentrations, this process is not an immediate agglutination but occurs progressively over several hours in culture. It has been suggested that such cluster formation may be a necessary prerequisite for blast transformation induced by a mitogen, as cells immobilised in single cell suspensions in agar will not transform[10], and increased cell density[11], presumably augmenting cell–cell interaction, enhances mitogenesis. In accordance with this hypothesis we have found that similar concentrations of the surface membrane-active drugs, chlorpromazine (CPZ) will inhibit both the blastogenic response as well as the clustering of mouse spleen cells by con A.

The effect of CPZ on con A-induced blastogenesis is shown in Fig. 1. Concentrations of CPZ > 0.005 mM totally inhibited the uptake of ³H-thymidine by con A-stimulated cultures. Concentrations of CPZ < 0.001 mM had little effect.

When dealing with pharmacological inhibition studies such as this it is imperative that any cytotoxic effects of the drugs themselves be evaluated. Mouse spleen cells were therefore incubated with inhibiting concentrations of CPZ for 24–48 h in the presence or absence of con A. No loss of viability was seen at concentrations ≤ 0.05 mM by Trypan blue exclusion or ⁵¹Cr release assays. In addition, if spleen cells were pre-incubated for 2 h in the presence of concentrations of the drug (0.01 mM) sufficient to inhibit mitogenesis, washed extensively, and then cultured with con A, there was no difference in the blastogenic response compared with untreated control cells (data not shown). Thus, CPZ in these concentrations was not detectably cytotoxic to lymphocytes and its effect was reversed by removal of the drug. To further prove viability and characterise the inhibition of blastogenesis, CPZ was added at intervals after incubation of spleen cells with con A. If CPZ was added with con A or 2 h later, marked depression of thymidine incorporation was observed, whereas if CPZ was added after 24 h a response very similar to cultures lacking CPZ was observed (Fig. 2). This experiment provides additional proof of viability, as ³H-thymidine incorporation in response to con A proceeded unaltered in the presence of the drug. In addition, the inhibitory effect of the drug seems not to derive from an inhibition of DNA synthesis, that is, once the con A-induced intracellular message had been sent and the lymphocyte was committed to respond, the addition of the drug had no effect on the subsequent blastogenic response.

Con A-treated lymphocyte cultures were observed by light microscopy. Aggregation was far advanced by 12 h in the

absence of CPZ. Con A-induced lymphocyte aggregation was inhibited by CPZ at concentrations equal to that which inhibits blastogenesis. CPZ (0.01 mM) added to con A cultures after 12 h, however, did not disperse already formed cell clusters.

One possible mechanism of both inhibition of blastogenesis and of cluster formation could be the inhibition by CPZ of binding of con A to the surface of the lymphocyte. To test this possibility, binding studies using ³H-labelled con A were carried out. A 1 : 5 dilution of ³H-con A (80–92 Ci mM⁻¹) was made and diluted in a solution of 100 µg ml⁻¹ unlabelled con A. This was added to a population of spleen cells (5 × 10⁵ cells ml⁻¹), incubated for 30 min at 37 °C, washed three times with 1% albumin solution in phosphate-buffered saline, collected as above, and counted in a scintillation counter. The
Fig. 1 CPZ dose–response inhibition of con A-induced ³H-thymidine incorporation of murine (C3H/HeJ) spleen cells: 5 × 10⁵ spleen cells were cultured in 0.2 ml medium 199 (GIBCO) containing 7.5% heat-inactivated human pooled serum and 1% penicillin and streptomycin. Cultures were carried out in triplicate in 96-well, flat bottom microtitre plates (Falcon). CPZ (Smith, Kline and French) was added in appropriate concentration immediately before addition of con A (5 µg ml⁻¹). At 18–24 h before collection, each well was pulsed with 1 µCi ³H-thymidine (6.7 Ci mM⁻¹). After 96 h culture, cells were collected in a 12-place mechanical collector (Otto Hiller), dried and counted in a Beckman LS330 scintillation counter. Each point represents the mean of triplicate cultures not differing by more than 10%.

concentrations of CPZ found to inhibit blast transformation had no effect on the binding of con A to the lymphocyte cell surface; however, α-methylmannose, an inhibitor of con A binding, did inhibit binding. As binding of ³H-con A is unaffected by CPZ, some event subsequent to lectin binding but necessary for both aggregation and blastogenesis must be at work. This is further supported by considerable data that CPZ acts primarily on the membranes of nerve, muscle and lymphocytes.

Studies of lymphocyte activation have focused on the role of cyclic AMP[12] and cyclic GMP[13] as well as mitogen-induced

Fig. 2 Effect of timed addition of CPZ (0.01 mM) on con A-induced ^{3}H-thymidine incorporation. Cells were cultured and pulsed as in Fig. 1. Cultures were collected at times indicated on the abscissa. Con A (5 µg ml^{-1}) was added to all cultures (5×10^5 cells) at initiation of culture. CPZ (0.01 mM) was added at various times after culture. ○, No CPZ added; ▲, CPZ added with con A; △, CPZ added 2 h after con A; ●, CPZ added 24 h after con A.

changes in Ca^{2+} flux[14]. CPZ is a well established Ca^{2+}-blocking agent producing inhibition of Ca^{2+} fluxes in muscle[15] and adrenal preparations[16]. This pharmacological action of CPZ has been shown to be reversed by high Ca^{2+} concentrations in the media[17]. If, however, lymphocytes are cultured in media containing 5 or 10 mM calcium no reversal of CPZ inhibition of con A-induced blastogenesis was observed (data not shown).

CPZ has also been shown to inhibit hormonally stimulated increases in adenylate cyclase activity of rabbit heart tissue without affecting the base level of enzyme activity[18], and to decrease the amphetamine-induced increase of cyclic GMP of murine cerebellum[19]. Preliminary data indicate that addition of a range of concentrations of cyclic AMP, or its dibutyryl derivative (10^{-6}–10^{-3}M) did not reverse CPZ-induced inhibition of transformation or lymphocyte aggregation (data not shown). Cyclic GMP or its dibromo derivatives in a dose range of 10^{-9}–10^{-3} M either added to cultures with con A and CPZ or added to cells for 15 min before culture with con A and CPZ, also did not reverse the inhibitory effect of CPZ (data not shown). It seems, therefore that a membrane phenomenon not reversed by Ca^{2+}, cyclic AMP or cyclic GMP, is involved in the inhibition of con A-induced lymphocyte transformation by CPZ.

The cellular requirements for mitogen stimulation and their interactions in the activation process are possible targets for CPZ action. Highly purified human T cells show a markedly reduced response to mitogen-induced blastogenesis (J.R.S., and S. Hatfield, unpublished). This response, however, could be restored by the addition of isologous, allogeneic or even xenogeneic macrophages to mitogen cultures. This suggests that the macrophage plays a significant role in the response of T cells to mitogens. Additional support for the importance

of cellular interactions in lymphocyte activation by mitogens is given by Moorhead[11] who demonstrated an inverse and linear relationship between the surface area on which equal numbers of lymphocytes were cultured and the log of ^{3}H-thymidine incorporation into mitogen-stimulated cells. Kondrocki[10] has shown that isolated 'single-cell' suspensions of lymphocytes in agarose respond poorly to mitogen but that addition of erythrocytes or erythrocyte stromata to such preparations markedly increases the blastogenic response. Implicit in the above observations is that cell membrane interactions play an important role in mitogen activation. CPZ, as shown above, inhibits mitogen-induced lymphocyte clustering seen in con A-stimulated cultures and thus removes the opportunity for cell-cell interactions.

Whether aggregation and blastogenesis are a manifestation of a common lectin-induced lymphocyte membrane perturbation or whether each is an independent consequence of mitogen binding is not known. Further studies to answer this question, utilising a surface membrane pharmacological approach to soluble and cellular *in vitro* antigen stimulation, in addition to mitogen activation, are in progress.

Temperature dependence of phenoxybenzamine effects and the adrenoceptor transformation hypothesis

ADRENOCEPTORS can be classified into two types, α or β, according to their sensitivity to agonists and antagonists. It has been claimed that the β-adrenoceptors mediating the effect of adrenaline on the contractility of frog isolated heart are changed to α-adrenoceptors by lowering the temperature from 24 to 14 °C (ref. 1). The evidence for this suggestion was that a high concentration of the α-adrenoceptor-blocking drug phenoxybenzamine inhibits the effect of adrenaline at the low temperature but not at the higher temperature, and that the frog heart binds almost twice as much phenoxybenzamine at

Table 1 Inotropic potencies of isoprenaline, adrenaline and phenylephrine (ED_{50}), and potency of propranolol (expressed as the dose ratio of isoprenaline) on the frog isolated ventricle at 24 and 14 °C

	Temperature (°C)	No. of expts	Negative log molar ED_{50} (mean±s.e.)	log Dose ratio of isoprenaline
Isoprenaline	24	7	8.48±0.31	—
Isoprenaline	14	9	8.76±0.50	—
Isoprenaline+0.34 µM propranolol	24	8	6.70±0.11	1.78
Isoprenaline+0.34 µM propranolol	14	9	6.97±0.12	1.79
Isoprenaline+3.4 µM propranolol	24	6	5.84±0.02	2.64
Isoprenaline+3.4 µM propranolol	14	6	5.85±0.02	2.91
Adrenaline	24	9	6.66±0.40	—
Adrenaline	14	9	7.37±0.62	—
Phenylephrine	24	4	5.29±0.23	—
Phenylephrine	14	5	5.46±0.22	—

Strips of frog ventricle were suspended in a solution consisting of 111 mM NaCl, 2.4 mM $NaHCO_3$, 1.9 mM KCl, 1.1 mM $CaCl_2$, 0.07 mM NaH_2PO_2, and 10 µg ml^{-1} disodium edetate. Contractions were elicited with a Grass stimulator (1–3 ms, voltage just above threshold) at a rate of 0.3 Hz (24 °C) or 0.2 Hz (14 °C) and recorded isometrically. Potencies of the agonists were determined from cumulative dose–response curves. Propranolol was present 60 min before isoprenaline was added. Potency of the antagonistic drug is expressed as the dose ratio: this is the ratio of the potency of the agonist in the presence of the antagonistic drug and in its absence. Frog experiments were carried out between the months of September and February.

the low temperature than at the higher temperature. Phenoxybenzamine, particularly in high concentration, does not, however, specifically block α-adrenoceptors, and the purpose of the present experiments was to test the hypothesis of the receptor transformation by procedures not dependent on the use of this drug.

The adrenoceptor is a descriptive term and its nature is unknown. A response is said to be mediated by α-adrenoceptors when the relative potency of a series of agonists shows that adrenaline is highest, phenylephrine is somewhat lower, and isoprenaline is very low, and when the response is susceptible to blockade by a low concentration of an α-adrenoceptor-blocking drug. A response is said to be mediated by β-adrenoceptors when the relative potency of a series of agonists shows that isoprenaline is highest and phenylephrine lowest, and when the response is susceptible to blockade by a low concentration of a β-adrenoceptor-blocking drug. The present experiments used these criteria to test the validity of the adrenoceptor transformation hypothesis; the results do not support the concept that β-adrenoceptors are changed to α-adrenoceptors at low temperature. Adenylate cyclase coupled β-adrenoceptors in frog heart[2] and erythrocytes[3] did not change with temperature.

Table 1 summarises the results of experiments to determine the inotropic potencies of isoprenaline, adrenaline and phenylephrine at 24 and 14 °C. Lowering the temperature had little effect on the potencies of the sympathomimetic drugs. Table 1

also shows the antagonism of isoprenaline by the β-adrenoceptor-blocking drug propranolol; the blocking effect of this drug was not altered by the change in temperature. It seems from these results that low temperature does not change the β-adrenoceptors mediating the inotropic effect on the frog heart.

Phenoxybenzamine is a highly lipid-soluble compound which is capable of alkylating nucleophilic centres after forming an aziridinium ion on neutralisation[4]. In isolated mammalian heart preparations nanomolar concentrations of phenoxybenzamine block α-adrenoceptors[5] and micromolar concentrations have additional effects, such as an acetylcholine antagonism at muscarinic sites[6]; an inhibition of tyramine effects[7], probably caused by blockade of neuronal uptake sites[8]; a potentiation of noradrenaline effects[7], probably the result of blockade of neuronal and extraneuronal uptake sites[9]; and a reduction in heart rate and inhibition of the chronotropic effect of noradrenaline, which is not the result of adrenoceptor blockade[10].

In agreement with previous observations[1] it was found that 7.4 µM phenoxybenzamine inhibits the response of the frog heart to adrenaline at 14 °C, that the inhibitory activity on incubation with phenoxybenzamine at low temperature persists when the temperature is raised to 24 °C, and that phenoxybenzamine had no effect when incubation was carried out in the presence of 10 µg ml^{-1} of the competitive α-adrenoceptor-

Table 2 Effect of interaction of phenoxybenzamine with acetylcholine, tyramine and noradrenaline on contractility of the frog isolated ventricle and the guinea pig isolated left atrium at 14 °C and 24 or 31 °C

	Treatment	Agonist	Temperature (°C)	log Dose ratio of agonist
Frog	0.1 µM atropine	Acetylcholine	Treatment+assay, 24	2.81
Frog	0.1 µM atropine	Acetylcholine	Treatment+assay, 14	2.58
Frog	2.9 µM phenoxybenzamine	Acetylcholine	Treatment+assay, 24	2.30
Frog	2.9 µM phenoxybenzamine	Acetylcholine	Treatment, 24; assay, 14	2.16
Frog	2.9 µM phenoxybenzamine	Acetylcholine	Treatment+assay, 14	0.79
Frog	2.9 µM phenoxybenzamine	Acetylcholine	Treatment, 14; assay, 24	0.36
Guinea pig	0.74 µM phenoxybenzamine	Acetylcholine	Treatment+assay, 31	1.96
Guinea pig	0.74 µM phenoxybenzamine	Acetylcholine	Treatment, 14; assay, 31	0.60
Guinea pig	7.4 µM phenoxybenzamine	Tyramine	Treatment+assay, 31	0.84
Guinea pig	7.4 µM phenoxybenzamine	Tyramine	Treatment 14; assay, 31	0.20
Guinea pig	7.4 µM phenoxybenzamine	Noradrenaline	Treatment+assay, 31	−1.16
Guinea pig	7.4 µM phenoxybenzamine	Noradrenaline	Treatment, 14; assay, 31	−0.08

Strips of guinea pig left atrial appendage were suspended in a solution consisting of 137 mM NaCl, 11.9 mM $NaHCO_3$. 2.7 mM KCl, 1.8 mM $CaCl_2$, 0.36 mM NaH_2PO_4, 5.55 mM glucose and 10 µg ml^{-1} disodium edetate which was aerated with 5% CO_2 in O_2. Contractions were elicited at a rate of 1 Hz (31 °C) or 0.2 Hz (14 °C). See Table 1 for details. Incubation with phenoxybenzamine was for 40 min after which bath fluid was repeatedly changed before agonists were assayed. A positive dose ratio indicates inhibition, and a negative dose ratio potentiation, of the inotropic effect of the agonist.

blocking drug phentolamine. It was also found, however, that 10 µg ml^{-1} of the membrane stabilisers procainamide or quinidine prevented the phenoxybenzamine effect and that 7.4 µM phenoxybenzamine inhibited the effect of isoprenaline, although isoprenaline acted on β-adrenoceptors. From these results we conclude that the frog heart at low temperature is sensitive to an inhibition by phenoxybenzamine of Ca^{2+} movements which are the result of β-adrenoceptor stimulation[11]. Although the effect was persistent, it may not be based on covalent bond formation. Tissues have a high binding capacity for unchanged phenoxybenzamine[12], and lowering of temperature stabilises the intermediate aziridinium ring and greatly reduces its reactivity[4].

Other experiments measured the negative inotropic effect of acetylcholine and showed that phenoxybenzamine antagonised this effect (Table 2). Unlike atropine, phenoxybenzamine was inactive at low temperature. The behaviour of phenoxybenzamine was persistent: incubation at 24 °C led to blockade, and incubation at 14 °C did not, whether acetylcholine was assayed at 24 or 14 °C.

Studies with guinea pig atria also demonstrated the inactivity of phenoxybenzamine at low temperature. Phenoxybenzamine pretreatment at 31 °C, but not at 14 °C, inhibited the effect of tyramine and potentiated the effect of noradrenaline, and there was no inhibition of the noradrenaline effect after phenoxybenzamine treatment at 14 °C (Table 2).

Our results show that phenoxybenzamine inhibits the effect of adrenaline on the frog heart at low temperature by an action which does not involve α-adrenoceptors and that the increased tissue retention of the drug is not associated with adrenoceptor blockade. Such experiments cannot be interpreted as indicating that β-adrenoceptors are changed to α-adrenoceptors at low temperature. Our experiments to test the relative effects of agonists at high and low temperature clearly indicate that the nature of the adrenoceptors changes little with altered temperature.

Effects of sodium on solute transport between compartments in intestinal mucosal epithelium

THE uptake of amino acids and of some monosaccharides into the intestinal mucosal cell across the brush-border membranes requires sodium in the intestinal lumen[1-3]. An hypothesis of the existence in brush-border membranes of systems for transport that depend on Na—for example, the 'Na gradient' hypothesis[4]—although necessary, is not sufficient to account for all the effects of Na on epithelial transport. Whereas in *in vitro* conditions[5] the accumulation of amino acids and monosaccharides within the epithelium depends markedly on Na in the intestinal lumen, movement of these substances from the lumen into the blood in *in vivo* conditions is less dependent on Na in the lumen[6-9].

Using a vascularly-perfused preparation of frog intestine, we have shown that removal of Na from the vascular bed causes an inhibition of solute transfer into the blood that is additional to that resulting from Na-free conditions in the lumen[8,10]; here, we present further evidence to distinguish between the effects of Na on epithelial, as distinct from membrane (that is, brush-border) transport processes.

Removal of Na from the vascular perfusate decreases the extracellular space as measured by the washout into the circulation of labelled sucrose initially added to the vascular perfusate (Fig. 1). Addition of Na to the vascular perfusate increases the rate of efflux of intracellular 3–O–methyl–D–glucose (3–O–MeG) into the vascular bed, the cells initially having been loaded from the vascular side in the presence of an extracellular marker (Fig. 2a).

Fig. 1 Effect of presence (●) or absence (○) of sodium in the arterial infusate on the washout into the portal vein of the extracellular marker sucrose U-^{14}C labelled sucrose (1 mM; Radiochemical Centre, Amersham) was infused into the mesenteric artery for 30 min. A non-radioactive perfusion medium was abruptly switched into the arterial bed and the washout collected in 1-min fractions. Accumulated appearance of sucrose during washout is plotted against time. Choline substituted for sodium for the period of Na-free vascular perfusion; the lumen was perfused with Na-free Ringer's solution containing 5×10^{-5} M phlorizin. Control and experimental periods were carried out on the same vascularly-perfused small intestine of *R. ridibunda*[10]. Note the substantial increase in extracellular space when Na is present in the vascular perfusate: other experiments showed that neither Li nor K could substitute for Na. Vascular flow rate was 2.73 ml per min per g dry weight; that in the lumen was 0.83.

After Na-free perfusion of lumen and vascular bed, return of Na to the lumen increased the rate of efflux of 3–O–MeG from the cells into the vascular bed (Fig. 2b); although the effect of Na in the lumen was not as great as that seen with return of Na to the vascular bed, the observation that Na in the lumen may partially substitute for Na in the vascular bed strongly suggests that the effects of Na depend on events within the epithelium and not in the underlying muscle. We also found that the total quantity of 'intracellular' 3–O–MeG loaded into the cells from the circulation is increased by 43% on addition of Na to the vascular perfusate.

To investigate the effects of Na in the vascular perfusate on the translocation of intracellular amino acids into the blood, a high concentration (10 mM) of the relevant amino acids in the lumen was used to saturate the brush-border amino acid uptake systems[14]; any additional appearance of amino acid in the perfusate after subsequent addition of peptide to the lumen will then be a consequence of separate peptide uptake. We found that the removal of Na from the vascular perfusate results in a large though reversible inhibition (67%) of the transfer of amino
Fig. 2 *a*, Effect of introducing sodium into the vascular bed (arrow) on fractional rate constant for 'intracellular' 3-O-MeG unloading from the small intestine into the effluent collected from the portal vein. Rate of 'intracellular' 3-O-MeG appearance in the circulation was calculated from the difference in the fractional appearance during washout (see refs 11 and 12) of 1-³H-3-O-MeG and of an extracellular marker, U-¹⁴C-sucrose (both from Radiochemical Centre, Amersham) following constant infusion of both substrates at a concentration of 1 mM into the mesenteric artery for 30 min. Scintillation counting of aliquots of 1-min fractions of the effluent appearing in the portal vein was as described previously[10]. Fractional rate constants (*K*) were calculated according to Caldwell and Keynes[13]. Control Na-free (O) and experimental periods (Na where indicated, ●) were carried out on the same vascularly-perfused small intestine of *R. ridibunda*[10], thus demonstrating reversibility following Na removal. Ringer's solution was as given in ref.10 except that Li rather than K substituted for Na; however, similar findings were made when Na was replaced with choline or K. The lumen was perfused with Na-free Ringer which additionally contained 5×10^{-5} M phlorizin to ensure that any observed Na-dependent effect on 3-O-MeG movement could not have arisen at the epithelial brush-border. Vascular flow rate: 2.73 ml per min per g dry weight; luminal flow rate: 0.83. *b*, effect of introduction of Na into the lumen on fractional rate constant (*K*) for 'intracellular' 3-O-MeG unloading into the effluent appearing in the portal vein. Note that the tissue was loaded from the vascular bed and the experimental protocol was as for *a* except that K rather than Li was substituted for Na Vascular perfusate was Na-free and that in the lumen contained 5×10^{-5} M phlorizin Note delay in increase of rate constant when Na is present in lumen. This effect was consistently observed in three preparations. *R. ridibunda*, vascular flow rate: 4.56 ml per min per g dry weight; luminal flow rate: 4.90.

acids initially taken up in the form of peptide into the vascular bed. This is in marked contrast to the uptake of peptide from intestinal lumen which is independent[14] of Na in the lumen.

A further effect of Na is found on solute flux across the epithelium. Unpublished experiments (C.A.R.B.) show that the rates at which both sucrose and 2-deoxy-D-glucose (2-DOG) enter the lumen from the vascular perfusate are substantially increased (by 100% and 97%, respectively) on addition of Na to the lumen. This entry is not influenced by the presence of phlorizin in the lumen. Sucrose is confined to the extracellular space[15] and is suitable as a paracellular probe only because of the extremely low intestinal sucrase activity in the frog[8]. The route taken from the vascular bed to the lumen by 2-DOG is less certain; but whatever it may be, it clearly depends on Na, although it is insensitive to phlorizin, a known competitive inhibitor of monosaccharide transport in brush-border membranes.

The rate of appearance of 3-O-MeG and of 2-DOG in the lumen from constant vascular infusion is presented in Fig. 3. 2-DOG, lacking the hydroxyl group on C-2, is known[16] to have no affinity for the brush-border, phlorizin-sensitive, glucose uptake system, whereas 3-O-MeG behaves like glucose at the brush-border but has the advantage of not being metabolised by frog intestine[17]. It is clear that 2-DOG appears at a faster rate in the effluent from the lumen than 3-O-MeG—which initially cannot be detected—and at a time when appreciable amounts of 2-DOG are already present. A pulse of 10 mM D-glucose in the lumen results in a sudden increase in the appearance of both sugars but the effect is proportionately five times greater for 3-O-MeG. The subsequent addition of phlorizin to the lumen increases the rate of 3-O-MeG appearance in the lumen, whereas it has no effect on the movement of 2-DOG.

A simple explanation for these effects is that a significant quantity of the 3-O-MeG that enters the lumen is recaptured by
Fig. 3 Rates of appearance in the lumen of U-¹⁴C-3-O-MeG (●) and of 1-³H-2-DOG (O); (Radiochemical Centre, Amersham) after arterial infusion of both sugars at a concentration of 1 mM into the vascularly-perfused small intestine of *R. ridibunda*[10]. For the periods indicated, 10 mM D-glucose (*a*) or 5×10^{-5} M phlorizin (*b*) was added to the luminal perfusate. Vascular flow rate: 6.05 ml per min per g dry weight; luminal flow rate: 6.57.

transport systems in the brush-border. Addition to the lumen of phlorizin blocks this reuptake, thus increasing net appearance of the sugar in the lumen. We also find that glucose added to the lumen competes with 3-O-MeG for reuptake, again increasing the net appearance in the lumen of the 3-O-MeG. The absence of an effect of phlorizin and the small effect of glucose on the rate of appearance of 2-DOG in the lumen is also in accord with this explanation, although the movement of 2-DOG into the lumen involves other factors (C.A.R.B., unpublished).
Fig. 4 *a*, Model of relationship between compartments of intestinal epithelium involved in solute transport. Rectangular box, pathway; circle, pool. Two epithelial cells and a single paracellular shunt are depicted. We suggest that Na, in addition to affecting the entry system, increases the intercellular space. LBP, Lumen bulk phase; LUL, lumen unstirred layer; IJ, intercellular junction; IS, intercellular space; IP, intracellular pool; BM, basement membrane; CW, capillary wall; P, plasma. *b*, Possible physical interpretation of the model proposed in *a*. C, Epithelial cell; Ca, capillary. Note importance of intercellular space in determining ease of access of substrate to capillary.

The presence of a compartment in the intestinal lumen adjacent to the epithelial sheet, which is unstirred[18-20] and from which specific reuptake may occur will minimise escape of substrates from the epithelium into the bulk phase of the lumen contents. Reuptake from such a compartment will be blocked by the presence in the lumen of an inhibitor of brush-border membrane transport, such as phlorizin in the case of monosaccharides, or by the presence of high concentrations of competing substrate. Axon and Creamer[21] have suggested different interpretations of similar observations.

In Fig. 4 we propose a model that may account for the effects of Na on epithelial transport. It is suggested that, in addition to the known effects on membrane transport at the brush-border (Na gradient hypothesis), Na influences the transfer of substances between compartments in the epithelium. Two of these compartments are extracellular, one intercellular within the epithelium, and the other, a stationary, unstirred layer in the lumen and adjacent to the brush-border membranes. In the light of this model, Csaky's proposal[17] that "a critical intracellular Na concentration is essential" for intestinal (sugar) transport is no longer in direct conflict with the Na gradient hypothesis. The model accounts for the fact that the presence of Na in the vascular bed is necessary for maximal rates of epithelial transport (see also ref. 22). The notion that one effect of Na on epithelial transport is to increase the size of extracellular spaces is in accord with our data on the sucrose space in the epithelium. Such an effect of Na on epithelial transport cannot be seen when the epithelium is disrupted, and has not been found[23,24].

The failure to demonstrate effects on solute transfer when the serosal Na is replaced in sheets of intestine *in vitro*[5] may depend on the presence of a substantial diffusion barrier restricting access of the bathing solution to the epithelium (intramural unstirred layer). This barrier is naturally circumvented by vascular perfusion.

We conclude that in addition to its role in membrane transport, an important function of Na in epithelial transport of solutes is in expanding extracellular spaces within the intestinal mucosa with consequential effects on the clearance of transported substrates from these spaces. The clearance may be forward into the blood stream or backwards into the unstirred layer in the lumen. Our data also suggest that the requirement for Na for this purpose can be completely fulfilled by its presence in the vascular bed, but only partially fulfilled by the addition of Na to the lumen when Na is absent from the vascular perfusate.

Synthesis and conformations of hypothalamic hormone releasing factors: two QRF-analogues containing backbone N-methyl groups

SINCE its isolation and characterisation[1,2], the hypothalamic hormone-releasing factor TRF (pGlu–His–Pro–NH$_2$) has been the subject of several conformational studies. Most investigations have indicated that the steric characteristics of the three adjacent rings strongly limit the backbone conformational flexibility and support a preference for an extended structure. The importance of each functional group in the molecule in terms of biological potency has been systematically investigated (for review, see ref. 3). With one exception (methylation of the histidyl side chain in the N$^\tau$ position) all the chemical modifications which have been made to date were accompanied by a substantial loss of biological activity. We have shown[4] that most of these modifications do not significantly affect the preferred backbone conformation of the hormone, emphasising the critical role of each functional group in TRF for optimal binding to the receptor sites.

To investigate the 'active' conformation of the hormone we tried to influence the conformational equilibrium of the tripeptide (without affecting its functional characteristics) by preparing an analogue which contains a methylated peptide group between the pyroglutamyl and histidyl residues, [N$^\alpha$MeHis^2]TRF, and a second analogue in which the prolyl residue was substituted by N$^\alpha$methylalanyl, [N$^\alpha$MeAla^3]TRF. This latter compound was previously suggested by Burgess *et al.*[5]. From model manipulations it was expected that the first modification would cause a further stabilisation of the molecule in an extended form. Steric interactions between the methyl group and the carbonyl group of the histidyl–prolyl peptide residue, on the one hand, and the β-methylene protons of the histidyl side chain on the other, are expected to affect

slightly the values for the backbone rotational angles of the extended form (φ_2, ψ_2) as well as the rotational isomerism of the histidyl side chain (χ_1, χ_2). This modification also prevents the formation of an intramolecular hydrogen bond between the pyroglutamyl–histidyl peptide proton and the N$^\pi$-nitrogen of the imidazole ring, and therefore provides an adequate test of the hairpin turn model[6] proposed[7] as the active three-dimensional structure of the hormone. In the second modification, replacement of the prolyl residue by N$^\alpha$methylalanyl introduces an additional degree of freedom for the rotational angle φ_3. For a typical φ_3 value, however, the N$^\alpha$methylalanyl residue sterically simulates the prolyl residue reasonably well.

Both analogues were synthesised by the solid-phase technique using a benzhydrylamine resin of 0.15 mEq g^{-1} substitution as support. The amino acid residues were introduced as Boc-derivatives (with the exception of ZpGluOH) and coupled in threefold excess in methylenechloride, using dicyclohexylcarbodiimide as coupling agent. The tripeptides were cleaved from the resin by the action of double-distilled hydrofluoric acid at 0 °C over a 45-min period.

The amino acid derivative N$^\alpha$methylhistidine was prepared as described previously[8]. Histidine hydrochloride was treated with a threefold excess of benzaldehyde in the presence of N,N-dimethylbenzylamine as base, to give N$^\alpha$benzylhistidine which was then methylated by refluxing a formic acid solution of the compound in the presence of an equimolar amount of formaldehyde for 15 min. After cooling, the solution was hydrogenated directly using 10% palladium–charcoal as catalyst. The crude product isolated as the monohydrochloride, was recrystallised twice from water–dimethylsulphoxide and once from water–ethanol (melting point 265–267 °C) and its purity confirmed by thin layer chromatography. It was characterised by mass spectroscopy (peak matching). The N$^\alpha$Me isomer can easily be differentiated from the N$^\tau$ isomer and from the bridged spinacin side product by ion-exchange chromatography as monitored on an amino acid analyser and by mass spectroscopy. The N$^\alpha$methylhistidine was then treated with an excess of *tert*-butyloxycarbonyl fluoride in a dioxane–water mixture at 0 °C and pH 8.5 until all the starting

Fig. 1 NMR spectrum (220 MHz) of [N$^\alpha$Me-His^2]TRF acetate in DMSO$_{d_6}$ at 22 °C. *a*, pGlu-NH; *b*, ProCONH$_2$ anti-*trans*; *c*, Im-C^{2}H; *d*, ProCONH$_2$ *syn-trans*; *e*, Im-C^{4}H; *f*, His-C$^\alpha$H; *g*, Pro-C$^\alpha$H; *h*, pGlu-C$^\alpha$H; *i*, Pro-C$^\delta$H$_2$; *j*, His-N$^\alpha$Me; *k*, His-C$^\beta$H$_2$; *l*, DMSO; *m*, pGlu-C$^\beta$H$_2$, C$^\gamma$H$_2$; Pro-C$^\beta$H$_2$, C$^\gamma$H$_2$.

materialwastransformedintoN$^\alpha$Me, N$^\alpha$Boc, N^{1m}BocHisO$^-$Na$^+$. After concentration of the solution *in vacuo*, it was acidified to pH 3.5 and extracted with a mixture of 20% ethyl acetate in ether, from which the *bis*Boc derivative was obtained as a colourless oil.

After cleavage from the resin, the tripeptides were purified by chromatography on carboxymethyl cellulose eluting with a 0.04 M solution of ammonium acetate, and then by partition chromatography on Sephadex G25 in a butanol–acetic acid–water (4:1:5) system. The products were found to be pure by thin layer chromatography and were characterised by amino acid analysis, mass spectroscopy (peak matching) and nuclear magnetic resonance (NMR) spectroscopy.

The biological potencies of the two analogues were determined as described previously[9,10]. The *in vivo* bioassay is based on the ability of TRF or active homologues to release thyroid-stimulating hormone (TSH) from the anterior pituitary, thereby increasing the blood level of ^{125}I-labelled thyroid hormones in appropriately prepared mice. The potencies relative to pGlu–His–Pro–NH$_2$ are as follows: [N$^\alpha$MeAla^3]TRF =4.5±1.3%; [N$^\alpha$MeHis^2]TRF=115±8%. [N$^\alpha$MeHis^2]TRF was assayed *in vivo* three times giving an average potency of 115% which is not statistically different from that of TRF; this analogue was also found to be indistinguishable from TRF in its ability to stimulate *in vitro* TSH secretion by cultured rat pituitary cells.

The 220-MHz NMR spectrum of [N$^\alpha$MeHis^2]TRF in DMSO$_{d_6}$ is shown in Fig. 1. The following differences from the spectrum of TRF were observed: an upfield shift of the anti-*trans* carboxamide resonance of 0.4 p.p.m.; a quasi-disappearance of the non-equivalence of the Pro-C^5 H$_2$ resonances; and an upfield shift of about 0.1 p.p.m. of the Im-C^{4}H resonance. These differences strongly suggest that the imidazole–carboxamide interaction which was found in TRF (in DMSO)[4] is destabilised in the case of [N$^\alpha$MeHis^2]TRF. This is further supported by the fact that the vicinal coupling constants in the C$^\alpha$-C$^\beta$ fragment of the histidyl side chain, which were non-equivalent in TRF (J_{AX}=5.3 Hz; J_{BX}=7.6 Hz), are equivalent in [N$^\alpha$MeHis^2]TRF (J_{AX}=J_{BX}=7.0 Hz). In terms of the relative populations of the side-chain rotamers, this means that the two *gauche* conformers which were unequally populated in TRF (b=0.42, c=0.22), are equally populated in [N$^\alpha$MeHis^2]TRF (b=0.37, c=0.37).

A quantitative interpretation of the ABX system of the histidyl side chain in [N$^\alpha$MeAla^3]TRF was not possible because of overlapping with the methyl resonance. The resonance positions of the anti-*trans* carboxamide proton and of the imidazole C4-proton in this analogue are the same as in TRF, however, which suggests that the imidazole–carboxamide interaction is also favoured in [N$^\alpha$MeAla^3]TRF dissolved in DMSO.

The differences between the NMR spectra of [N$^\alpha$MeHis^2]TRF and TRF itself can be explained by a change in the preferred conformation of the histidyl side chain and a small distortion of the preferred backbone conformation. The high biological potency of this analogue in *in vivo* as well as in *in vitro* tests clearly shows that the steric constraints which were introduced on methylation of the pyroglutamyl–histidyl peptide bond did not affect the binding of the hormone to its receptor sites. For the same reason, the hypothetical hydrogen bond between the pyroglutamyl–histidyl peptide proton and the N$^\pi$ of the imidazole ring does not seem to be a conformational requirement for hormone–receptor interaction.

Transformation of human cells in culture by N-methyl-N'-nitro-N-nitrosoguanidine

THE development of *in vitro* cell culture systems in which healthy cells can be transformed (converted to malignant cells) by chemicals, and detailed studies of the interaction of chemical carcinogens (or their activated forms) and cells, have aided the study of chemical carcinogenesis. *In vitro* chemical transformation of various rodent cells has been well established[1–3]. Many attempts have been made to transform various cultured normal or genetically abnormal human cells with chemical carcinogens without success[4,5]. We have tried to transform human cells from both normal and abnormal individuals and as has been the experience of others, have failed to observe any changes in such cultures. Therefore, the possibility of using continuous lines of human sarcoma cells for chemical transformation was investigated, since certain human sarcoma cell lines are susceptible to transformation by both DNA and RNA tumour viruses[6–8]. This communication reports results of experiments showing that human osteosarcoma clonal cells can be transformed *in vitro* by N-methyl-N'-nitro-N-nitrosoguanidine (MNNG), a known potent carcinogen[9,10] and that these transformed cells produced tumours when injected into NIH nude athymic mice.

A human osteosarcoma clonal cell line designated as TE-85 clone F-5 originally established by McAllister *et al.*[11], was obtained from Naval Biomedical Research Laboratory, Oakland, California. The line had cytological and karyological characteristics similar to those of the parent tumour: it grew to high saturation density, formed colonies in agar medium and was aneuploid but did not produce tumours in anti-thymocyte serum-treated hamsters or mice. This line was also found to be highly susceptible to transformation by a feline sarcoma virus[7]

*Number of subcultures after chemical or DMSO treatment.

and the Kirsten sarcoma virus (KiSV)[8,12]. Growth and maintenance medium consisted of Eagle's minimal essential medium (MEM) with 10% foetal bovine serum (FBS), 2 mM glutamine, 100 units of penicillin and 100 µg of streptomycin ml⁻¹ (MEM+10% FBS).

One day after plating 2×10^5 cells ml⁻¹ from the 31st subculture in Falcon plastic Petri dishes, the medium (MEM+10% FBS) was removed and replaced with media containing MNNG at various concentrations (5.0 µg ml⁻¹ to 0.01 µg ml⁻¹) in 0.5% dimethyl sulphoxide (DMSO). The control medium contained 0.5% DMSO. After 7 d treatment with the carcinogen, the cultures were washed, fed again with carcinogen-free growth medium and subsequently passaged by trypsin treatment every 7 d. When changes in morphology and growth patterns appeared, some cultures were fixed in alcohol and stained with Giemsa for further microscopy. Both transformed and untransformed cultures were established as continuous cell lines.

In the MNNG-treated cultures, morphological alterations of cells and abnormal pattern of growth were noted in the sixth subculture, 55–59 d after treatment (Table 1); a similar change was not observed in the control cells treated with DMSO or in the untreated human cells. Doses of 1.0 µg MNNG ml⁻¹ or greater were lethal. The change was first observed in the cells treated with 0.1 µg MNNG ml⁻¹; however, the alteration observed in the MNNG (0.01 µg ml⁻¹) treated cells became more pronounced after further subcultivation.

The morphological changes observed in these cultures were similar to those observed in a previous study in which KiSV alone transformed TE-85 clone F-5 cells[8,12]. Foci of transformed cells consisted largely of criss-crossed, randomly oriented, spindle-shaped cells with nuclear and cytoplasmic overlapping which stained heavily with Giemsa (Fig. 1a and b). In contrast, the cellular morphology remained unchanged in the untreated, control human cell line, which continued to grow in monolayers of normal-appearing, fibroepithelial-like cells (Fig. 1c) for 18 subcultures during the 112 d after treatment. An increased growth rate (double that of controls) was observed in the MNNG-treated cells, and they had to be subcultured much more frequently than untreated cells.

The relationship between the transformed and control cells was established by chromosome analysis (Table 2). Untreated cells had remarkable marker chromosomes by conventional staining; the same markers were noted in cells of the transformed cultures. Trypsin–Giemsa banding of cells revealed banded markers previously reported in the parental untreated cells, TE-85 clone F-5 (ref. 13). The fluctuation in polyploidy does not seem to be related to the transformation state, since cells near diploid as well as near triploid were involved.

The MNNG-treated cells, as well as untreated control cells, were tested for their ability to transplant and produce tumours in nude athymic mice. Cells were trypsinised, centrifuged, suspended in growth medium, and inoculated subcutaneously (Table 3). All the inoculated nude mice given 5×10^6 cells from MNNG (0.01 µg ml⁻¹) treated cells developed tumours within 2 weeks at the site of inoculation. The tumours were poorly-differentiated sarcomas. A few of the cells were producing a matrix which had some resemblance to osteoid. Moreover, three of five mice given cells from MNNG (0.1 µg ml⁻¹) treated cells produced small, persistent nodules. The nodule tumours resembled osteosarcoma and there was considerable matrix resembling osteoid around many of the cells. No tumours developed over a period of 50 d in a group of nude mice inoculated subcutaneously with the same number of cells from the untreated cultures (Table 3). The tumours were progressive and transplantable. Cells established from the tumours resembled the MNNG-treated cells (Fig. 1d).

The human osteosarcoma clonal cells treated with MNNG had the following properties: (1) The MNNG-treated cells were morphologically altered and grew as randomly oriented multilayers; (2) the treated cells showed increased growth rates; (3) when inoculated into nude athymic mice, one concentration (0.01 µg ml⁻¹) produced subcutaneous tumours and another (0.1 µg ml⁻¹) produced small persistent tumour nodules. It thus seems clear that we have demonstrated the transformation *in vitro* by MNNG of human cells from a continuous cell line. Other continuous cell lines of hamster origin, BHK-21 (ref. 14), of mouse origin, 3T3 (ref. 15) and BALB/c 3T3 (ref. 16), are all susceptible to transformation by

Table 3 Tumours produced in NIH nude mice by human osteogenic sarcoma cells (TE-85, clone F-5) obtained by treatment with MNNG*

Fig. 1 Human osteosarcoma clonal (TE-85, Clone F-5) cells treated with MNNG for 7 d followed by seven subcultures in nutrient medium. Giemsa stain ×39. Note the morphological alterations in human cells treated with 0.01 µg ml⁻¹ and 0.1 µg ml⁻¹ of MNNG: criss-crossed, spindle-shaped cells with nuclear and cytoplasmic overlapping (*a* and *b*). *a*, Human cells treated with 0.01 µg ml⁻¹ MNNG; *b*, human cells treated with 0.1 µg ml⁻¹ MNNG; *c*, human cells (0.5% DMSO); *d*, typical field of culture originating from a primary tumour induced by the MNNG (0.01 µg ml⁻¹) treated human cells.

both DNA and RNA viruses[6] as well as by chemical carcinogens[9]. We confirmed the *in vitro* human sarcoma cell transformation by MNNG and also found that a carcinogenic polycyclic aromatic hydrocarbon, 7,12-dimethylbenz(a)anthracene induced transformation in the human osteosarcoma (TE-85, clone F-5) cell system described here (our unpublished work). Although unfortunately an aneuploid sarcomatous cell line had to be used for this investigation, in view of the fact that little, if any, successful *in vitro* transformation of normal human cells by chemical carcinogens[4,5] had been reported, the system presented in this report may offer an initial advancement in this direction.

It is interesting to note that the chemically altered human cells like the KiSV-transformed TE-85 cells[12] produced tumours when implanted subcutaneously into NIH nude athymic mice whereas control, untransformed cells did not. Although human TE-85 clone F-5 cells which we used in our experiment had cytological characteristics similar to those of the parent tumour[11], they did not form subcutaneous tumours in anti-thymocyte serum (ATS) treated hamsters or ATS-treated mice and did not induce fibrinolytic activity. Subcutaneous inoculation of the original lines TE-85 clone F-5, both from the NBRL repository and our control culture never produced nodules or tumours following implantation of 5 × 10⁶ viable cells. In addition, it is interesting that KiSV-transformed human TE-85 clone F-5 cells induce fibrinolytic activity and yield tumours in ATS-treated hamsters (R. M. McAllister,

personal communication). Studies are in progress to determine whether the chemically altered cells do induce tumours in ATS-treated hamsters and also whether they induce fibrinolytic activity like KiSV-transformed cells.

MNNG, a known potent carcinogen and mutagen that does not require metabolic activation, has been repeatedly demonstrated to transform mammalian cells[9,10]. Henderson *et al.*[17] have reported an increased transformation frequency of human peripheral lymphocytes following treatment with MNNG, possibly by activation of Epstein–Barr virus. Attempts to activate type C virus or virus expression in MNNG-altered cells are in progress.

Detection of DNA complementary to pathogenic viroid RNA in exocortis disease

A LOW molecular weight (about 10⁵ daltons) free RNA has been identified as the pathogenic agent of the exocortis disease of citrus (CEV) by Semancik and Weathers[1]. This minimal 'infectious' RNA (viroid), characterised by a highly ordered structure rich in G–C base pairs[2] does not contain polyadenylate sequences[3] nor can it be translated *in vitro*[4]. The CEV–RNA induces the identical symptom expression in tomato and potato as the spindle tuber viroid[5], thus supporting the class relationship of these unique pathogenic RNAs. The limited genetic potential of these extremely low molecular weight pathogenic RNAs lends credence to the suggestion of host-dependent synthesis[6] and the homology of the pathogenic CEV–RNA with the host genome. This relationship is supported by the detection of a CEV-like DNA, reported here, presumably resulting from the action of host polymerase[7]. The final pathogenic response induced by the viroid RNA might then reflect simply an aberrant expression of the host genome. These functions, resulting in pathogenic RNA synthesis by means of a DNA intermediate as well as the intimate interaction with
Fig. 1 Electrophoresis on 5% polyacrylamide gels of ^{125}I-labelled CEV–RNA (*a*) as iodinated from a purified preparation as shown in the A_{260nm} scanning pattern (*b*) and a DNA-rich preparation from exocortis-infected *Gynura aurantiaca* before (*c*) and after (*d*) treatment with pancreatic DNase I. CEV–RNA was purified as previously reported[2] and iodinated with ^{125}I as reported[9] to a specific activity of about 10[7] d.p.m. µg[-1] RNA. DNA-rich preparations were derived from extraction of fresh tissue with cold phenol and winding high molecular weight DNA from a 2 M LiCl-soluble fraction after addition of three volumes of ethanol. After sedimentation in 1.73 g cm[-3] CsCl for 64 h at 10 °C and 35,000 r.p.m. in a Beckman 65 rotor, the DNA in the supernatant was again removed by winding on to a glass rod after removal of CsCl by dialysis and addition of three volumes of ethanol. Final samples were resuspended and dialysed against TKM buffer (0.01 M Tris, 0.1 M KCl, 10[-4] M MgCl, *p*H 7.4). Sample (*d*) was treated with 15 µg ml[-1] pancreatic DNase I at room temperature for 15 min immediately before electrophoresis[10]. Gels were scanned in a Beckman ACTA CII spectrophotometer, sliced on a Mickle model 140 gel slicer, and either incubated for 48 h at 37 °C in omnifluor toluene scintillator +3% protosol before counting, or eluted overnight in distilled H_2O for recovery of nucleic acid species. Samples from gel areas 1,2,3,4, indicated in (*c*) and (*d*) were hybridised in 40% formamide with ^{125}I-CEV–RNA according to Friedrick and Feix[8] with the RNase-resistant c.p.m. as follows: Area 1, 958; 2, 17; 3, 62; 4, 375.

prepared from healthy and infected gynura and tomato (*Lycopersicon esculentum* Mill, cv. Rutgers) as well as CEV-resistant tobacco (*Nicotiana tabacum*) and cowpea (*Vigna unguiculata* (L.)) Walp. cv. Early Ramshorn. Table 2 indicates that ^{125}I-CEV–RNA specifically hybridises only with DNA extracted from diseased tissues. The existence of a CEV-like DNA is further supported by the reduction in activity in the presence of added carrier CEV–RNA as well as the dependence of RNase resistant activity on DNA concentration. Pre-treatment with DNase, however, could not completely reduce the count level to background, presumably because of the ability of DNA fragments to hybridise with the ^{125}I-CEV–RNA, as suggested by gel electrophoresis (Fig. 1*c*, *d*).

Verification of the presence of a CEV-like DNA was made by analysis of DNA preparations in 5% polyacrylamide electrophoresis and CsCl equilibrium sedimentation. The quality of the isolated CEV–RNA preparation before and after iodination is shown in the gel patterns of Fig. 1*a* and *b*. *In vitro* labelling with ^{125}I as reported by Prensky *et al.*[9] results in the degradation of a portion of the CEV–RNA population to approximately 2/3 and 1/3 fragments (Fig. 1*a*). Since DNA preparations were not RNase treated, contaminating RNA species, principally 4S and 5S RNA, are observed even following successive windings from 75% ethanol medium coupled with centrifugation in 1.73 g cm[-3] CsCl for 65 h.

The position of DNA on the 5% gels (Fig. 1*c*) was identified by the action of DNase (Fig. 1*d*). Areas of these gels (indicated in Fig. 1*c* and *d* as areas 1, 2, 3, 4) containing the region of native DNA (area 1) and the oligodeoxynucleotides (area 4) were eluted and concentrated. Hybridisation with ^{125}I-CEV–RNA indicated the presence of the CEV-complement in the region of native DNA as well as the DNase-produced product. This further supports the existence of a CEV-like DNA species but does not obviate the possible existence of an RNA moiety trapped in the DNA matrix which is complementary to CEV–RNA and demonstrates a distinctly different mobility in a DNase-treated preparation.

For this reason, DNA preparations were subjected to CsCl equilibrium sedimentation (Fig. 2), and samples recovered from the DNA band as well as any pelleted RNA, were hybridised with ^{125}I-CEV–RNA. A CEV-like DNA is contained in the CsCl banded DNA. No evidence was detected for RNA–RNA hybridisation of CEV–RNA to either pelleted RNA or tRNA-like species concentrated at high CsCl densities. Sedimentation in 56% (w/w) CsCl (Fig. 2) indicated heterogeneity in the DNA preparations from healthy gynura

the host cell, offer striking parallels to the oncogenic viral processes operating at a minimal level.

In an attempt to localise and identify the CEV–RNA template, total nucleic acids extracted from subcellular fractions of infected *Gynura aurantiaca* were hybridised[8] with iodinated ^{125}I-CEV–RNA[9] (Table 1). The most significant level of RNase-resistant ^{125}I-CEV–RNA binding was observed with nucleic acid from the 250-g pellet which contained the bulk of the nuclear DNA as judged by the diphenylamine test. This fraction also contained pathogenic CEV–RNA as indicated by the relative 'infectivity' assay.

To determine whether a CEV-like DNA was specific to exocortis disease tissues, high molecular weight DNAs were
Fig. 2 Equilibrium sedimentation of DNA-rich preparations from healthy and exocortis-infected gynura in 56% (w/w) CsCl and 10 °C in the SW 50 Beckman rotor for 65 h in 0.01 M Tris, pH 8.0. The tubes were fractionated by bottom puncturing and 30–40 samples collected from 5-ml columns. Alternate samples were diluted to 1 ml with TKM buffer and A_{260nm} recorded. Densities were determined on undiluted samples by refractive index. Samples to be used for hybridisation with ^{125}I-CEV–RNA were dialysed overnight against 0.1 × TKM buffer followed by lyophilisation and resuspension in 100 μl H_2O and hybridised as in Fig. 1. The specific activity of c.p.m. per A_{260nm} (■■■■) records the recovery of RNase-resistant ^{125}I-CEV–RNA in selected samples included sedimented RNA. △, Healthy plants; ○, infected.

with the presence of a fraction of lower density than the main-band DNA. This light satellite DNA is more easily resolved in DNA preparations from diseased gynura and demonstrates a greater affinity for CEV–RNA than mainband DNA. Since the CEV–RNA is 58% G+C (ref. 2) the putative DNA complement would be correspondingly high in A+T and therefore characterised by relatively low intrinsic buoyant density. Furthermore, the enhanced resolution of the light DNA in preparations from diseased tissue suggests the pro-portionately higher concentration of the light DNA possibly induced by the pathogenic activity of CEV–RNA.

These data indicate the existence of a DNA sequence in diseased tissue with an affinity for the CEV–RNA resulting in an RNase-resistant RNA–DNA hybrid. Previous studies[1] demonstrated that the pathogenic RNA contained in 2 M LiCl supernatant preparations from exocortis disease tissue could be localised after sedimentation in Cs_2SO_4 in a region inter-mediate to dsRNA (1.60 g cm⁻³) and tRNA (1.51–1.58 g cm⁻³). If the CEV–RNA became associated with relatively high molecular weight species of DNA then a shift of the pathogenic activity to lower density Cs_2SO_4 might be expected.

Figure 3b shows the separation of single-stranded RNA (ssRNA), double-stranded RNA (dsRNA), tRNA and DNA along with the distribution of CEV–RNA by the relative infectivity index. Aliquots of the sample (Fig. 3b) were sub-jected to conditions of melting and rapid (Fig. 3c) or slow (Fig. 3a) cooling. A shift in the density of the DNA sample (Fig. 3a, c) from 1.40 g cm⁻³ to 1.44 g cm⁻³ resulted from the melting at 100 °C for 10 min. The demonstration of patho-genic activity was not affected by the thermal treatment,

Fig. 3 Sedimentation of DNA-rich preparation from exocortis-infected gynura (b) in 43% (w/w) Cs_2SO_4, after heating to 100 °C for 10 min and slow (a) or rapid cooling (c), in SSC buffer (0.1 M NaCl, 0.01 M sodium citrate, pH 7.0) centrifuged in the Beckman SW 50.1 rotor at 10 °C and 30,000 r.p.m. for 65 h. Samples were fractionated and analysed as in Fig. 2 and dialysed against TKM buffer before bioassay. Biological activity was determined by the appearance of stunting and epinasty symptoms on gynura over a 30-d period following inoculation by razor-slashing of the stems. The total number of 'infected-plant-days' on 3–4 gynura plants per sample comprised the relative infectivity[11] value (shaded areas). ○, A_{260nm}.

reflecting the unusual stability of the viroid RNA. The relatively normal distribution of relative infectivity in Cs_2SO_4 gradient observed in the control preparation (Fig. 3b), however, was

Table 1 Distribution of hybridisable nucleic acid in subcellular fractions from *Gynura aurantiaca* infected with CEV

Supernatant	584	8	2.4	3	0	0

*35 µl of each DNA fraction used for hybridisation treatment. RNase-resistant ^{125}I was determined as described in Fig. 1.

altered in both the rapid and slow-cooled treatments to include a broader density range, encompassing the region of DNA. The distribution of the preparation reannealed in slow cooling conditions (Fig. 3a) is particularly striking, since a significant portion of the CEV–RNA now cosediments with the gynura DNA.

The CEV-specific DNA, concentrated in the 250-g pellet (Table 1) supports a nuclear phase in the synthesis of viroid RNA[12]. This is not to imply that the pathogenic RNA is totally restricted to the host nucleus[13]. Whether the DNA complementary to CEV–RNA is synthesised *de novo* by the action of an induced RNA-directed DNA polymerase, or exists in a limited number of copies and is amplified by normal DNA polymerase activity in the process of pathogenesis, remains to be determined. The mode of synthesis of CEV–RNA as well as the mechanism involved in the production of the pathological condition is critical to the description of the

unique class of pathogenic RNA, the viroids. The CEV–RNA reflects neither the structural[2] nor the biological properties[3,4] of most plant viral nucleic acids. This report further supports a unique role for the viroid RNA as a regulator of the expression of the normal host genome resulting in the production of a 'disease-like' symptom. The implied participation of a DNA intermediate reported here as well as the observed requirement for cell division in the synthesis of CEV–RNA (J.S.S., unpublished) further supports the intimate interaction between the viroid RNA and host cell, resulting in a condition analogous to cell transformation.

Presence of sequences hybridisable to dsRNA in cytoplasmic mRNA molecules

IN recent years, a precursor–product relationship between heterogeneous nuclear RNA (HnRNA) and cytoplasmic messenger RNA (mRNA) has been investigated intensively[1,2]. The HnRNA was shown to have a double-stranded hairpin structure within its long molecules[3–5]. This particular region has been isolated as a double-stranded RNA (dsRNA) after treatment with ribonucleases, followed by purification on cellulose[5] or hydroxyapatite[3,4]. The HnRNA of higher organisms is degraded largely in the nucleus and, at most, 10% of the nuclear content

is transported to the cytoplasm[2]. It remains unknown whether the double-stranded structures in the HnRNA molecules are totally degraded in the nucleus or whether sequences involved in this structure are preserved in part or *in toto* during nuclear processing and possibly become parts of cytoplasmic mRNA.

We investigated the possibility that sequences from double-stranded structures are present in cytoplasmic mRNA molecules and present data showing that there are sequences hybridisable to denatured dsRNA in mRNA molecules and that these sequences are 6.1% of the total mRNA. We also tried to investigate the relative position of these sequences in mRNA molecules using 5'-exonuclease and polynucleotide phosphorylase.

The experiment consists of the molecular hybridisation between labelled mRNA and unlabelled dsRNA, both prepared from rat livers. To estimate the percentage hybridisation of mRNA to dsRNA, purified mRNA was annealed to dsRNA at varying concentrations, but at a fixed input ratio (dsRNA: mRNA, w/w) of 1:1. This input ratio was chosen since hybrids formed at low input ratio, that is, 1:1, exhibited a sharp melting profile with a T_m only 6 °C below that of the original dsRNA (ref. 6), indicating a reasonably good fidelity of base pairing.

mRNA hybridised to dsRNA on annealing (Fig. 1) and the hybridisation reaches a plateau at a value of approximately 30 mg ml^{-1} h^{-1}. Since contamination of nuclear RNA, including dsRNA, in the mRNA preparation was extremely low[6], this observation did not result from the hybridisation of labelled dsRNA (contaminating the labelled mRNA preparation) to the added dsRNA, but certainly represents the hybrid formation between labelled mRNA and dsRNA added. The hybridisation curve shows that dsRNA hybridised to 6.1% of mRNA added. Assuming that the average value for the length of an mRNA molecule is approximately 1,000 nucleotides[11], then the total length of the sequences involved would be approximately 60 nucleotides. This is within the size range of purified rat liver dsRNA, as estimated by electrophoresis on 10% acrylamide gels[6] and by electron microscopy according to the aqueous technique of David *et al.*[12]. The purified dsRNA showed a broad size distribution.

This observation is of particular importance with respect to the hypothesis that HnRNA is a precursor of cytoplasmic mRNA (ref. 13). It has been demonstrated that all dsRNA is of nuclear origin and is not derived from ribosomal, preribosomal and transfer RNAs (refs 3—5). In particular, dsRNA obtained from high molecular weight nuclear RNA is in the form of a hairpin structure in the HnRNA molecule with a linking nucleotide sequence at the top of the hairpin (refs 3, 4 and R. P. Monckton and H. N., unpublished). No definite double-stranded structure has been detected in the cytoplasm[5] or in the cytoplasmic mRNA[3,6]. Electron microscopic observations of isolated mRNA molecules did not reveal any double-stranded structure either. Although a secondary structure for particular species of eukaryotic mRNA has been suggested after examining amino acid sequences[14,15] and performing hyperchromicity experiments[16], no conclusive evidence has yet been reported. In addition, denatured dsRNA prepared from nuclear RNA and completely free of cytoplasmic mRNA also hybridised to mRNA. Therefore, the presence of sequences in the mRNA molecule hybridisable to dsRNA indicates that, if no post-transcriptional addition of these sequences to mRNA occurs, mRNA is most likely to be derived from sequences contained in HnRNA. The absence of actual double-stranded structures in mRNA is presumably because only a portion of the sequences necessary for double-stranded hairpin structuring is retained during the processing of HnRNA to mRNA. There is considerable evidence supporting the hypothesis of a precursor-product relationship of HnRNA and mRNA. What doubt there is arises mainly from the fact that most of the experiments did not completely eliminate the possibility of the presence of cytoplasmic mRNA contaminating the HnRNA preparation[17,18]. Our present observations support the possible precursor-product relationship between HnRNA and mRNA

without any doubt of contamination by mRNA, since purified dsRNA is derived from HnRNA and is free of cytoplasmic mRNA (ref. 5).

We then investigated whether sequences hybridisable to dsRNA are located at or near the 5'- and (or) 3'-end of the cytoplasmic mRNA molecule. The hybrids between dsRNA

Fig. 1 Hybridisation of ^{3}H-labelled mRNA to unlabelled dsRNA. For preparation of ^{3}H-labelled mRNA, ^{3}H-orotic acid (300 μCi) was injected into rat portal vein 4 h before decapitation. Polysomes were obtained from labelled livers according to the method of Schreier and Staehelin[7] and then polysomal RNA was extracted by treatment with chloroform–phenol[8]. mRNA was isolated from polysomal RNA by sucrose density gradient centrifugation as described previously[6]. Our mRNA preparation has already been characterised and exhibited messenger activity in a cell-free protein-synthesising system[6]. dsRNA was prepared and purified from rat livers as previously[5]. The preparation procedure involved extensive treatment of whole cell or nuclear RNA with DNase, Pronase and RNases (A and T₁). The crude preparation of dsRNA was purified on a cellulose column. The dsRNA preparation was completely free of DNA[5]. All hybridisation reactions were carried out at 72 °C for 24 h in hybridisation solution (10 mM phosphate buffer, pH 7.6, 0.3 M NaCl) by a modification of Schonberg *et al*[9] and Shimotohno and Miura[10]. Larger values of mg ml^{-1} h^{-1} were obtained by increasing the concentration of RNA and not by lengthening the reaction time. After annealing, the reaction mixture was diluted to a final volume of 0.2 ml with hybridisation solution and subjected to treatment with 10 μg ml^{-1} of RNase A and 0.5 μg ml^{-1} of RNase T₁ at 37 °C for 30 min. It was shown that the RNase-resistance observed after annealing certainly results from hybrid formation[6]. The dsRNA–mRNA hybrids formed were precipitated in the presence of carrier RNA with trichloroacetic acid, collected on glass fibre filters and the radioactivity determined[6]. Since 0.6% of mRNA became RNase resistant after annealing without dsRNA, this 'blank' value was subtracted from the measured values. The RNase-resistant materials obtained after annealing without dsRNA did not behave as typical double-stranded structures, since this resistance to RNases was clearly not lost after thermal denaturation.

and labelled mRNA were treated with either spleen phosphodiesterase (with or without added phosphomonoesterase) or polynucleotide phosphorylase. The secondary structure of polynucleotides is insensitive to these enzymes, which attack

only single-stranded polynucleotides from the 5'-end (spleen phosphodiesterase[19]) or 3'-end (polynucleotide phosphorylase[20]) of the molecule.

Treatment of ^{3}H-labelled heat-denatured hybrids or cytoplasmic mRNA alone with spleen phosphodiesterase in the conditions described in Fig. 2 released radioactivity almost linearly with incubation time (Fig. 2). Hydrolysis of the intact hybrids took place at a much slower rate in the same conditions during incubation for 60–180 min. Since commercial preparations of spleen phosphodiesterase contain contaminating

between intact and denatured hybrids suggests that sequences hybridisable to dsRNA do not occur in clusters along the entire molecule, as may be the case in a special class of RNA which would be a small proportion of the mRNA population, and that most of the mRNA molecules possess sequences hybridisable to dsRNA. This is indeed the case, since hybrids were formed between dsRNA and 98% of the ^{3}H-labelled mRNA population as evidenced by the retention of ribonuclease-untreated hybrids on a hydroxyapatite column. The mRNA molecule seems likely to be composed partly of sequences

Fig. 2 Hydrolysis of dsRNA–mRNA hybrids by spleen phosphodiesterase. The hybrids formed with denatured dsRNA and ^{3}H-labelled mRNA (approximately 1,000–1,500 c.p.m.) at an input ratio of 1:1 at a value of 10–15 mg ml^{-1} h^{-1} were treated at 37 °C with 250 μg ml^{-1} of spleen phosphodiesterase (Worthington Biochem. Corp.) in hydrolysis solution (50 mM Tris-HCl, pH 8.0, 10 mM MgCl$_2$, 0.3 M NaCl) based on the conditions used for reducing the activity of contaminating endonucleases[21]. Phosphodiesterase activity still remains at high pH (ref. 22). The hybrid preparations used here were not purified after annealing and so contained some residual unhybridised mRNA. After incubation, the samples were chilled in ice and trichloroacetic acid was added to terminate the reaction. The radioactivity of the acid-insoluble residue was measured as described in Fig. 1. Heat-denatured (100 °C for 10 min, followed by immediate cooling in ice) hybrids (●) were used as a control for comparison of the susceptibility of intact hybrids (×). Hydrolysis of mRNA alone (○) was also monitored. This occurred in exactly the same fashion as that of denatured hybrids.

Fig. 3 Phosphorolysis of dsRNA–mRNA hybrids by polynucleotide phosphorylase. The hybrids formed in the conditions described in Fig. 2 were treated at 37 °C with 125 units ml^{-1} of polynucleotide phosphorylase (*Micrococcus lysodeikticus*, Sigma Chemical Co.) in the presence of 1 M NaCl under the conditions described by Soreq *et al.*[24]. After incubation, the samples were treated as described in Fig. 2. ○, Heat-denatured; ×, intact hybrids.

phosphomonoesterase activities[23], addition of phosphomonoesterase (0.45–1.7×10^{-3} units per μg RNA, Sigma Chemical Co.) to the incubation mixture resulted in only a 10–15% increase in hydrolysis. The low susceptibility of the intact hybrids to spleen phosphodiesterase suggests that there are almost no long single-stranded tails on the 5'-end of the hybrids. This suggests the presence of sequences hybridisable to dsRNA at or near the 5'-end of mRNA molecules. The possibility that mRNAs contain these sequences also at or near the 3'-end cannot, however, be excluded. In fact, intact hybrids were also less susceptible than denatured hybrids to degradation from the 3'-end by polynucleotide phosphorylase (Fig. 3).

The remarkable difference in susceptibility to these enzymes

hybridisable to dsRNA, partly of a unique sequence coding for polypeptide and partly of a poly(A) segment. The results obtained here reveal nothing of the presence or absence of sequences hybridisable to dsRNA in the internal positions of the mRNA molecule; however, since a major portion of the mRNA molecule is the unique sequence coding for polypeptide, sequences hybridisable to dsRNA are unlikely to be in the middle of the molecule. Such sequences would seem to be at or near the 5'-end and also between the unique sequence and the poly(A) segment at the 3'-end. There is evidence suggesting the presence of these sequences at or near the 5'- and 3'-ends of the mRNA molecules. First, sequences transcribed from repetitious DNA sequences, from which dsRNA is transcribed, have been detected at or near the potential 5'-end of the mRNA portion of HnRNA molecules[25]. Second, repetitious sequences were actually found at the 5'-end of *Xenopus* embryo mRNA[26], and both at the 5'- and 3'-ends of slime mould mRNA and nuclear RNA (ref. 27).

Taking all these facts into account, it is suggested that with the exception of some mRNAs, cytoplasmic mRNA is at least

composed of a sequence corresponding to a portion of one strand of dsRNA both at, or near, the 5'-end and probably between the unique sequence coding for polypeptide and the poly(A) segment at the 3'-end. The existence of sequences hybridisable to dsRNA is consistent with the hypothesis that the dsRNA hairpin structure of the HnRNA molecule is a cleavage point which may be specifically recognised by a nuclear processing enzyme. This implies that the poly(A) segment linked to the unprocessed HnRNA molecule would be detached during the maturation process and a new poly(A) segment would be added to the 3'-end after completion of the processing. Recent experiments have revealed that much of the poly(A) segment attached to nuclear RNA decays in the nucleus and is not conserved[2,28]. None of the experiments carried out so far on polyadenylation excludes the possibility that poly(A) may be added to new 3'-ends generated by the processing of HnRNA as well as to the 3'-end of the unprocessed HnRNA molecule[2]. Moreover, it seems likely that addition of a poly(A) segment takes place both before and after nuclear processing of HnRNA molecules[29].

Identification of the high and low affinity CO₂-binding sites of human haemoglobin

THE unloading of oxygen in the tissues is facilitated by lowering the oxygen affinity of haemoglobin (Hb) by both CO_2 and diphosphoglycerate (DPG)[1]. This occurs because CO_2 and DPG are oxygen-linked, that is, they are bound more firmly to deoxyhaemoglobin than to oxyhaemoglobin[2,3]. The binding of

CO_2 to Hb takes place by a reaction of CO_2 with the α-amino groups to form carbamino compounds[4,5], and binding curves can be measured by rather laborious methods[4,6]. Perrella *et al.*[7] have modified these methods so that much smaller amounts of Hb, such as the specifically carbamylated Hbs[8], can be used. In this method, Hb equilibrated with CO_2 is rapidly taken to pH 11 to stabilise the carbamino CO_2 and BioRad AG 1×8 resin added to remove carbonate and bicarbonate ions. The carbamino CO_2 is displaced from the Hb by acidification and measured in a Van Slyke apparatus. DPG-free human deoxyhaemoglobin gave diphasic CO_2 binding curves[7] showing that the affinities of the α and β chain α-amino groups for CO_2 are different, but it was impossible to establish which group had the higher affinity.

We have used the specifically carbamylated Hbs, $\alpha_2^C\beta_2$ and $\alpha_2\beta_2^C$ where c denotes specific reaction of the α-amino group with cyanate[8], to identify the low and high affinity sites for CO_2 in Hb.

As a control experiment we first measured the CO_2 bound to $\alpha_2^C\beta_2^C$; this amount was very small but not negligible and was about 10% of that bound to normal Hb in the same

Fig. 1 CO_2 bound by $\alpha_2^C\beta_2$ (*a*) and $\alpha_2\beta_2^C$ (*b*) at pH 7.4, 37 °C. Haemoglobin concentration 3.5 mM in tetramer, ionic strength 0.18. O, Deoxy; □, deoxy + 2 mol DPG per tetramer; ●, CO, ■, CO + 2 mol DPG per tetramer. The data were corrected for a 5% contamination with normal Hb. The P_{CO_2} can be converted to mM CO_2 by multiplying the value of mmHg by 0.031. The solid lines through the points are the calculated curves with values of the pH-dependent association constants λ of λ_β = 579 M⁻¹ and λ_β^{CO} = 120 M⁻¹ for deoxy and CO $\alpha_2^C\beta_2$ and λ_α = 190 M⁻¹ and λ_α^{CO} = 100 M⁻¹ for deoxy and CO $\alpha_2\beta_2^C$ The broken line is the curve calculated from equation (1) (using a program written by Dr A. P. Minton) with K_p = 5 × 10³ M⁻¹, K_p' = 1,700 M⁻¹, and K_p'' = 500 M⁻¹.

conditions. This small amount of oxygen-linked CO_2 could be bound to a site different from the α-amino groups or could be the result of about 10% contaminating normal Hb. The CO_2 bound to $\alpha_2^C\beta_2$ and $\alpha_2\beta_2^C$ is shown in Fig. 1.

In the DPG-free deoxy forms $\alpha_2^C\beta_2$ binds more CO_2 than $\alpha_2\beta_2^C$, while in the CO forms both bind CO_2 equally. The calculated pH-dependent association constants (Fig. 1) show that in the deoxy form the β chain α-amino group has about a threefold higher affinity for CO_2 than the α chain α-amino group. This is about the same difference found between the

two unidentified binding sites in normal human deoxyhaemo-globin[7], and is in agreement with the effect of CO_2 on the oxygen affinity of $\alpha_2^C\beta_2$ and $\alpha_2\beta_2^C$ (ref. 8).

Figure 2 shows that the addition of the CO_2 bound by $\alpha_2^C\beta_2$ and $\alpha_2\beta_2^C$ is nearly the same as the total CO_2 bound by normal Hb. This indicates that the free α-amino groups in $\alpha_2^C\beta_2$ and $\alpha_2\beta_2^C$ bind the same amount of CO_2 as the same groups in normal Hb and these derivatives can thus be considered good model compounds for the study of normal Hb.

DPG does not affect the CO_2 binding of deoxy $\alpha_2\beta_2^C$ or the CO forms of $\alpha_2\beta_2^C$ and $\alpha_2^C\beta_2$, but reduces the CO_2 binding of deoxy $\alpha_2^C\beta_2$ by about 30% (Fig. 1), in agreement with the fact that DPG interacts with the β chain α-amino group of deoxy-

Fig. 2 CO_2 bound by normal deoxyhaemoglobin (– – – –) and CO-haemoglobin (– . – . – . –) in the same conditions as Fig. 1, taken from ref. 7. The symbols are the sum of the two sets of CO_2 binding data for deoxy (×) and CO (+) $\alpha_2^C\beta_2^C$ and $\alpha_2\beta_2$ taken from Fig. 1.

haemoglobin[9]. The total CO_2 bound to $\alpha_2^C\beta_2$ and $\alpha_2\beta_2^C$ in the presence of DPG equals that bound to normal deoxyhaemo-globin in the same conditions. Thus at 42 mmHg P_{CO_2}, deoxy $\alpha_2^C\beta_2$ and $\alpha_2\beta_2^C$ bind, in total, 0.64 mol CO_2 per tetramer (Fig. 1) compared with the 0.68 mol CO_2 per tetramer found, in this study, bound to normal deoxyhaemoglobin. A similar reduction in CO_2 binding by DPG or ATP was found by Brenna *et al.*[1].

X-ray crystallography shows that binding of two CO_2 molecules to the β chain α-amino groups[10] would decrease the binding of DPG, but it is very difficult to make a quantitative estimate from these data. The CO_2 binding data of deoxy $\alpha_2^C\beta_2$ in the presence of DPG can be used to estimate values of K_p' and K_p'' (the DPG association constants when one or two CO_2 molecules are bound) provided that the value of K_p (the DPG association constant of $\alpha_2^C\beta_2$ in the absence of DPG) is known. We have used $\alpha_2^C\beta_2$ rather than normal Hb because complications caused by CO_2 binding to the α chain α-amino group are avoided. The K_p values measured in conditions similar to ours (that is, concentrated deoxyhaemoglobin at 37 °C) are 10^4 M^{-1} (ref. 11) and 5×10^3 M^{-1} (ref. 12) at pH 7.2 and ionic strength 0.12 and 0.15, respectively. Our conditions of pH 7.4 and ionic strength 0.18 should decrease these values only slightly[3]. The K_p for $\alpha_2^C\beta_2$ is likely to be the same as for deoxyhaemoglobin because DPG causes the same change in log P_{50} as in normal Hb[8]. This shows that the difference between the DPG association constants of the oxy- and deoxy-forms of $\alpha_2^C\beta_2$ are the same as for normal Hb, and it is likely that their absolute values are the same.

If DPG binds to only one site in deoxyhaemoglobin and CO_2 and DPG can simultaneously bind at this site, then the data can be analysed by the following scheme

$$
\begin{array}{ccccc}
& 2\lambda_\beta & & \tfrac{1}{2}\lambda_\beta & \\
\text{Hb} & \rightleftarrows & \text{HbCO}_2 & \rightleftarrows & \text{Hb(CO}_2)_2 \\
K_p \updownarrow & & K_p' \updownarrow & & K_p'' \updownarrow \\
\text{HbDPG} & \rightleftarrows & \text{HbCO}_2\text{DPG} & \rightleftarrows & \text{Hb(CO}_2)_2\text{DPG}
\end{array}
$$

where Hb represents $\alpha_2^C\beta_2$, λ_β is the association constant for CO_2 binding to the β chain α-amino group[7], K_p is the association constant for DPG binding to deoxy $\alpha_2^C\beta_2$ in the absence of CO_2, and K_p' and K_p'' the DPG association constants when one CO_2 or two CO_2 molecules are bound. The number of mol per tetramer of CO_2 (φ) bound to the β chain α-amino group in the presence of DPG, is

$$
\varphi = \frac{2\lambda_\beta[CO_2](1+\lambda_\beta[CO_2]+K_p'[DPG]+\lambda[CO_2]K_p''[DPG])}{(1+\lambda_\beta[CO_2])^2+K_p[DPG]+2\lambda_\beta[CO_2]K_p'[DPG]+ \\ +\lambda_\beta{}^2[CO_2]^2K_p''[DPG]} \quad (1)
$$

The value of K_p in equation (1) can be determined when the ratio K_p/K_p'' is known. When K_p/K_p'' is less than 10, then large values of $K_p(>2\times10^4$ $M^{-1})$ will fit the data in Fig. 1. As K_p/K_p'' is progressively increased, then K_p must be decreased to fit the data. Thus, if $K_p/K_p''>100$ then K_p must be less than 10^3 M^{-1}, a value clearly too small in respect to the directly-measured values of K_p (refs 11, 12). Figure 1 shows the fit obtained with $K_p/K_p'' = 10$ and K_p set at 5×10^3 M^{-1} to comply with the directly-measured values[11,12]. This low ratio of K_p/K_p'' shows that substantial populations of the species HbCO$_2$DPG and Hb(CO$_2$)$_2$DPG must exist.

Brenna *et al.*[1] attempted to identify the high affinity CO_2 binding site from the CO_2 binding data of normal deoxy-haemoglobin in the presence of ATP or DPG. They used $K_p = 10^4$ M^{-1} but erroneously assumed, in absence of crystallo-graphic data, K_p' and K_p'' to be zero. When these values of K_p, K_p', and K_p'' are used in equation (1) a low value of λ_β is calculated, suggesting that the high affinity CO_2 binding site in deoxyhaemoglobin is the α chain α-amino group. Clearly our finding of substantial populations of HbCO$_2$DPG and Hb(CO$_2$)$_2$DPG species invalidates the simplified analysis of Brenna *et al.*[1].

Our data are partly in agreement with the crystallographic work of Arnone[10] who found clear evidence of CO_2 binding to the β chain α-amino group but no CO_2 on the α chain α-amino groups and instead CO_2 bound to the interior of the protein near the β chain haem group. It is not clear whether this CO_2 would still be bound in solution in the red cell or whether it would be oxygen linked. The failure to observe CO_2 binding to the α chain α-amino group is surprising because $\alpha_2\beta_2^C$ clearly binds CO_2, which is practically abolished when its free α-amino group is blocked in $\alpha_2^C\beta_2^C$.

We thank Drs A. Szabo and A. P. Minton for discussion, and Mr M. Chimisso for experimental help. This research was supported by the Consiglio Nazionale delle Ricerche, Rome.

Spectral changes and allosteric transition in trout haemoglobin

PREVIOUS results have shown that two of the haemoglobin components from trout blood, Hb trout I and Hb trout IV, have different functional properties, which may be correlated directly with their physiological role (see ref. 1 for review). Thus, Hb trout I, which displays cooperative ligand binding at all pH values, completely lacks heterotropic interactions; on the other hand, these interactions are clearly evident in Hb trout IV, for which lowering of pH, or addition of organic phosphates, produces a large decrease in oxygen affinity and in cooperativity (n drops from 2.3 at pH 8 to ~ 1 at pH 6)[2,3].

Although the molecular interpretation of the Root effect in Hb trout IV is certainly complex, it is probably related to the stabilisation, induced by protons, of a "low affinity" conformational state of the molecule, according to a simplified "two states" model[1]. Such evidence has been provided through EPR experiments on the NO-derivative of Hb trout IV (ref. 4). Here we report further evidence that protons and inositol hexaphosphate (IHP) can induce characteristic shifts in the absorption spectrum of the carbon monoxide derivative of Hb trout IV.

Haemoglobin components from trout blood (from Salmo irideus) were purified as described previously[2]. All reagents were analytical grade and were used without further purification. Absolute and difference spectra were recorded with a Cary 14 spectrophotometer thermostated at 20 °C.

The Soret absorption band of Hb trout IV fully saturated with carbon monoxide is redshifted by about 1 nm going from pH 8 to 6, as shown by the difference spectra reported in Fig. 1a. Control experiments have shown clearly that the observed difference spectra cannot be attributed to the presence of methaemoglobin contaminations, or to changes in the saturation with CO. In addition it should be emphasised that no pH-dependent difference spectra of comparable magnitude have been detected for the deoxygenated derivative of Hb trout IV, or for Hb trout I both in the carbomonoxy- and in the deoxyform.

Figure 1b points out that somewhat similar difference spectra are obtained, at constant pH, by addition of IHP. The effect of the organic phosphate seems, however, to be more complex, as different isosbestic points were observed at low and high pH

Fig. 1 Effect of pH and IHP on the spectrum of carbomonoxyhaemoglobin trout IV in 0.05 M bis-Tris at 20 °C. a, Difference absorption spectra at various pH, as indicated (reference cell, pH 8.1). b, Difference absorption spectra $\pm 10^{-3}$ M IHP at constant pH, as indicated. Protein concentration 6 μm (in haem).

values. The results obtained at constant proton activity indicate, in agreement with the functional data[5], an additional stabilising effect of IHP on the "low affinity" form of liganded Hb trout IV. The titration of Hb trout IV–CO with IHP is shown in Fig. 2. It corresponds to a simple hyperbola, with a value for the overall affinity constant (K) of 1.4×10^4 M^{-1} at pH 6.2 and

Fig. 2 Binding curve of IHP to Hb trout IV–CO in 0.05 M bis-Tris at 20 °C. Δ Absorbance are the amplitudes of the difference spectra obtained in the presence of increasing amounts of IHP.

20 °C. This value is considerably smaller than that reported for oxygenated human haemoglobin ($K \approx 10^6$ M^{-1} at pH 7.0 and room temperature)[6]. The difference, although puzzling, is not inconsistent with the known changes in some of the amino acid residues involved in the interactions with IHP within the central cavity of the tetramer[7].

The existence of isosbestic points, at 420 and 437 nm, in the pH-dependent difference spectra, is in agreement with the presence of only two spectral species in pH-dependent equilibrium. The experimental data in bis-Tris (0.05 M) can be fitted with a simple titration curve, with pK 6.5 (Fig. 3), suggesting that only one type of ionisable group is involved in the Root effect. In the presence of IHP (10^{-3} M) a similar effect is observed

Fig. 3 pH-induced transition in Hb trout IV–CO in the absence (O) and in the presence (●) of 10^{-3} M IHP (solvent 0.05 M bis-Tris buffer) at 20 °C; Δ Absorbance as in Fig. 2.

(Fig. 3); the higher pK of the transition is consistent with the cumulative effect that both protons and the organic phosphate exert on the stabilisation of the "low affinity" form. It cannot be excluded, however, that in the presence and absence of IHP the proton induced transition may occur among different states. The greater steepness of the transition observed in IHP is probably related to the fact that Hb trout IV is not fully saturated with the phosphate at all pH values.

It is difficult to interpret the redshift of the maximum of absorption of the CO derivative of Hb trout IV, induced by lowering pH. For instance, it is not possible to correlate unequivocally the position of the peak to the strength of the bond between the iron and the ligand, although obviously the observed changes must reflect a perturbation in the distribution of electrons in the porphyrin–metal–ligand complex. The observed redshift may suggest a weakening of the π-bonding and an increase in the iron–ligand bond length correlated to a movement of the proximal imidazole relative to the metal (R.J.P. Williams, personal communication). Apart from detailed interpretations of the observed effect, it is of interest to correlate the spectral change with other properties of Hb trout IV, which are also pH dependent and occur over the same pH region. First, the dramatic change in functional properties and in particular the well known drop in ligand affinity which is experienced between pH 8 and 5. It seems especially relevant to remark that such a drop in affinity, common to fish haemoglobins, can be largely attributed to a great increase in the dissociation velocity constant of the ligand[8], which in itself is an indication of a destabilisation of the ligand–protein complex. Second, the fact that pH-dependent ultraviolet difference spectra of Hb trout IV saturated with CO have been observed (M. F. Perutz, personal communication and unpublished data from this laboratory). These difference spectra show a characteristic "fine structure", centred between 280 and 290 nm, which in the case of human haemoglobin has been directly correlated

with the ligand-induced change in the quaternary structure of haemoglobin, and thus should reflect the allosteric conformational transition[9].

By correlating this information, it seems reasonable to propose that the spectral changes we have reported are themselves an indication of the pH-induced structural transition which, according to the simple model outlined above, is expected to occur in liganded Hb trout IV. This being the case, we may be provided with a method to test possible correlations between the spin state of the molecule and its quaternary structure, and to follow the dynamics of the allosteric transition in Hb trout IV. Experiments along these lines are in progress.

We thank Mr S. Polzoni for this help in preparing the purified Hb components, and R. J. P. Williams for suggesting the possible interpretation of the spectral shift.

Corrigendum

In the article "Domoic and quisqualic acids as potent amino acid excitants of frog and rat spinal neurones" by T. J. Biscoe, R. H. Evans, P. M. Headley, M Martin and J. C. Watkins (*Nature*, 255, 166–167; 1975) the structural formula given for quisqualic acid in Fig. 1*d* and Table 2 is incorrect! The structure proposed by Takemoto et al. (Takemoto, T., Nakajima, T., Arihara, S., and Koike, K., *Yakagaku Zasshi*, 95, 326–322 (1975) and 95, 448–452 (1975) is reproduced below

In paragraph 2, line 11, the word isoxazolidinedione should read dioxo-oxadiazolidine.
reviews

In the diversity of today's astrophysics, where does radio astronomy stand? That question arises when reading the book by the staff of the National Radio Astronomy Observatory (NRAO) in the United States, a book whose title aims without restriction at the entire Universe beyond the Solar System. One would expect it, then, to cover the vast terrain of astrophysical interactions and phenomena, as seen in the radio window's perspective. A survey of the approximately 1,000 entries in the subject index confirms that indeed an immense variety of objects and processes are touched upon. There are 12 chapters each by a single author; the only chapter on technique *per se*, on "Interferometry and Aperture Synthesis", was written by a pair of authors, synthesising expertise nurtured at Caltech and Cambridge, respectively. It is a wise choice of the editors and a valuable contribution by these authors, providing so clear an exposition of what is the outstanding observation technique at radio wavelengths whenever imaging elements smaller than one arc minute, positional accuracy better than one arc second, and sensitivities per beam lower than a few milli Jansky are called for. Having begun using 1–5-km arrays so successfully at decimetre and centimetre wavelengths, this extremely versatile technique that so thoroughly exploits current computer capacities, is spreading to millimetre-wavelength astronomy and to transcontinental interferometry. The chapter on observation (and reduction) technique conveniently separates the first nine

Bridging the gap in radio astronomy

H. van der Laan

Galactic and Extra-Galactic Radio Astronomy. By the Staff of the National Radio Astronomy Observatory. Edited by G. L. Verschuur and K. I. Kellermann. Pp.x+402. (Springer: Berlin and New York, 1974.) DM 98.30; $40.10.

chapters that deal with galactic subjects, from the last three, which explore extragalactic objects.

The book more than spans the gap that exists between current textbooks and current reviews in radioastronomy. (Of the former there are, because of the swift developments in all fields of astronomy, only one or two worth buying; the latter are, however, numerous, both under auspices of the International Astronomical Union and in several annual and summer school series.) There is no editorial uniformity in the treatment of first principles or the completeness with which current insights are presented. The editors seem to have limited their rule to the choice and sequence of chapters and authors, and thus achieve coherence without blurring their authors' diversity. Some of the chapters are authoritative reviews,

others unpretentious sketches, and a few are highly personal accounts. All are worth reading, some deserve and require close study. Many chapters, singly or in groups, provide an admirable means of progressing soundly from basic matters to current journal literature; thus they attain a major purpose of all postgraduate courses. Active research astronomers found time to write this excellent book and aspiring researchers will spend their time well in reading from it, to each his own selection.

No completeness is possible on this vast plain of astronomy. Of the omissions only the topic of continuum emission from normal galaxies and their nuclei is regrettable, all the more so since the present director of this same NRAO did the pioneering work. But I regard this book as a fitting closure of radio-astronomy's adolescence. Well nigh every astronomical object and astrophysical process is now touched by this technique and this scope makes it imperative to deal with themes and subjects in a multi-spectral context; this is the case even when discussing objects that are first and foremost radio sources.

Symposia or books confined to radio astronomy will increasingly combine subjects that lack all affinity and separate those which are naturally all of one piece. To acknowledge this means to adapt courses of instruction, conferences and even the structure of organisations such as the International Astronomical Union; it is the recognition that radioastronomy has come of age. □

Now that Magnus Pyke has become a television personality, known to the public for his extraordinary antics which somehow succeed in explaining scientific principles, a new book bearing his name might be expected to use the same type of technique. Those who buy *Success in Nutrition* expecting a good laugh combined with a little painless and easily assimilated knowledge are likely to be disappointed. This book, although well-written and easy to read, is a straightforward and orthodox textbook, aimed at 'O' level and 'A' level students of food and nutrition, 'A' level students in home economics and those taking OND and HND courses in catering and

hotel management. It is also recommended for the serious reader following a self-study course. As a

Pyke's guide to nutrition

Success in Nutrition. By Magnus Pyke. Pp. x+227. (John Murray: London, 1975.) £1.95.

textbook it is excellent. All the various constituents of our diet are described, details being given of their occurrence in different foods,

and the effects of cooking and preparing them on the different ingredients. Dr Pyke is always careful to point out gaps in our knowledge, and to ridicule the absurd statements produced by the faddist and the crank. Some readers may think that he is overgenerous in his commendation of the food-processing industry. The only gap in the text is the omission of any statement about 'roughage'. There seems little doubt that civilised people may suffer from the lack of fibre in their food, and that its replacement relieves constipation and many more serious complaints. I would have been interested in Dr Pyke's comments. **Kenneth Mellanby**

Particles in the sea

Suspended Solids in Water. (Marine Sciences, vol. 4.) Edited by Ronald J. Gibbs. Pp. xiii+320. (Plenum: New York and London, 1974.) $34.90.

THE pioneering observations by N. G. Jerlov of the light-scattering properties of sea water, obtained during the Swedish Deep-Sea Expedition (1947–48), established their usefulness for delineating the distribution and relative concentrations of suspended particles in the sea. Interest in this topic has been revived fairly recently by advances in several disciplines, including those concerned with the influence of dilute particle suspensions on the stability and mechanism of fine-grained sediment motion, with the widespread occurrence of high concentrations of particles close to the deep-sea floor (the so-called nepheloid layer) and with developments in marine optics, which have produced some novel designs of *in situ* light-scattering and transmission meters. This volume represents the proceedings of a symposium of the same title, held in Santa Barbara, California, during March 1973, at which recent work on these topics was intensively reviewed.

The first section of the book contains an introductory chapter by the editor and a chapter describing a theoretical study of the settling and reaction of particles in natural waters. In Section II, five chapters deal with the requirements of optical instruments for *in situ* use and the problems of measuring certain optical parameters of sea water. This section is a useful summary of the state-of-the-art.

Sections III and IV, occupying the major part of the book, contain case studies of suspended matter in nearshore and offshore environments using, in most cases, a combination of *in situ* light-scattering data and some measure of the total quantity of suspended material in discrete water samples. The interest here has been to use the optical data as a convenient measure of the concentration of suspended particles and then to examine the role of such material in the redistribution and sedimentation of organic and inorganic solids in the sea.

A particularly good example of an integrated approach to this type of problem is provided by Biscaye and Eittreim who describe a time series of observations of the nepheloid layer at two stations in the western North Atlantic, using measurements of excess radon to study the effect of vertical mixing on the distribution of bottom particles.

The last two chapters show that it is possible to identify sources of suspended particles from a knowledge of their chemical and mineralogical composition. This type of information will be required in studies of the generation and dissipation of nepheloid layers and the role these layers might have in the overall sedimentary economy of the deep sea. What seems to be required is a calibration of these techniques by determining the major and minor element composition of suspended material over an entire water column, and not simply the near-bottom layers in isolation. Such information will, I hope, be made available by the GEOSECS programme of the US International Decade of Ocean Exploration.

S. E. Calvert

Behaviour differences

Sex Differences in Behavior. (Seminars in Human Reproduction.) Edited by Richard C. Friedman, Ralph M. Richart and Raymond L. Vande Wiele. Pp. xvi+495. (Wiley: New York and London, December 1974.) £12.50.

THIS book contains 24 chapters by over 30 different authors, based on a conference held in New York in September 1973. The common theme is behavioural sex differences, but many of the chapters have little else in common. A wide variety of different approaches within psychology and biology are represented, so that the subject is considered from physiological, clinical, evolutionary, psychoanalytical, cognitive developmental, ethological, and experimental psychological viewpoints. Such diversity has resulted in a very uneven book, and this is further intensified by there being a mixture of research papers, surveys of an author's own research, and more general reviews.

The most useful chapters are those which present a survey of an author's own research, particularly where this covers several years' work. Such chapters include those by Moss, on human mother–infant interactions, Phoenix, on prenatal hormones and primate behaviour, Ehrhardt and Baker, on foetal androgens and human sex differences, Sackett, on sex differences in responses to maternal deprivation, Rosenblum, on mother–infant attachment in primates, and Green, on boys who preferred a feminine role. All of those chapters will be useful to research workers, and possibly to advanced undergraduates. Other chapters of that type—for example, that by Lewis and Weinraub on sex differences in infant attachment—are marred by the excessive detail the authors present in reporting their own data.

Chapters consisting of critical but selective reviews are also very useful in a book of this sort, and so are reviews which attempt to organise and integrate previous findings in a new way. I found the reviews by Meyer-Bahlberg, on the XYY syndrome, Levine, on sex differences in rats' responses to neonatal stress, Korner, on human neonatal differences, and Whalen, on problems and concepts in research on sexual differentiation, the most useful. Two other reviews, by Moyer, on sex differences in aggression, and Hamburg, on an evolutionary perspective on behavioural sex differences, both conspicuously lacked critical appraisal of their material. In addition, the former merely presented material which will be published elsewhere.

Several other chapters give incomplete accounts of research work in progress, sometimes based on very small samples, and thus meriting at best only a short report in a journal. For example, Michael *et al.* base a chapter on the bisexual behaviour of female monkeys simply on observations from two animals; Kohlberg and Ullian, on the development of gender concepts, report data from two subjects (out of 70 studied); Meyer-Bahlberg *et al.*, on cryptorchidism and gender identity, use results from 10 subjects (out of 67 studied). Perksy's chapter on the menstrual cycle and psychological test measures also uses partly analysed data. The only really successful chapter reporting original experimental work is that of Doering *et al.*, on testosterone and psychological test measures in men, and even that is really more appropriate for a journal.

Overall, the book is very diverse and very uneven, so that at £12.50 it is unlikely to attract many buyers. Parts of it will be useful to a wide variety of people for a wide variety of reasons, and I would anticipate that there will be a heavy demand for library copies.   **John Archer**
